PREFACE

DURING the past twenty-five years the applications of Physics to Industry have grown enormously. The National Physical Laboratory was opened in 1900, while Universities and Technical Colleges have multiplied, and recent years have seen the growth of the Department of Scientific and Industrial Research, with its Research Associations in many fields, its studentships, and its skilled Research workers.

Meanwhile, the results of the labours of the past are, for the most part, scattered in the *Proceedings* of learned Societies or stored in the brains of the active workers to whose efforts they are due.

To find out what are the latest methods of Calorimetry, what exactly is known about the laws of Friction, how far has the theory of the Steam Engine advanced, what are the principles on which methods of accurate gauging or of the determination of the many factors which come into the lay-out of a big electrical plant, the design of a Dynamo, or the methods of Pyrometry are based, means a long search in Libraries and, not infrequently, a futile journey to some place where it is hoped the wished-for information may be found.

The Science of Aeronautics, the Design of Optical Instruments, the Methods of Metallurgy, the Construction of Clocks, Telescopes or Microscopes, the Laws of Music and Acoustics are all based on Physics.

The manufacturer who is concerned with these and, indeed, with countless other subjects must know, not perhaps all that has been done—that would be too heavy a task—but where he may find the latest and most accurate information on the subject with which he is mainly concerned. This it has been the object of the *Dictionary of Applied Physics* to give. Applied Physics is a wide subject and the task has been a heavy one.

The Dictionary will appear in five volumes of 800-1000 pages each, and, as will be seen from the names of some of the principal contributors, the Editor has been fortunate in securing the help of those most competent to write on each subject. His thanks are due, in the first place, to these colleagues, without whose cordial help the Dictionary could not have been produced. He is also indebted to a number of Scientific Societies whose Councils have allowed use of illustrations from their *Proceedings* to be freely made. Among these should be mentioned in particular the Royal Society, the Institution of Mechanical Engineers, and the Institution of Electrical Engineers. The same help has been readily afforded by a number of Publishers.

It is clear that, with so large a range of subjects, any individual worker will, probably, be concerned mainly with one branch, and, with this in view, the volumes have been arranged, as far as possible, in subjects. To obtain information as to the latest advances of Applied Electricity it will not be necessary to purchase the sections of the Dictionary dealing with Aeronautics or Meteorology. The arrangement in each volume is alphabetical, but, at the same time, it has been thought best to deal with each main subject—for example, the Thermodynamics of the Steam Engine—in a continuous article; references are given, each in its own alphabetical position, to the headings of the various sections of an article and to the more important subjects which it includes.

Absolute Scale of Temperature (Kelvin). If a perfectly reversible heat-engine takes in a quantity of heat Q_1 at temperature T_1 and rejects Q_2 at temperature T_2, then $Q_1/T_1 = Q_2/T_2$ provided the temperatures T_1 and T_2 are measured on the absolute thermodynamic scale. Hence the ratio of two temperatures on that scale is equal to the ratio of the heat taken in to the heat rejected by any perfectly reversible engine working between those temperatures. See "Thermodynamics," §§ (17), (22); "Engines, Thermodynamics of Internal Combustion," § (7).

AIR-PUMPS

INTRODUCTION

§ (1) COMPRESSORS, EVACUATORS, BLOWERS.—An air- or gas-pump is a device whereby gas is transferred from a low-pressure vessel (L.P.V.) to a high-pressure vessel (H.P.V.). The term "vessel" includes the free atmosphere, and the term "gas" includes vapours. It is assumed, unless the contrary is stated, that the L.P.V. and H.P.V. are at the same temperature.

If the L.P.V. and H.P.V. are separated by a gas-tight partition, and if the gas is not a saturated vapour, the pump will diminish the pressure in the L.P.V. and increase it in the H.P.V.; it will act at the same time as a compressor and as an evacuator. In practice one of the two vessels is almost always maintained at atmospheric pressure, and variations of pressure in the other vessel alone are important. If this condition is fulfilled, a compressor may be defined as a pump of which the L.P.V. is at atmospheric pressure, an evacuator as one of which the H.P.V. is at atmospheric pressure.

The L.P.V. and H.P.V. are seldom completely separated, except in laboratory evacuators; there is a continual stream of gas from one to the other. If the energy required to produce this stream is comparable with the whole work done on the gas, the pump may be termed a "blower," or, if it is of one constructional type, a "fan." The distinction between pumps and blowers, though formally indefinite, is perfectly clear in practice. Blowers are usually, but not always, compressors, producing pressures greater than atmospheric. In blowers there can be no single and definite p_H or p_L, capable of general scientific definition; but there is usually some pair of places along the stream of gas passing through the blower at which it is obviously convenient to measure p_H and p_L. These places may be regarded for our purpose as constituting the H.P.V. and L.P.V.

§ (2) NOTATION.—Suffixes L and H denote quantities referring to the L.P.V. or H.P.V. Many of the formulae given will still be true if the suffixes L and H are interchanged; this feature is indicated by writing before them ("L or H").

p, p_L, p_H = pressure.
p_0 = initial pressure (the same for L.P.V. and H.P.V.).
$p_L{}^0$, $p_H{}^0$ = final pressures.
$\kappa = p_H{}^0/p_L{}^0$ = range.
Π = atmospheric pressure.
P = vapour pressure.
V_L, V_H = volumes of L.P.V. and H.P.V.
u_L, u_H = maximum and minimum volumes of "cylinder."
T_0, T_L, T_H = absolute temperature of atmosphere, L.P.V. and H.P.V.
m = mass of gas.
v = velocity.
S = volumetric speed.
W = work.
w = power.
ρ = density.
η = viscosity.
ϵ = friction coefficient.
$E = E_{\text{mech.}}$ = mechanical efficiency.
$E_{\text{vol.}}$ = volumetric efficiency.

§ (3) WORKING CHARACTERISTICS.—Pumps may be distinguished either according to their working characteristics or according to the principles on which the action depends. Of the working characteristics the following are the most important of those applicable to pumps of all types:

Range of Pressure.—If any pump be worked continuously between closed vessels, there will ultimately be established in them constant pressures, $p_H{}^0$, $p_L{}^0$. By the range of pressure is meant either (*a*) the ratio $p_H{}^0/p_L{}^0$, or (*b*) the difference $p_H{}^0 - p_L{}^0$. (*a*) is generally the more important quantity and will here be termed the "range," denoted by κ; for it is often approximately independent of the absolute values $p_H{}^0$, $p_L{}^0$. But it is never completely independent; for all pumps have a minimum below which they will not reduce p_L whatever is the value, above this limit, of p_H, and all have a maximum p_H, though it may be determined only by mechanical strength.

The range of a pump of any given type may be increased by working two or more similar pumps in series to form a "composite" pump, the L.P.V. of one being the H.P.V. of the next. In all important cases, the range of the composite pump is approximately or exactly the product of the ranges of the components. But a composite pump can also be built up of components of different types; no general statement can be made about the relation between the range of such a composite pump and those of its components.

§ (4) SPEED OF PUMPING.—The speed is the rate at which gas is transferred from the L.P.V. to the H.P.V. The amount of gas is usually estimated by its volume at the pressure of the L.P.V., whether the pump is a compressor or an evacuator. The speed so estimated is called the "volumetric speed," S, and is expressed in volume per unit time.

Measurements of S are usually made by observations of the change of p_H in a compressor or of p_L in an evacuator, the H.P.V. or L.P.V. being completely closed. If δp during the measurement is small compared with p_H or p_L, the gas may be regarded as perfect. Consequently for an evacuator

$$S = \frac{1}{\rho}\frac{dm}{dt} = \frac{V_L}{p_L}\frac{dp_L}{dt} = V_L\frac{d}{dt}(\log_e p_L). \quad . \quad (1)$$

In a compressor, p_L is constant and equal to Π. Therefore

$$S = \frac{V_H}{\Pi}\frac{dp_H}{dt}. \quad . \quad . \quad . \quad (2)$$

In blowers the volume involved in S is usually estimated at p_H. It is conveniently measured by some type of flow-meter placed in the outlet or inlet pipe. If the pressure at the point where the meter is placed differs considerably from p_H, a correction must be applied to the readings of the meter.

S is usually a function of p_H and p_L, as well as of the nature of the pump; but there are important exceptions. The range κ or the maximum difference of pressure $p_H{}^0 - p_L{}^0$ is given by a pair $(p_H{}^0, p_L{}^0)$ such that $S = 0$.

§ (5) The Efficiency.—Several kinds of efficiencies are recognised as applicable to pumps and blowers; of these the mechanical efficiency, or the ratio of the useful work done to the total work expended, is alone applicable to all types. Both terms of the ratio need further definition to rid them of ambiguity. The work expended is usually taken to mean either (*a*) the work expended on the gas in giving to it energy, compressive, kinetic, or thermal, or (*b*) the work supplied to the mechanism of which the pump consists, including that lost in friction of solid or liquid parts. The efficiency reckoned with (*a*) is often termed the "gas" efficiency; that reckoned with (*b*) the "over-all" efficiency.

In pumps, where the L.P.V. and H.P.V.'s are separate, the useful work is always taken to be that required to transfer the gas that has actually passed from the former to the latter. This work will be least if the transference is effected reversibly; if the L.P.V. and H.P.V. are at the same temperature, the reversible transference must be isothermal, and any change of temperature during the process involves the expenditure of more work. If the transference is reversible and isothermal, the work required to transfer a mass of gas between the atmosphere at constant pressure Π and a closed vessel, the pressure in which is changed by the transference from Π to p_1, is given by

$$W = \int_{\Pi}^{p_1} (\Pi - p)dV, \quad . \quad . \quad . \quad (3)$$

where $V = f(p)$ is the isothermal characteristic of the mass of the gas occupying the closed vessel at the pressure p_1. If the gas is perfect, (3) applied to an evacuator or compressor becomes

$$(\text{L or H}) \quad W = p_H V_H \int_{\Pi}^{p_H} (\Pi - p)d\left(\frac{1}{p}\right) \quad . \quad (4)$$

$$= p_H V_H \left(\log_e \frac{p_H}{\Pi} - 1 + \frac{\Pi}{p_H}\right). \quad (5)$$

If $\Pi - p_H = \delta p$ is small, (5) becomes

$$(\text{L or H}) \quad W = \tfrac{1}{2}\frac{(\delta p)^2}{\Pi}V_H. \quad . \quad (6)$$

If p_L is small, as in a high evacuator, it becomes

$$W = (\Pi - p_L)V_L. \quad . \quad . \quad (7)$$

In some text-books, the work done by the atmosphere is left out of account; the term in Π is omitted from (3), and the second and third terms in the bracket from (5). But since work is always done by or on the atmosphere in compressing or evacuating, the efficiencies reckoned without these terms would seem to have no practical significance.

In blowers the useful effect is usually estimated by the volume of gas produced at a given pressure. The work required to force a mass of gas from the atmosphere into a vessel in which the pressure is maintained constant and equal to p_H (by increasing the volume of the vessel as the gas enters) is given by

$$W = (p_H - \Pi)V, \quad . \quad . \quad . \quad (8)$$

where V is the volume of the gas at pressure p_H. Consequently, if S is the volumetric speed, and w the work done per second,

$$w = (p_H - \Pi)S. \quad . \quad . \quad . \quad (9)$$

The stream of gas issuing from a blower possesses kinetic energy. If the work expended in giving to it this energy is to be included as useful work, there must be added within the bracket in (9) the term $p_v = \frac{1}{2}\rho v^2$. It is often impossible practically to convert this kinetic energy into energy of any other form without stopping the flow which is the main purpose of the blower; accordingly the total efficiency, as it is called, reckoned from the relation

$$w = (p_H + p_v - \Pi)S \quad . \quad . \quad (9a)$$

is often misleading. But it may be noted that ideally it is always possible to reduce p_v to zero without changing S, and thus to "convert velocity into pressure"; for if the cross section of the stream is made infinitely large, an infinitely small v will give a finite S.

In addition to the mechanical efficiency, there is recognised for many pumps a quantity known as the volumetric efficiency. But since this quantity cannot be defined generally for all types of pump, it will be discussed in connection with those to which it applies.

§ (6).—The remaining working characteristics common to all pumps are less capable of precise measurement; but they are none the less important. They include simplicity and convenience, first cost and cost of maintenance, adaptation to available sources of power, and so on. When several types of pump are permissible, it is usually these characteristics rather than any measurable efficiency which determine the choice. They will be noticed in connection with particular types.

§ (7) Principles of Action.—For the detailed consideration of the various types of pump, it is more convenient to adopt a classification based upon the principles underlying the action. Here pumps fall into three great classes:

A. Aerostatic.
B. Aerodynamic.
C. Molecular or High-vacuum.

In an *aerostatic* pump the transference of gas is effected by forces that are at any instant in statical equilibrium. For any particular pump the range of pressure is independent of the speed of working within wide limits; the pump can be worked infinitely slowly without loss of range or of efficiency. (This statement is not strictly true when the viscosity of a lubricating liquid is used to secure gas-tightness; such pumps are dynamic, but not aerodynamic.) In all practical examples the statical forces are those due to compression, but those due to change of temperature might conceivably be used.

In an *aerodynamic* pump the forces on the gas are dynamical, and vary with the motion of the parts of the pump; they cease when the speed of working becomes infinitely small, so that the range and speed of the pump vanish together. These dynamical forces arise from the inertia or viscosity of the gas.

The distinction between the two classes can be expressed less formally, but perhaps more clearly, by saying that in the first class, but not in the second, the action is "positive" in the engineering sense; or that, while it is impossible to blow through a pump of the first class, it is possible to blow through one of the second.

In both these classes the forces are such as are associated with a continuous medium. In the third class the action is due to "forces" appreciable on the molecular but not on the molar scale. The class would properly be termed "*molecular*," but since that term has been appropriated to a particular member of it, the less scientific expression "*high-vacuum*" pumps will be used.

In addition to these three classes of pump, there are some methods of evacuation which scarcely satisfy the definition of pumping, but will be conveniently noticed briefly at the end of this article.

A. Aerostatic Pumps

§ (8) Range and Speed.—The working part is always a vessel (U) of variable volume, u. U is

(1) connected to the L.P.V. when its volume is a maximum u_L;
(2) disconnected from the L.P.V. and the volume decreased to the minimum u_H;
(3) connected to the H.P.V.;
(4) disconnected from the H.P.V. and the volume increased to u_L.

This ideal cycle is never attained in practice but forms the basis of any calculations. Even if the ideal cycle were attained, the general formulae giving the relation between p_H, p_L, p_0 after a number of cycles n would be extremely complicated. But if it is assumed that the gas is perfect, and that the transference is isothermal, the relation between $(p_H)_n$ and $(p_H)_{n+1}$, the values of p_H after the nth and $(n+1)$th cycles, is

$$\text{(L or H)}\quad (p_H)_{n+1} = \frac{(p_H)_n V_H + p_L u_L}{V_H + u_H}. \qquad (10)$$

In a compressor or evacuator we have from (10)

$$\text{(L or H)}\quad \frac{(p_H)_n}{\Pi} = \frac{u_L}{u_H} + \left(1 - \frac{u_L}{u_H}\right)\left(1 + \frac{u_H}{V_H}\right)^{-n}, \quad (11)$$

(11) is true whatever the ratio of u to the V's; if it is small and if N, the number of cycles per unit of time, is large, (11) becomes

$$\text{(L or H)}\quad \frac{p_H}{\Pi} = \frac{u_L}{u_H} - \left(\frac{u_L}{u_H} - 1\right)\exp.\left(-\frac{Nu_H}{V_H + u_H}t\right). \qquad (12)$$

From (12) and (1) we obtain for the volumetric speed of an evacuator

$$S = \frac{NV_L}{V_L + u_L}\left(u_L - \frac{\Pi}{p_L}u_H\right), \qquad (13)$$

and for that of a compressor

$$S = \frac{NV_H}{V_H + u_H}\left(u_L - \frac{p_H u_H}{\Pi}\right). \qquad (14)$$

The range of pressure is given by $S = 0$. Consequently

$$\text{(L or H)}\quad \frac{p_H{}^0}{\Pi} = \frac{u_L}{u_H}. \qquad (15)$$

The range, measured by the ratio of the pressures, is independent of the initial pressure and of the volumes of the L.P.V. and H.P.V.

These relations become very simple when u_H, the volume of the "dead space," is zero. Then (11)-(14) become

$$\frac{p_H}{\Pi} = 1 + \frac{nu_L}{V_H}\ \text{(compressor)}, \qquad (16)$$

$$\frac{p_{\mathrm{L}}}{\Pi}=\left(\frac{\mathrm{V}_{\mathrm{L}}}{\mathrm{V}_{\mathrm{L}}+u_{\mathrm{L}}}\right)^{n} \text{ (evacuator)}, \quad . \quad (17)$$

$$\mathrm{S}=\mathrm{N}u_{\mathrm{L}} \text{ (compressor)}, \quad . \quad . \quad (18)$$

$$\mathrm{S}=\mathrm{N}u_{\mathrm{L}}\frac{\mathrm{V}_{\mathrm{L}}}{\mathrm{V}_{\mathrm{L}}+u_{\mathrm{L}}} \text{ (evacuator)}. \quad . \quad (19)$$

Thus the volumetric speed of such a pump would be independent of the pressure against which it worked; its range would be infinite.

§ (9) VOLUMETRIC EFFICIENCY.—In no actual pump is the ideal cycle performed; the yield is always less than that given by (10)-(14), and *a fortiori* less than that given by (16)-(19) on the assumption of no dead space. The deficiency is due to incomplete "connection" and "disconnection" of the L.P.V. and H.P.V. with U and with each other, *i.e.* to leakage and to a failure to establish pressure equilibrium.

The comparison of an actual with an ideal pump is made in terms of the "volumetric efficiency" ($\mathrm{E}_{\mathrm{vol.}}$), which may be roughly defined as the ratio of the number of cycles in which an ideal pump would produce a given effect to the number of cycles in which the actual pump produces the same effect. The ideal pump is assumed to have the same u_{L} (*e.g.* cylinder volume) as the actual pump; it is also usually assumed to have no dead space u_{H}. This last assumption is not necessary, for the effect of the dead space can be readily calculated if the pump is otherwise ideal; but in the pumps for which the conception of volumetric efficiency is most important, u_{H} is always made as small as possible, and its magnitude is important in judging the excellence of the design.

The "effect" by which $\mathrm{E}_{\mathrm{vol.}}$ is estimated must be defined. It is usually either (1) the attainment of a given p_{L}/Π or p_{H}/Π, or (2) the transference of a given quantity of gas with a fixed p_{L} or p_{H}. In either case, $\mathrm{E}_{\mathrm{vol.}}$ is a function of p_{L} or p_{H}, and the value of this pressure must be stated. For a given p_{L} or p_{H}, $\mathrm{E}_{\mathrm{vol.}}$ will not in general be the same for (1) and for (2).

If (1) is adopted, and if n is the number of cycles in which the actual pump establishes the assigned p_{H}/Π or p_{L}/Π, then from (16) and (17)

$$\mathrm{E}_{\mathrm{vol.}}=\frac{(p_{\mathrm{H}}-\Pi)\mathrm{V}_{\mathrm{H}}}{nu_{\mathrm{L}}\Pi} \text{ (compressor)} \quad . \quad . \quad (20)$$

$$=\frac{\log(p_{\mathrm{L}}/\Pi)}{n\log[\mathrm{V}_{\mathrm{L}}/(u_{\mathrm{L}}+\mathrm{V}_{\mathrm{L}})]} \text{ (evacuator)}. \quad (21)$$

If (2) is adopted, and if N is the number of cycles per unit time required for a given volumetric speed S, we have from (18) or (19)

$$\mathrm{E}_{\mathrm{vol.}}=\frac{\mathrm{S}}{\mathrm{N}u_{\mathrm{L}}} \text{ (compressor)}, \quad . \quad (22)$$

$$\mathrm{E}_{\mathrm{vol.}}=\frac{\mathrm{S}(\mathrm{V}_{\mathrm{L}}+u_{\mathrm{L}})}{\mathrm{N}u_{\mathrm{L}}\mathrm{V}_{\mathrm{L}}} \text{ (evacuator)}. \quad . \quad (23)$$

If the H.P.V. or L.P.V. is not at atmospheric temperature, (20)-(23) must be corrected by the substitution of $\mathrm{V}_{\mathrm{H}}/\mathrm{T}_{\mathrm{H}}$, $\mathrm{V}_{\mathrm{L}}/\mathrm{T}_{\mathrm{L}}$, $u_{\mathrm{L}}/\mathrm{T}_{0}$ for V_{H}, V_{L}, u_{L}.

§ (10) OTHER CHARACTERISTICS.—The advantage which aerostatic pumps possess over other types lies in the great range which can be obtained with them. They are, therefore, well suited for the production of very high or very low pressures in a single operation; but extreme pressures can be obtained with other types combined into composite pumps. They are in general less well suited for the transference of large volumes of gas under moderate differences of pressure, although some types (*Ac*, *d*) are used for this purpose.

Their disadvantage is that they cannot exhaust vapours satisfactorily, especially when designed for a large range, for the vapours condense in U when its volume is reduced and do not pass readily into the H.P.V.; when the volume is increased again, they evaporate once more, return to the L.P.V., and keep p_{H} permanently at or above the vapour pressure of the substance. Permanent gas mixed with the vapour is removed very slowly after its partial pressure in the L.P.V. has fallen to that of the vapour.

The various types of aerostatic pump are distinguished by the construction of U and the means adopted for connecting and disconnecting it with the L.P.V. and H.P.V. The following sub-classes include conveniently all the important types:

A*a*. Solid Piston Pumps.
A*b*. Liquid Piston Pumps.
A*c*. Flexible Container Pumps.
A*d*. Rotary Aerostatic Pumps.

A*a*. *Solid Piston Pumps*

§ (11) THE VON GUERICKE PUMP.—This is the oldest type of gas-pump, and its invention is generally attributed to Otto von Guericke (1672); it was probably developed from the similar water-pump. It has still a wider sphere of use than any other type, being used for the attainment of pressures from 1000 atmos. to 10^{-6} mm., and for volumetric speeds from many cubic feet to a few cubic millimetres per minute. It is equally familiar in heavy engineering, in delicate laboratory work, and, as the tyre pump, in everyday life. Broadly, the advantages of the type are a great range of pressure and great mechanical strength; the disadvantages, cumbrousness and mechanical inefficiency. It is unrivalled for high-pressure compressors, and for small portable laboratory evacuators; for all other purposes it can be replaced by other types. However, it is still widely used even for blowers, the purpose for which its disadvantages as compared with other types are most marked. Its survival is probably due partly to its long history and to its resemblance to the reciprocating steam-engine, of which the constructional problems have been studied so completely.

The principle of the pump is familiar to all. The vessel U is a cylinder in which moves a piston. Connection is made to the L.P.V. and H.P.V. either (*a*) through ports in the cylinder wall opened and covered by the piston, or (*b*) through valves moved "positively" by the piston or the mechanism that actuates it, or (*c*) through valves opened and closed by the excess gas pressure. (*c*) is the oldest arrangement and the simplest to construct, but it represents a departure from the ideal cycle and necessarily reduces the range below the ratio u_L/u_H; for the connection between U and the L.P.V. or H.P.V. ceases before the pressures have become equal. It is still standard practice in high-pressure compressors; in evacuators for moderate vacua (*a*) is often used; in those intended for the lowest possible pressures, one at least of the valves must be of type (*b*).

§ (12).—Three kinds of piston pump may be considered rather more fully. The *high-pressure compressor*, shown diagrammatically in *Fig.* 1, is always composite. It would not be impossible to obtain a range of pressure of 200 and a final pressure of 200 atmos. by a simple pump, but there are several reasons why the multi-stage pump is preferable. Thus, it is possible to cool the gas between the stages by the "intercoolers" C. By spacing the cranks evenly round the crank-shaft a more even torque and a balanced motion can be obtained. The construction of each pump can be adapted to the pressures between which it has to work; the thickness of the metal can be increased, as shown in the figure, as the pressure increases; special piston packings and forced lubrication can be used in the H.P. cylinders. Some makers prefer water to oil as a lubricant at high pressures, and at the highest pressures the substitution seems necessary because oil would burn explosively.

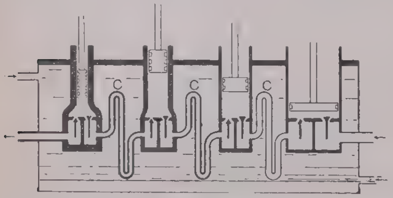

FIG. 1.

The volumetric efficiency of such a pump should be not less than 80 per cent; the gas efficiency also about 80 per cent; and the over-all efficiency about 60 per cent. The work done on the gas may be measured, for the determination of the gas efficiency, by indicator diagrams taken from the cylinders. These efficiencies are determined largely by the completeness of the cooling, which is one of the most important features of these pumps; they are also determined by leakage and by throttling at the valves.

§ (13).—*Fig.* 2 shows a large-scale two-stage evacuator, such as is used for the condensers of steam-engines and for working pneumatic tubes. The slide-valves are similar to those of a steam-engine, but to secure smooth working connection is made between the L.P.V. and the H.P.V. when the piston is in the extreme position. The pistons are connected in tandem. If the pump is to be worked by a reciprocating steam-engine it would be possible to use the same piston-rod for the driving piston, and thus to avoid rotary motions and bearings and to reduce moving parts to a minimum; but this arrangement is seldom adopted; pump and motor are usually separate.

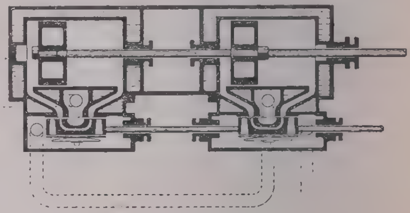

FIG. 2.

The volumetric efficiency should be about 85 per cent when $p_L=20$ cm. of mercury or more; about 80 per cent at $p^L=5$ cm.; for lower values of p_L, $E_{vol.}$ will fall rapidly, and p_L^0 will not be less than 1 cm. The over-all efficiency should be not less than 50 per cent at the higher pressures.

§ (14).—*Fig.* 3 shows part of a *laboratory evacuator* in very general use. The pump is composite with two stages; the high-pressure member presents no special features and is not shown; it is connected to H. In the low-pressure member shown, the piston is covered with oil which is ejected at the end of the stroke through the valve V, carrying the air with it. At the same time the crank J, worked by the piston guide K, forces oil into the space O by means of the oil-pump R; from O the oil flows on to the top of the piston as it descends. It is claimed that the pump will attain 10^{-6} mm., if the gas and oil are free from vapour. A drying tube with P_2O_5 is necessary in the connection L to the L.P.V., and another, which can be filled with $CaCl_2$, is desirable in the outlet of the H.P. cylinder to keep the oil dry. The pump is very efficient and convenient down to pressures of 0·01 mm., but to obtain the highest vacua of which the pump is capable needs great care in its treatment.

A piston pump for extremely low pressures has also been developed by Gaede[1] (1); in principle it does not differ greatly from that shown. In order to free the oil from water, and thus to dispense with a drying agent, the oil is forced through a special woven material which effects a separation of the two liquids. Gaede claims that his pump without any drying agent will attain a pressure of 10^{-5} mm.

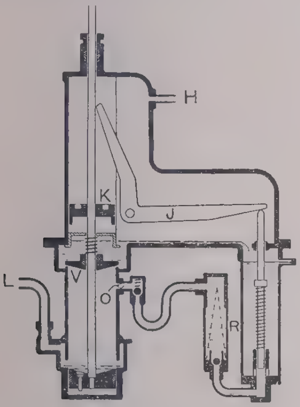

Fig. 3.

Ab. *Liquid Piston Pumps*

§ (15) Torricelli's Pump (2), (3).—It is impossible to make a perfect fit or a gas-tight joint between solid bodies movable relatively to each other; and therefore all truly solid piston pumps have some leakage and some dead space. Leakage can be wholly prevented and dead space very nearly abolished by using a liquid in place of a solid for the moving portion of the vessel U. The ratio $(p_{\mathrm{H}}{}^0/p_{\mathrm{L}}{}^0)$ can be increased by the substitution, and higher vacua (or higher compressions—though this result is not so important practically) obtained in a single operation. In fact a liquid is actually used in this manner, in pumps which are usually regarded as of the solid piston type. In the pump described last, the oil covering the "piston" and passing through the valves is really the piston, and the same purpose is served, in part at least, by the lubricating liquid of other pumps of section A*a*. However, the typical liquid piston pumps were developed historically from Torricelli's, and not Guericke's, method of evacuation; and the distinction between solid and liquid pistons, though slight from the standpoint of scientific principle, is perfectly clear in all practical examples.

In the Torricellian pump the vessel to be evacuated is completely filled with a liquid of density ρ; the open end is placed beneath the free surface of a liquid, which is usually the same as that filling the vessel. If, in this position, any part of the vessel is at a height above the free liquid surface greater than h_0, where $h_0\rho g = (\Pi - \mathrm{P})$, the surface of the liquid will sink to the height h_0, and the upper part of the vessel will contain only the vapour of the liquid at the pressure P corresponding to the prevailing temperature. As a liquid for such a pump, mercury is especially suitable, both on account of its high density and small "barometric height," h_0, and on account of its low vapour pressure.

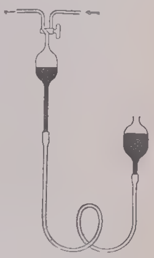

Fig. 4.

This method of evacuation has the obvious disadvantage that the whole L.P.V. has to be filled with liquid and inverted. A very obvious modification of it was described in principle by Swedenborg (1722) and put into a practical form by Geissler (1855). The action is clear from *Fig.* 4; the mercury is alternately raised and lowered and the two-way cock alternately connected to the air and to the vessel to be evacuated. The pump is a true liquid piston pump, differing from Guericke's pump only in the nature of the piston and the valves.

§ (16) The Töpler Pump.—A greatly improved form of the pump originally due to Töpler (4), but realised practically by Hagen and Neesen (5), is shown in *Fig.* 5; no stop-cocks are required. It was used in many classical researches on low vacua at the end of the nineteenth century, being at that time rivalled only by the Sprengel pump (see below) as a means of attaining low pressures.

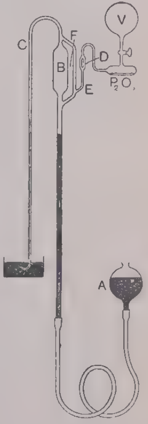

Fig. 5.

By raising the reservoir A, mercury is driven up into the cylinder B, thereby driving out the gas from the cylinder through the capillary tube C, from which it may be collected in the mercury trough. Mercury is prevented from flowing over into the vessel to be exhausted (V) by the small glass valve D.

---

[1] Figures in brackets refer to references at the end of the article.

On lowering the reservoir, the mercury flows back from the cylinder, and when the mercury reaches the lower part of the cylinder gas will enter from the vessel V through the side-tube E, ready for expulsion at the next stroke.

The *lowering* of the reservoir must be done very slowly so long as the pressure in V is more than 2-3 mm., otherwise air entering the cylinder through the side-tube E will carry mercury violently up the tube F, and this may easily shatter the glass-work of the cylinder.

When the vacuum becomes high, the *raising* of the reservoir must be done very slowly, otherwise the "hammer" of the mercury at the top of its travel in the cylinder will break the cylinder head.

The reservoir A should have about twice the capacity of B. The volume of the cylinder B is fixed by the work required from the pump, but in ordinary laboratory models is from 500 to 600 c.c. The capillary tube C is about 800 mm. long and 1 mm. bore. The tube F should have a bore 12 mm., and the tube E about 4 mm. This ensures that gas entering from E to F will tend to travel in bubbles upward through the mercury in F, instead of carrying the mercury solidly up with it.

The P_2O_5 tube is, of course, inserted to absorb water-vapour, which presents the same obstacle to this as to all aerostatic pumps.

The lowest pressure which it is possible to obtain with this pump is determined as in (15), by the ratio u_L/u_H. u_L is the volume of B, while u_H is the volume of the smallest bubble which the mercury will carry down the capillary C. This volume is approximately that enclosed between the convex surfaces of two mercury meniscuses which just touch; it decreases with the bore of the capillary. But there is some gas adhering to the glass in addition to actual bubbles left behind by the mercury, which makes it useless to decrease that bore beyond a certain limit. The lowest pressure recorded as attained by a Töpler pump is 0·000025 mm.—in addition, of course, to the vapour pressure of the mercury.

The working of a Töpler by hand is extremely tedious, for several hours may be required to reach the limit of pressure. Numberless devices for rendering its action automatic have been proposed; electrical contacts worked by the mercury, or else the weight of the mercury, are used to control the operation. But no description of them is necessary to-day, for the problem of the automatic Töpler seems to have been solved finally by Gaede (6), who proposed to move the solid vessel rather than the liquid piston.

§ (17) GAEDE ROTARY MERCURY PUMP.—The general action of the pump can be seen from *Figs.* 6, 7, which are vertical sections parallel and at right angles to the front of the pumps. The outer casing A contains mercury to about two-thirds of its height, and is connected through the pipe R with a rough vacuum pump (*e.g.* an ordinary piston pump) capable of maintaining a pressure of about 10 mm. An ingenious device shown in *Fig.* 8 is used for cutting off the rough pump after the preliminary exhaustion. Inside this casing rotates a drum B, made of porcelain, to the side of which is attached a smaller porcelain drum C. The two drums communicate through the port D.

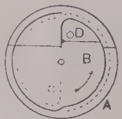

FIG. 6.

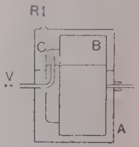

FIG. 7.

It will be seen from this diagram that if B is rotated in the direction of the arrow, the portion of B above the mercury will communicate with the pipe V, connected to the vessel to be exhausted, so long as the port D is not immersed. As soon as D is immersed, the communication with V is closed, and when the tail end E of the drum rises above the mercury, the gas will be passed on to the rough vacuum.

In the pump as actually manufactured two or three drums are spaced symmetrically on the same axle; a second drum is indicated by the dotted line in *Fig.* 6. The speed of the pump is thereby increased, but the construction made much more complicated.

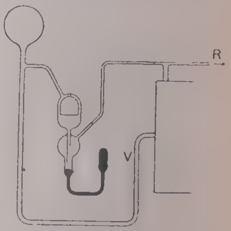

FIG. 8.

The range of the Gaede pump is probably somewhat less than that of the Töpler, for the conditions for the expulsion of small bubbles from U are less favourable. But since $p_H{}^0$ is less, owing to the use of the auxiliary pump and since its speed is much greater, the least pressure practically attainable is at least as low; a pressure of 0·00005 mm. is well within its power. The volumetric speed is not constant, as it would be according to (19); it is about 110 cm.^{3}/sec. at 0·01 mm., and falls off continuously at the lowest pressures.

§ (18) THE SPRENGEL PUMP.—A liquid piston pump, using mercury but working on a somewhat different principle from those just described, was invented by Sprengel in 1865 (7). It has over the Geissler (and later Töpler) pump the greater advantage that its action is more nearly continuous and automatic. The gas is carried out of the L.P.V. by the fall of mercury down a capillary tube, as in the Töpler pump; but it is not forced into that tube; it enters the tube under the pressure in the L.P.V. and is there trapped between successive drops of mercury falling into the top of the tube from a reservoir. In another and more convenient arrangement (*Fig.* 9) the drops are formed in the capillary by the entrance of gas from the L.P.V. through a side tube. But the principle is the same; the liquid column in the capillary will break up into drops, trapping the gas between them, if the gain in surface tension energy due to the formation of a liquid-gas surface is greater than the loss in hydrostatic energy due to the accompanying displacement of the liquid. The precise calculation of the conditions for drop formation is complicated; but it is clear that the bore of the capillary must be below the limit at which drops could be formed in the tube without completely occupying its cross-section.

The volumetric speed of a "single-fall" Sprengel is extremely small, not more than a few cubic millimetres per second. It can be increased by connecting in parallel several capillary tubes all fed from the same reservoir, and thus making a "multiple-fall" pump. The lowest pressure attainable is fixed by the same considerations as in the Töpler pump, but it may be increased by small quantities of air carried into the vacuum by the stream of mercury from the reservoir exposed to the atmosphere. Many devices have been suggested for avoiding this defect. (See (3).)

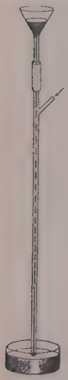

FIG. 9.

The Sprengel pump can be made completely automatic, if it is arranged that the mercury which has fallen down the capillary is restored periodically to the reservoir. Such an automatic form was at one time in universal use for the exhaustion of electric lamps (8). It is shown in *Fig.* 10, and the method of operation is obvious from that figure.

The outlet is connected to an auxiliary pump maintaining a pressure of a few cm. The capillary fall tubes A, into which mercury flows from D through the jets C, are therefore relatively short (about 20 cm.). The bent tube B enables the end of the exhaustion to be seen by the disappearance of gas-bubbles from the mercury.

The reservoir E is normally connected to H; an occasional admission of air, in order to restore the mercury to D, is controlled by a simple timing device set once and for all. It can also be controlled by the weight of the mercury in the reservoir.

The common laboratory mercury still is in effect a Sprengel pump whereby gases introduced by the mercury are removed.

For high-vacuum work, mercury pumps of these types, with the possible exception of the Gaede pump, are obsolete, and replaced by those of Class C. They may, however, be used as auxiliary pumps in series with those of that class when it is desired to collect gases pumped out from a vessel. For this purpose the Töpler pump is most suitable.

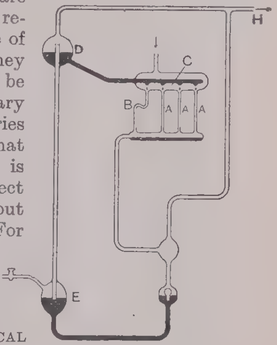

FIG. 10.

§ (19) CHEMICAL AND OTHER PUMPS.—The foregoing pumps are designed to attain low pressures. But liquid piston pumps are also of service for pumping chemically active gases, which would attack any of the metals or other materials suitable for the construction of solid piston pumps. Thus for the compression of chlorine, pumps are used of which the cylinder and valves are made of lead-covered steel, while the piston consists of oil or sulphuric acid. The liquid piston is set in motion either by compressed air or by a solid piston working in one limb of a U-tube, the other limb of which is the chlorine pump.

Laboratory pumps essentially similar to the Töpler, but using oil or glycerine or sulphuric acid in place of mercury, have also been used for some purposes. The lower densities of these liquids enable the pumps to be made of glass with a volume much greater than that set by the mechanical strength of the glass if mercury were used; or the gas to be pumped may be one which attacks mercury.

Again, air compressors for high pressures have been constructed in which water is used as the piston in order that the cooling of the gas may be more efficient. In some of these metal chains hanging into the water from the top of the piston have been used to facilitate the transference of heat between the gas and the liquid.

Ac. *Flexible Containers*

§ (20) BELLOWS.—In these pumps the vessel U has flexible walls and its volume is varied by changing its shape. The advantages of the type are high mechanical efficiency due to the absence of friction, simplicity of construction, and consequent cheapness and reliability. On the other hand, they have a small range of pressure, partly because the ratio u_H/u_L is comparatively great, partly because the flexibility of the walls makes it impossible to use them at pressures differing greatly from atmospheric. They are usually made for hand-working or very low power mechanical drives.

The earliest examples of the type are the lungs of air-breathing animals; the later improvements of the original model for this purpose are insignificant. The type is almost equally familiar in bellows of all kinds, for blowing up a fire, for vacuum cleaning, for piano-players and squeaking toys; in the fountain-pen filler, now partially replaced by a piston pump; in the bulb for scent and other sprays. But it is also used for less commonplace purposes.

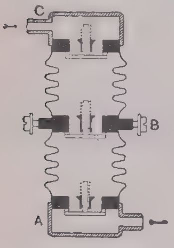

FIG. 11.

The action of the blacksmith's bellows is shown diagrammatically in *Fig.* 11. The end plates A and C are fixed, while B is given a reciprocating motion. Some bellows of this kind for smiths' hearths are several feet in diameter, with the flexible sides of leather. The air is usually pumped into a reservoir bellows in which a pressure of about 6 in. of water is maintained by a weight.

Fig. 11 also represents, on a different scale, a useful laboratory pump. The bellows are here made from the inner tube of a motor tyre, the corrugations being obtained by large metal rings inside the tube and small rings outside placed alternately. The cylindrical discs A, B, C are of aluminium, and B is driven by a crank from a small motor.

§ (21).—The most elaborate pump of this class is the organ bellows, shown on *Fig.* 12; the bellows compressor, called the "feeder" bellows, is at F. The upper board A of the feeder is fixed and the lower board B is hinged to A by a leather joint. The wedge-shaped volume between A and B is enclosed by the wooden ribs R; the ribs are hinged to each other and to A and B with leather and cloth. The board B falls by its own weight and the air enters through the flat valve V_1. Air is compressed in the feeder by a hand lever, and the air is driven through the valves V_2 into the reservoir bellows D, from which the air passes to the organ. The pressure on D depends on the weight W on the top board. To ensure a uniform pressure in D whether it is expanded or contracted a double set of ribs is used, the upper set R_3 folding outwards and lower set R_2 folding inwards; the frame H between the two sets of ribs is connected by a mechanism shown so that both halves of the reservoir bellows expand equally.

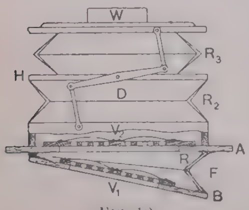

FIG. 12.

§ (22).—At the opposite extreme of the type is the squeezed rubber tube pump (*Fig.* 13) (10).

This pump consists of a rubber tube A_1A_2 (*Fig.* 5) wrapped inside a hollow cylinder B and squeezed by two or more rollers C_1 and C_2 so that the way through the tube is stopped at the squeezed portion. The rollers C_1 and C_2 roll round the inside of the cylinder driven by the shaft D, and gas (or liquid) is transferred from A_1 to A_2 as the shaft revolves.

The squeezed portions act as pistons, and these "pistons" are formed at A_1 and travel along the tube to A_2 where they disappear.

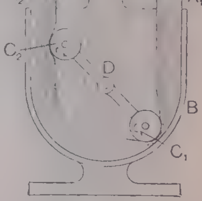

FIG. 13.

The action of the pump is somewhat similar to the rotary pump of *Fig.* 16, with the important difference that the "piston" of the rotary pump requires to be carried across from A_2 to A_1 and is thus liable to cause leakage of air or liquid. The tube pump has no dead-space and is only limited in range by the strength and tightness of the rubber tube to resist the pressure difference; but its speed is small and mechanically it is inefficient. The tube pump is particularly suitable for transferring gases or liquids without contamination, as the plain tube can be easily cleaned and no other portion of the pump can come into contact with the fluid being pumped.

An even simpler pump of the same type can clearly be made out of a plain piece of rubber tubing pressed with the fingers.

Ad. Rotary Pumps

§ (23) BLOWERS.—In this class the variation of the volume of U is effected by the rotary motion of solid bodies constituting part of its walls. The pumps are usually driven by power, and are intended for continuous action; they compete therefore with solid piston pumps rather than with other types of Class A. Over solid piston pumps they have the advantages in mechanical efficiency; in mechanical simplicity and consequently in cost, both initially and for upkeep; in compactness; in steadiness of air current when used as blowers. They have disadvantage in a smaller range of pressure, in greater leakage, and usually in noisiness. But pumps of this type compete also with those of Class B (especially B*g*). For blowers type B*g* generally has the advantage in mechanical efficiency and simplicity. For compressors there is little to choose between B*g* and A*d*, for though the latter has the greater range both types would be replaced by A*a* if a greater range were required. For evacuators B*g* is useless, while A*d* provides the standard machines of modern practice for all pressures between 10 mm. and ·01 mm.

The chief examples of the class can be divided into two groups, one (1) developed from the Root Blower, the other (2) from the Beale Blower. The development has been so gradual that it is difficult to associate any of the pumps, or even the two archetypes, with the name of any inventor. The groups are usually distinguished by the nature of the "abutment," that is the line or surface dividing the H.P.V. from the L.P.V.; group (1) is then characterised by a movable abutment, (2) by a fixed abutment; for though in (2) the bodies forming the abutment move, the line or surface which is the abutment is at rest relatively to the housing.

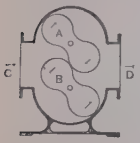

FIG. 14.

§ (24) MOVABLE ABUTMENT.—These pumps are chiefly used for moving large quantities of gas against a small pressure difference (say up to 5-10 feet water pressure).

An early example of this type was exhibited at the Paris Exhibition by Elihu Root in 1867 (*Fig.* 14). It consists of two two-toothed wheels, A, B, which are made to revolve at the same rate in opposite directions by means of gears outside the box or pump body; the space included between the wheels and the housing is U, and its volume varies with the position of the wheels. If they rotate as shown in the figure air would be sucked in at C and delivered through D.

To prevent leakage the wings are machined as accurately as possible, and are often covered with wood or other packing material. The volumetric efficiency against small pressures (say 10 inches of water) may be as high as 96 per cent, while at higher pressures (6 feet of water) it will drop to 80 per cent. The over-all mechanical efficiency is about 75 per cent.

Fig. 15 shows another type where the impeller vanes V are fastened at one end to a disc which causes them to rotate around the fixed core. The vanes after the delivery stroke come into the openings in the rotating body A (called the idler), which is caused to rotate at the same speed as the vanes by gears on the outside. On rotating further the vanes come into the suction chamber, whence they start again on the compression stroke.

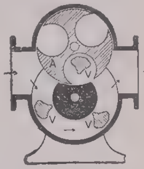

FIG. 15.

The pump is more complicated than the Root, but several advantages are claimed. Thus surfaces can be used to separate the two chambers where lines only are possible in the Root blower; air is compressed by one rotating part only; there is no contact between parts moving with different velocity, and thus there is less friction; the mechanical construction is simple and cheap; the pulsations of gas are reduced.

In another type the rotating parts are spiral vanes, which give a more even delivery of gas and make less noise; the mechanism is not easily shown in a diagram. Many other devices have been adopted, some varying widely in detail from those mentioned, but all based on the same principle; descriptions of them are to be found in makers' catalogues.

§ (25) FIXED ABUTMENT.—These pumps, of which the Beale blower is an early example, are used extensively as compressors, as blowers, and as evacuators. They are used in gasworks for pumping the gas to the holders, and in the factory or laboratory for attaining pressures down to ·001 mm. The general principle employed is shown in *Fig.* 16.

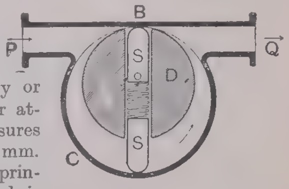

FIG. 16.

The cylinder D rotates about an axis O, so that it touches the containing cylinder C at the fixed abutment B. A slot in D carries the plates or "scrapers," the outer ends of which are held against the containing cylinder C. The plates divide the space between C and D into two parts; as D rotates the volumes of these two parts vary in a manner readily seen from the figure, in which P is the suction and Q the compression inlet.

The friction of the scrapers on the cylinder involves considerable loss and wear, and many alternative arrangements have been devised to avoid it. In one, contact between the scrapers and the cylinder is preserved by a circular guide with its centre coincident with that of C. In another there is a single solid scraper which slides freely in the slot in D; the section of the cylinder D is not circular, but such that the two ends of the scraper are in contact with the walls whatever the position of D. In another the scrapers are pushed out by springs, but they bear on an idly rotating cylinder C′ fitting closely within C and pierced with holes; the clearance between C and C′ is made so small that the leakage between the two is inappreciable; the friction is thus reduced to that of C′ on its bearings. In any pump of this type, the number of scrapers may be increased. *Fig.* 17 shows a type with three or more scrapers, hinged at the central axis M of the box B, and sliding in cylindrical stuffing boxes C fastened to the rotating drum D; this drum touches the casing in the fixed abutment E.

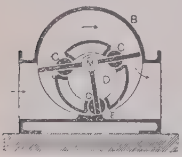

FIG. 17.

In pumps of this type designed as evacuators oil is always introduced into the cylinder to prevent leakage and to fill up the dead space. The scrapers are usually arranged as in *Fig.* 16. In order to prevent hammering by the oil when the vacuum is high, a valve is fitted which limits the quantity of oil flowing from the compression side; it also helps to separate the air from the oil. Such evacuators are often run in tandem, or one of them is used in series with an auxiliary pump of some other kind. If p_H is 4 to 10 mm., p_L may be reduced to ·0001 mm.

Scraper vacuum pumps are largely used as auxiliaries to high-vacuum pumps (C); they are also the chief type employed in the preliminary evacuation of electric incandescent lamps, which are subsequently "cleaned-up" by the discharge (D).

B. AERODYNAMIC PUMPS

§ (26).—In aerodynamical pumps, the pressures are functions of S and of the velocity of the gas in different parts of the apparatus. The fundamental connection between the pressure and velocity of any fluid is given by the familiar hydrodynamical equation

$$\delta(p+\tfrac{1}{2}\rho v^2)=0, \quad . \quad . \quad . \quad (24)$$

or

$$p_1-p_2=\tfrac{1}{2}\rho(v_2{}^2-v_1{}^2). \quad . \quad . \quad . \quad (25)$$

It is deduced on the assumptions (1) that the energy required to change the pressure of a volume V of the gas from p_1 to p_2 is (p_1-p_2)V, (2) that the energy of any such change of pressure which occurs is equal to the change in the kinetic energy of the gas. (1) implies that the fluid is incompressible,[1] or that the change in pressure is infinitely small; (2) that there is no loss or gain of energy to or from other sources, *e.g.* friction of the moving gas. By "the pressure" must be understood the force per unit area on a surface at rest relative to the gas; in a frictionless fluid it is equal at any point to the "static" pressure on a surface parallel to the flow at that point, but moving relatively to the gas; the "dynamic" pressure, or that on a surface perpendicular to the flow and at rest relative to the pump, is $p+\frac{1}{2}\rho v^2$, and, when (24) is true, is constant along the whole stream.

Be. *Injectors and Ejectors—Gaseous Stream*

(General Reference (11))

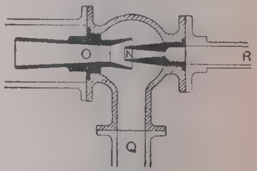

FIG. 18.

§ (27).—These are wholly analogous to liquid jet pumps (see "Hydraulics"). A gas or vapour (called "the fluid" to distinguish it from the gas to be pumped) is forced through a tube N from a reservoir R, at pressure p_R, into a larger tube O communicating with the atmosphere (see *Fig.* 18). If the flow satisfied assumption (2) above, the stream would not be brought to rest in the atmosphere unless p_R were equal to Π, and if $p_R=\Pi$ there would be no stream. But owing to viscosity and friction, p_R may be greater than Π, so that a high velocity v_N is obtained in N, and yet v may be zero when the atmosphere is reached. In these conditions, the difference $\Pi-p$, where p is the pressure at N, is not so great as $\frac{1}{2}\rho v_N{}^2$ given by (24); but it is still finite and of the same sign; p is less than Π.

If gas in the space surrounding N is given access to the stream through the gap between N and O, it will flow into the stream of fluid and be carried away by the stream, so long as its pressure is greater than p. The fluid streaming from N to O will suck gas through the pipe Q and will act as an evacuator or "ejector." In an "injector" or compressor, Q communicates with the atmosphere, and the space with which O communicates, and in which the stream comes to rest, is at a pressure greater than Π, but, of course, still much less than p_R. p is equal to $p_L{}^0$ in an ejector and to $p_H{}^0$ in a compressor; but if there is a continual stream of gas through the pump, p_L or p_H will not be equal to p, (1) because of the drop due to flow of the connecting tubes Q and O, (2) because the mixing of the gas with the fluid affects greatly the velocity and pressure of the latter.

---

[1] Confusion is sometimes introduced by a failure to observe that the chief part of the pressure of a gas is inseparable from its compressibility; it is not due, like that of a liquid, to its weight. The pressure of an incompressible gas is a meaningless conception. The application of the theory to gases is justified only because, for small changes of pressure at constant temperature, $pd\mathrm{V}=-\mathrm{V}dp$.

In calculating the performance of a pump, allowance has to be made for departures from (25) owing to friction and viscosity. The allowance is usually made by introducing on the right hand of (25) an empirical factor ζ, less than 1, and writing

$$p_1 - p_2 = \tfrac{1}{2}\zeta\rho(v_2{}^2 - v_1{}^2), \quad . \quad . \quad (26)$$

where v_1, v_2 are the mean velocities over a cross-section of the stream. The principle of the calculation is then simple. There are three equations (26) for the three tubes N, O, Q; and there is the equation of conservation of mass when the streams meet. (The momentum is *not* conserved, for there is a reaction on the tubes.) These four equations suffice to determine the four unknowns, viz. p, v_N, v_O, v_Q, in terms of p_R, p_L, p_H, the densities ρ_g and ρ_f of the gas and fluid, the three empirical constants for the three tubes, ζ_N, ζ_O, ζ_Q, and F_N, F_O, F_Q, the cross-sections of the three tubes at their openings. The algebra need not be set out, for the numerical results depend wholly on the values attributed to the empirical constants; it is given in (11). Here it will suffice to state some of the most important qualitative conclusions, which are confirmed by experiment. These were first stated by Zeuner (12).

The variables considered are p_R, p_L, p_H, v_R, F_N, F_O, F_Q, ρ_g, ρ_f, and S, the volumetric speed, which is equal to v_QF_Q. In each statement the variables not mentioned are supposed constant.

(1) $p_H - p_L$ is proportional to p_R and $v_R{}^2$, so long as p_R is great compared with p_H or p_L.

(2) S is proportional to $\sqrt{p_R}$, to v_R, and to $p_H - p_L$, subject to the same condition.

(3) $p_H - p_L$ depends only on the ratios of the F's, and not on their absolute values.

(4) S is proportional to the F's, if their ratios are constant.

(5) Given one of these ratios, there is an optimum value for the other two, giving maximum S, but the same maximum S can be obtained with different values of the ratios.

(6) S is independent of ρ_g and ρ_f, so long as v_R is constant.

(7) S may be considerably greater than the volume of fluid issuing per second from N, *e.g.* two or three times as great.

Owing to the circumstances in which the pumps are used, the efficiency is seldom important. But the mechanical efficiency reckoned on the basis of the work done in driving the fluid stream appears seldom, if ever, to exceed 25 per cent.

§ (28).—In practice the fluid used is generally steam or compressed air. Ejectors using these fluids are used for vacuum brakes, vacuum cleaners, and grain conveyors. Their great advantage is, of course, their simplicity and freedom from maintenance charges. *Fig.* 18 shows a pump used for railway vacuum brake operation. It will reduce p_L to about 15 cm. of mercury. A more elaborate pump is shown diagrammatically in *Fig.* 19. Here a common supply of steam works two pumps in series. The first consists of the plain nozzle A, the second in the annular gap B, from which the gas is carried into the surrounding annular space C. It is claimed that this pump will attain a pressure of 3 cm. of mercury. Remark should be made that the application of the simple theory to such pumps is extremely precarious, for the assumption that the change of pressure of the gas is infinitesimal is clearly false.

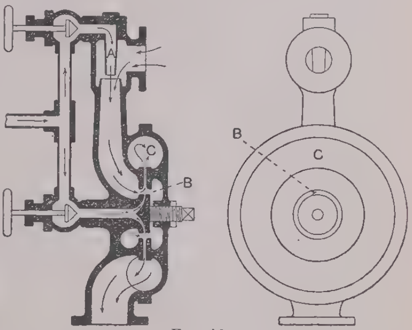

FIG. 19.

Fig. 20 shows a blower used for moving large quantities of air in ventilation under a pressure of a few inches of water. Air or steam is used as fluid; the concentric cones are designed to make the velocity of the gas nearly parallel to that of the fluid, so that the direction of flow of the latter is not disturbed by irregularities in the flow of the former. A somewhat similar arrangement is adopted in the smoke-box of a locomotive, where the exhaust steam is made to create a draught through the boiler flues.

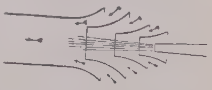

FIG. 20.

§ (29).—The most modern development of the type is the mercury vapour jet pump used in conjunction with "condensation" high-vacuum pumps (*q.v.*). Indeed, as will be seen, the line between vapour jet pumps and condensation pumps cannot be drawn sharply; roughly it may be set at the pressure where the mean free path of the vapour molecules becomes comparable with the dimensions of the tubes; but there is no justification for overlooking the distinction entirely. The construction of these vapour jet pumps is essentially similar to *Fig.* 18, but the apparatus is made of glass; the vapour stream is produced by boiling mercury, and condensing arrangements are provided for returning the vapour to the boiler. A practical form designed by Volmer (13) will reduce the pressure from $p_H = 20$ mm. of mercury to $p_L = \cdot 001$ mm. But it is doubtful whether they will replace generally the rotary aerostatic oil-pump for producing the auxiliary vacuum of high-vacuum pumps. Fragility is their great fault.

B*f*. *Injectors and Ejectors—Liquid Stream*

§ (30).—This type of pump, of which the laboratory filter pump (*Fig.* 21A) is a common example, is often regarded as a mere modification of B*e*, gas or vapour being replaced by a liquid as fluid. But the difference is really greater. If the theory of B*e* is applied to pumps with liquid as fluid, then, even if all plausible corrections are made, the calculated performance is far less (*e.g.* 10 times) than the actual. The error arises in assuming that the gas and fluid are miscible. The flow of the gas into the fluid is not determined simply by the pressure difference, and relative motion of the fluid and gas is possible, even after they are mixed in the exit tube O.

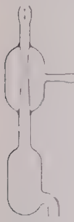

FIG. 21A.

It seems preferable to look at their action from a different point of view. Two processes are involved: first, the entangling of the gas by the liquid stream; second, the conveyance of the entangled gas from the L.P.V. to the H.P.V. During the second process the gas will move relatively to the liquid nearly as if the liquid were at rest relative to the walls. The difference of pressure ultimately obtainable is limited only by the condition that the velocity of the liquid entering the L.P.V. by N is sufficient to carry it out through O against the pressure $p_H - p_L$, and is also greater than the velocity with which the bubbles of entangled gas travel through the liquid in the opposite direction. It is the second process which determines the greatest possible value of $p_H^0 - p_L^0$.

On the other hand, the speed of the pump is determined by the first process. Its nature is obscure; probably the liquid stream carries along a layer of gas on its surface, in virtue of friction and viscosity (cf. § (39)), as would a solid rod travelling with the same velocity. When the liquid breaks into drops in virtue of the inherent instability of liquid jets, this gas becomes entangled between the drops.

On this view the performance of a pump of this type appears quite incalculable. No calculations confirmed by experiment seem to have been based on any view, and few data of performance or of its variation with the construction of the pump seem available.

§ (31).—The filter pump of *Fig.* 21A fed with water at a head of 50 ft. or more will reduce p_L to the vapour pressure of the water. But no measurements of S under varying conditions have been found. It is recorded that the pump is more efficient if placed at the top of a building so high that the exit tube can be made as long as the water barometer.

A variant on the usual design is shown in *Fig.* 21B, which is similar in construction to the Venturi meter. But since the action is improved by a baffle at *b* which breaks up the stream, it is probable that, as suggested, the formation of drops is an important part of the process. A non-return valve, as shown at V, is useful with either of these types to prevent the flow of water into the apparatus if the head becomes insufficient.

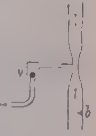

FIG. 21B.

Evacuators of these types are applied outside the laboratory to vacuum cleaning and to grain conveyors. Compressors working on the same principle, but with a different construction, have also important commercial uses; they are known as "trompes." In a very simple form (*Fig.* 22), used for blowing blacksmiths' fires, a stream of water flowing down a pipe with a few holes in it drags with it air from the atmosphere, which is subsequently separated from the water in a closed vessel. A more elaborate form has been developed in America for supplying compressed air to mines where a great head of water is available. The pressure obtainable is a considerable fraction of that corresponding to the head of the water.

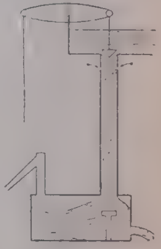

FIG. 22.

B*g*. *Centrifugal Pumps*

(General Reference (11) and (14))

§ (32).—Centrifugal air-pumps are analogous to centrifugal liquid pumps (see "Hydraulics"). They are generally called "fans," and are used as fans or blowers according to the definition of the introduction. The principle is shown in *Fig.* 23, which illustrates the simplest type. The gas entering the circular central aperture O in the housing is whirled round by the rotating vanes, acquires velocity, and issues through B.

Suppose that the conditions necessary for (24) are fulfilled, and that the gas leaves the tips of the vanes with a radial velocity v_1, uniform over the whole surface of the circular cylinder surrounding the vanes. The area of this surface is $2\Pi rd_1 = F_1$, where r is the radius of the vanes and d their breadth perpendicular to the diagram. Then

$$S = F_1 v_1. \qquad . \quad . \quad . \quad (27)$$

If F_2 is the area of the opening, and v_2 is the velocity of exit uniform over the opening,

$$S = F_2 v_2. \qquad . \quad . \quad . \quad (28)$$

If the gas in acquiring its velocity from the vanes preserves its original pressure p_L, then from (25)

$$p_H - p_2 = \tfrac{1}{2}\rho(v_1{}^2 - v_2{}^2) = \tfrac{1}{2}\rho S^2\left(\frac{1}{F_1{}^2} - \frac{1}{F_2{}^2}\right). \quad (29)$$

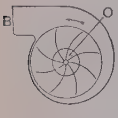

FIG. 23.

But, as in Section B*e*, (24) is not true and allowance has to be made for losses of energy due to friction and to sudden changes in the direction of the gas stream. Further, the velocities are not uniform over the surfaces F_1 and F_2. Again, it is convenient to express $p_H - p_L$ and S in terms of the velocity of the vanes which can be measured directly; it is usual to represent this velocity by v_0, the linear velocity of the tips. It may be assumed that v_1 and v_2 are proportional to v_0. The losses may be then represented by one or more terms proportional to $v^2{}_0$ or to S^2, or to Sv_0, and the general equation for the performance of the pump written

$$p_H - p_L = \alpha v_0{}^2 + \beta v_0 S + \gamma S^2. \qquad (30)$$

The constants α, β, γ are usually regarded as depending on the angles at which the stream of gas strikes the vanes and the housing; they certainly depend on the geometrical quantities characteristic of the pump. Some progress towards calculating them directly from those magnitudes can be made, but some purely empirical constants are always necessary. In designing the forms of the vanes and of the housing such calculations are a useful guide; here reference can only be made to discussions in (11) and (14). It may be noted that in (30), α is always, β usually, positive, while γ is negative.

Three kinds of efficiency are recognised for centrifugal pumps:

§ (33).—(i.) The manometric efficiency $E_{man.}$ is taken as $(p_H - p_L)/\rho v^2$, p_L (usually Π) and p_H being the static pressures of the inflowing and outflowing gas. If v_1 were equal to v_0, the maximum value of $E_{man.}$ would be $\frac{1}{2}$, but since v_1 may be either greater or less than v_0, $E_{man.}$ might theoretically have any value; actually it is seldom if ever greater than 1.

(ii.) The mechanical efficiency $E_{mech.}$. The useful work is generally taken to be given by (9), so that if w is the power exerted at the pump shaft, $E_{mech.} = S(p_H - p_L)/w$. Sometimes the useful work is reckoned by (9*a*); the corresponding efficiency is called the total efficiency, but it is seldom important, as previously explained. $E_{mech.}$ is a true efficiency and can never be greater than 1.

(iii.) The volumetric efficiency $E_{vol.}$, which is taken by some writers to be $S/v_0 r^2$ and by others to be $S/2\pi rdv_0$. The latter quantity would be unity if v_1 were equal to v_0; the former seems to have no general significance, but, being a no-dimensional magnitude, is convenient for comparing similar designs. $E_{vol.}$ is often greater than 1 if the first expression is chosen, sometimes if the latter is chosen.

It is apparent from (30) that the pressure and the efficiencies will vary with S, if S is controlled by changes in the area F_2 or by other changes in the resistance to the flow of the gas. *Fig.* 24 shows typical curves relating the brake H.P. w, the pressure difference $p_H - p_L$, and the mechanical efficiency to the volumetric speed S, the velocity of the vanes being constant. It will be observed that this efficiency is zero for $S = 0$ and for high values of S and has a maximum for some intermediate value. If mechanical efficiency is required the pump must be designed for its special work. If the velocity of the pump is varied over a moderate range, S varies as v_1, $p_H - p_L$ as v^2, and the power expended is v^3. For extreme varieties the "constants" of (30) change.

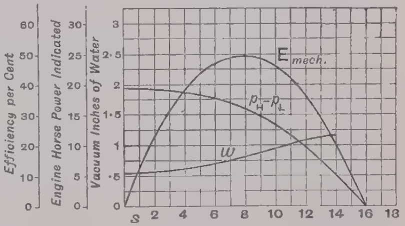

FIG. 24.

§ (34).—Simple centrifugal fans differ in size, in the number and shape of the vanes, and in the shape of the housing surrounding them. This is often divided into a "diffuser," or portion with parallel sides immediately outside the vanes and a "volute," or portion of circular section, outside the diffuser. The cross-section of the volute increases towards the outlet in order to make some use of the kinetic energy (see § (5)). Some fans have inlet openings on both sides of the fan, some only on one. But in their performance, they all have common characteristics; they are all used as low-pressure blowers, the maximum pressure obtained being about 12 in.

of water; p_H/p_L does not exceed 1·03, and assumption (1) of § (26) is justified. In large sizes their mechanical efficiency may reach 80 per cent, but usually it is more nearly 70 per cent and intermediate between that of piston pumps and of Root's Blowers. Over either of these types they have the advantage of simplicity and of being proof against hot and dusty gases if the bearings are suitably protected.

Composite, or multi-stage, centrifugal fans are also common. The fans of successive stages run on the same shaft; the discharge from the circumference of one fan is led by a tube to the central intake of the next. Since $p_H - p_L$ is proportional to ρ by (25) and ρ is proportional to p_L or p_H, we have in successive stages $\delta p \propto p$, or $p_n/p_1 = \kappa^n$, where κ is the range of the simple pump and n is the number of stages. The range of the composite pump is the product of the ratio-ranges of the individual stages. Such multi-stage fans with ten or more stages, each giving $\kappa = 1{\cdot}1$ when driven by a turbine or electric motor at 4000 r.p.m., are used to deliver air to blast furnaces at a pressure of 2½ atmos. They are also used for "super-charging" petrol motors on aeroplanes. In *Fig.* 25 a 3-stage fan of this kind is shown; details of bearings, rings to prevent leakage, and the water-jacket of the outer casing have been omitted. A, B, C are the revolving "impellers," while the parts drawn solid are fixed.

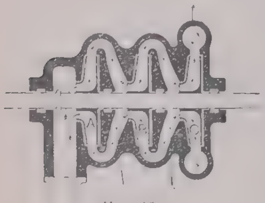

FIG. 25.

Rateau constructed a simple fan, running at 20,000 r.p.m., which gave $\kappa = 1{\cdot}5$; experiments on extremely high speeds have also been made by Parsons and others. But such simple fans seem to have no practical advantage over the composite type.

Bh. Airscrews

(General References (11) and (14))

§ (35).—In type B*g*, the velocity of the gas produced by a rotating solid is perpendicular to the axis of rotation; if the velocity is mainly parallel to that axis, the fan may be called a "propeller," or, better, airscrew. In all that concerns the general relations between the velocity of the solid and the velocity or pressure of the gas, airscrews are indistinguishable from centrifugal pumps. Thus the pressure produced by an airscrew is proportional to the square of its velocity, the volumetric speed to the velocity, and the power to the cube of the velocity. (35) is still true, at least approximately, and similarly defined efficiencies might be employed to state the performance.

The difference between airscrews and centrifugals lies in the connection between the constants of these equations and the geometrical magnitudes. Much more is known of this connection for airscrews, perhaps on account of their importance for other purposes; for this knowledge reference may be made to "Aerodynamics"; since airscrew pumps are not very important, no further account of their theory need be given here.

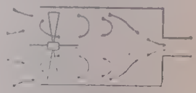

FIG. 26.

§ (36).—Airscrews are largely used for ventilation, either stirring up the air in a room or extracting it into the atmosphere through a hole in the wall. A plain airscrew is very inefficient for the second purpose, since the difference of velocity between the centre and circumference of the screw produces a circulation within the fan itself, as shown in *Fig.* 26. The loss due to this circulation is greater when, as in *Fig.* 26, it is the H.P.V. that is partially closed than when it is the L.P.V. To reduce the loss the centre of the airscrew is often covered with a disc to prevent the return flow; the volumetric speed for a given diameter and velocity is thereby decreased, but the mechanical efficiency is increased.

It is impossible to secure that all the energy given to the gas shall produce axial flow; some inefficient tangential and radial flow is always produced at the same time. In the Rateau screw fan, shown in *Fig.* 27, the tangential and radial flow is greatly reduced by causing the gas to strike the blades (B) with a velocity opposite to that of their rotation. This velocity is imposed on the inflowing gas by the fixed vanes V. The centre of the blades is covered by the fixed disc D. *a* shows a transverse section through the fan, *b* a "cylindrical" section made by a cylinder coaxial with the fan, cutting B and V and developed into a plane. In *b* the motion of the blades B is upwards. The Rateau screw fan resembles in its performance a simple centrifugal.

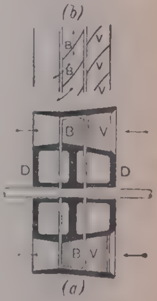

FIG. 27.

Some fans, described as of "mixed flow," are intermediate between centrifugals and airscrews, the flow of gas being partly radial or tangential and partly axial. But they do not differ sufficiently in principle from the many types of pure airscrews and centrifugals, which are also described in makers' catalogues, to warrant special notice. For small powers there seems little to choose between these classes of fans; for larger powers the centrifugal is more suitable; it is also more suitable for the individual members of a composite pump.

Bi. *Thermal Pumps*

§ (37).—The principle of these is sufficiently discussed under "Convection." The chimney of the open fire which ventilates a room and the gas jet in the flue of the chemical fume cupboard are familiar examples of "blowers" of this type. The draught produced by a flame in a flue has also been used to work small wind channels for aeronautical investigation; and generally, if only very small powers are concerned and efficiency is unimportant, chimneys and small fans may be regarded as mutually interchangeable.

C. High-vacuum Pumps

(General References (21), (23))

§ (38).—During the last few years pumps have been invented which will attain pressures definitely lower than those that can be reached with any of the pumps described so far. They depend upon "molecular" processes, that is to say, processes explicable by molecular theory and not by hydrostatic or hydrodynamical theories, which regard a gas as a continuous medium. These processes become important only when the pressure of the gas is below some definite limit, which is usually far below that of the atmosphere. The pumps must therefore be run in series with an auxiliary pump which reduces and maintains the pressure below the limit at which the action of the molecular pump begins; this pressure is of the order of 0·1 mm. As auxiliary pumps, those of type (A*d*) are now usually employed. Further, since the vapour pressure of water is much above the limiting pressure, a drying agent must be used in conjunction with the auxiliary pump; on the other hand, a molecular pump does not distinguish between vapours and permanent gases, and no device is needed to remove from the low-pressure side of the pump any vapours except those which arise from the action of the pump itself.

Two molecular processes have been employed for such pumps, both originally suggested by Gaede. Since the first type was the only member of its class when first invented, it was called by its inventor the "molecular pump." It is convenient to retain the term and confine it to this type, although the second type, invented later, has an equal right to it.

Cj. *Friction Pumps*

§ (39) Gaede Molecular Pump.—The action depends upon the forces between a gas and a solid (or liquid) surface moving relatively to it. At ordinary pressures these forces are determined by the viscosity of the gas, and the influence of the solid boundary enters into the calculation of the flow only through the assumption that v_0, the velocity of the gas at that boundary, is zero and that there is no "slip." But at sufficiently low pressures Kundt and Warburg (15), confirmed by many later observers, showed that the measured flow agreed with that predicted hydrodynamically only if it was assumed that there is some slip, that v_0, the velocity of the gas at the boundary and parallel to it, is finite, and that the force exerted on the gas by the boundary is ϵv_0. ϵ is called the friction coefficient and ϵ/η the coefficient of slip.

From the molecular standpoint the matter appears somewhat differently. The condition $v_0=0$ means that the velocities of the molecules leaving the boundary are symmetrical on either side of the normal. The appearance of slip at low pressures does not mean that this condition is no longer fulfilled. For if the pressure is greater on one side of the normal than on the other, more molecules will arrive at the boundary from the first side: if the molecules leave the boundary equally distributed on both sides, then there will be on the whole a flow of gas from the first side to the second, so long as the distance travelled by the molecules leaving the boundary before they collide is finite. On the other hand, the flow will be less than it would be if the molecules left the boundary with their velocity parallel to it unchanged. Accordingly the condition $v_0=0$ is not inconsistent at low pressures with the hydrodynamical assumption of a finite slip coefficient.

Knudsen (16) has calculated the friction coefficient from such a molecular theory. He assumes that whatever the direction of the incident molecules, the number with any velocity leaving the boundary within a cone of solid angle $d\omega$ making an angle θ with the normal is proportional to $\cos\theta d\omega$ and that the distribution of velocities is Maxwellian. He concludes that $\epsilon=\epsilon_0 . p$, where

$$\epsilon_0=\tfrac{3}{8}\sqrt{\frac{\pi}{2}}\rho_0, \quad . \quad . \quad . \quad (31)$$

and ρ_0 is the density of the gas at unit pressure and the prevalent temperature. (31) has been confirmed by experiments at pressures less than 0·001 mm. Gaede (17) has shown that at higher pressures ϵ_0 is greater, probably owing to the presence of a gas film on the bounding surface.

Consider a layer of gas between two infinite parallel plates, distant h from each other, moving relatively to the gas with velocities v_1, v_2. Let p_1, p_2 be the pressures of the gas at points distant L along the direction of motion. If the pressure is so high that the mean free path is small compared with the distance between the plates, the forces on the gas are due to its viscosity; the relation between p_1 and p_2 is given by the equation similar to that of Poisseuille:

$$(p_1 - p_2) = \frac{6\eta}{h^2} \cdot \mathrm{L}(v_1 + v_2). \qquad (32)$$

But if the distance between the plates is small compared with the mean free path, the conception of a viscosity depending on collisions between molecules becomes insignificant, and the equation must involve only ϵ, depending on collisions with the walls. It is found that

$$\log_e \frac{p_2}{p_1} = \frac{\epsilon_0}{h} \mathrm{L}(v_1 + v_2). \qquad (33)$$

The ratios of the pressures at opposite ends of the plates is a function of the velocities and of the geometrical quantities: it is independent of the pressures. If any geometrical arrangement other than that of parallel plates is used, this proposition is still true, so long as the pressure is sufficiently low, and so long as the velocities are considerably less than the mean velocity of the molecules. If this last condition were not fulfilled the distribution of velocities among the molecules leaving the boundary would be no longer Maxwellian, and ϵ_0 would be greater—which would clearly be desirable for the purpose in view.

§ (40).—The construction of Gaede's pump (18) in which this principle is applied is shown diagrammatically by transverse and longitudinal sections in *Fig.* 28. A is a cylinder rotating in the closely fitting housing B; in the surface of A are cut grooves into which project the obstructions C attached to the housing; the pipes n and m open into the grooves on either side of C. If A rotates clockwise the friction between the rotating cylinder and the gas lowers the pressure at n and increases it at m. The grooves are in series from the middle outwards; m of the middle groove is connected to n of each of the grooves on either side, and so on; m of the outermost grooves are connected to the auxiliary vacuum (H.P.V.) and n of the middle groove to the L.P.V. A is run at about 140 revs. per sec. by a pulley and motor. The axle passes through an oil box which seals the interior of the housing from the atmosphere. The intrusion of oil from the oil box is prevented by an Archimedean screw cut on the axle, which drives the oil backward; this arrangement makes it of great importance that the auxiliary vacuum should be turned on after the pump is started, and turned off before it stops.

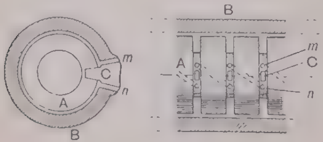

FIG. 28.

The precise calculation of the pressures obtained is very complicated; for there has to be taken into account, besides the driving of the gas from n to m by the friction of the rotating cylinder, the leak of the gas back from m to n past the obstruction C and over the surface of the cylinder between successive grooves. But theory shows and experiment confirms that at a sufficiently low pressure the ratio of initial and final pressures is proportional to the speed of rotation and independent of the pressure, but the ratio falls off when the pressure in any part of the pump rises above that (about 0·02 mm.) at which b is equal to the mean free path. At a speed of 140 revs. per sec. and an auxiliary vacuum of 0·1 mm. $p_{\mathrm{H}}/p_{\mathrm{L}}$ is about 10^5, so that a pressure of 10^{-6} mm. can be obtained. But the ratio varies with the gas, in virtue of the occurrence of ρ_0 in (31); it is less with hydrogen than with air; probably hydrogen formed a large part of the gas with which this measurement was obtained. Lower pressures could be obtained with a better auxiliary vacuum; but the vacuum attainable is definitely limited by that of the auxiliary pump.

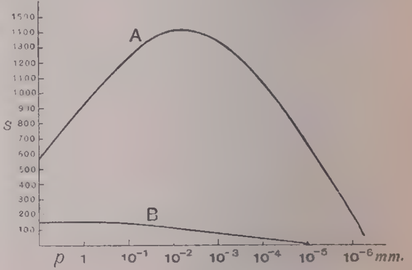

FIG. 29.

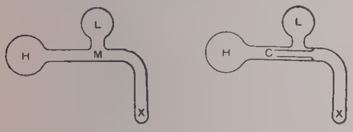
An important feature of these pumps is the great speed of pumping. *Fig.* 29 A shows S (in cm.³/sec.) plotted against the pressure (log. scale); for comparison, B shows S for the Gaede rotary mercury pump (*Ab*).

The molecular pump would have made possible modern high-vacuum work; but all its advantages, except one, are possessed by the next type of pump to be considered. This one advantage is that it will remove *all* vapours, while all other high-vacuum pumps leave mercury vapour, which has to be removed by condensation. But the advantage is of little practical importance for most work since the pump will maintain the vacuum only while it is running; if it is to be stopped and the vacuum preserved, some form of tap or trap must be inserted, and such devices always introduce vapours. On the other hand the molecular pump is necessarily expensive and requires skilled attention. Despite its novelty and ingenuity it is already practically obsolete.

Ck. Diffusion Pumps

§ (41) Diffusion Pumps.—In *Fig.* 30 (*a*) let H be the H.P.V. in which is maintained a constant pressure, L the L.P.V. to be evacuated. Let X be a vessel in which some liquid can be heated, while H, but not L, is cooled so as to condense its vapour. If the liquid is heated to a temperature at which its vapour pressure P is large compared with p_H, a continual stream of vapour will pour along the tube XMH, driving the gas before it and condensing in H; if the stream is sufficiently rapid the gas in H will be unable to diffuse back into the tube against it. On the other hand, the gas in L will diffuse out into the vapour stream and be carried by it into H. For this diffusion is not opposed by a vigorous stream in the contrary direction; since L is not cooled, the vapour will not condense in L, and vapour will enter it only at a rate sufficient to replace the gas diffusing out. Accordingly, after some time L will be completely evacuated of gas and contain only vapour. If L is now cooled, the vapour will condense and an almost perfect vacuum be left in L. The vacuum will not be quite perfect because some gas from H will diffuse back against the stream of vapour, however low is p_H and however rapid the stream; but a consideration of the magnitudes involved will show that the residual pressure could easily be made inappreciable.



(*a*) (*b*)

Fig. 30.

Such is the principle of the diffusion pump in its simplest and ideal form. In practice it is impossible to maintain the whole of L (the apparatus to be evacuated) at or above the temperature of the boiling liquid during the evacuation. L as well as H is cooled sufficiently to condense the vapour, and consequently if the simple arrangement of *Fig.* 30 (*a*) were adopted, the diffusion of gas out of L would be opposed by a vigorous stream of vapour entering; if the gas from H could not diffuse against the stream neither could the gas from L; there would be no pumping. Some device, therefore, must be adopted to prevent a stream of vapour entering L.

§ (42) Gaede Diffusion Pump.—The device originally adopted by Gaede (19) was to place in the tube leading to L an obstruction with a very small opening. If the linear dimensions of this opening are small compared with the mean free path of the molecules, the laws of the flow of gas and vapour through the opening are not those of hydrodynamical streaming, but those of diffusion. The flow depends on the partial pressure of the constituents of the mixture and not on their total pressure. Since the partial pressure of the gas in the tube XMH is zero, the gas will diffuse out through the entering vapour in spite of the fact that the total pressure of the vapour is greater in the tube than in L. The problem can be treated exactly by molecular theory. If d is the diameter and σ the area of the opening at M, λ the mean free path, ρ_0 the density of the gas at a pressure of 1 dyne per cm.^{2}, then the volume of the gas, measured at p_L, issuing through M per sec. is given by

$$S = \alpha\frac{\sigma}{\sqrt{2\pi\rho_0}}; \quad . \quad . \quad . \quad (34)$$

where

$$\frac{\alpha}{2} = x^2 - e^{-1/x}(x + x^2), \text{ and } x^2 = \frac{8\lambda^2}{d^2},$$

α attains the maximum 1 when d/λ is small; but σ decreases with d. The maximum value of S, when λ is fixed, is given approximately by $d = \lambda$. This maximum will increase with λ, which, since the vapour pressure of the liquid must be greater than p_H, is limited by p_H. Accordingly the speed of the pump depends greatly on the auxiliary vacuum, and also on the temperature of the liquid. For if P is too small, gas will diffuse back from H; if it is too large, the diffusion of gas from L will be hindered by the opposing flow. The conditions in the pump need therefore careful adjustment. On the other hand, S is independent of the pressure of the gas and dependent only on its nature and temperature: this is the most striking feature of all diffusion pumps. S is greater for the lighter gases; the variation of S with the nature of the gas is the contrary of that for the molecular pump.

§ (43).—Any liquid could be used in a diffusion pump, so long as it could be maintained at the appropriate temperature. Actually mercury is used, for the appropriate temperature is convenient (P = 0·3 mm. at 100° C.);

moreover it is chemically stable and does not wet glass. But its universal adoption is probably due in part to the previous association of mercury with air-pumps—an association based on quite different properties.

The vapour of the liquid used in the pump at the pressure corresponding to atmospheric temperature is left by the pump in L. It is easily removed from the apparatus connected to L by making the connection through a trap cooled in liquid air. The introduction of the cooled trap involves, of course, a continual stream of vapour opposing the diffusion of the gas through L; but at atmospheric temperatures the vapour pressure of mercury is so low that the consequent diminution in the speed of the pump is inappreciable. However, Gaede (19) has pointed out that the existence of this stream causes a slight error, appreciable at the lowest pressures, in the measurement of the pressure in L by a McLeod gauge. Since vapour is streaming from the gauge to L, the pressure of the gas in L is slightly higher than its pressure in the gauge.

§ (44).—The original diffusion pump of Gaede involved complicated glass construction: since it is no longer used, it need not be shown. The maximum value of S obtainable was about 80 cm. and far below that of the molecular pump at the higher pressures. On the other hand S was, as theory predicts, independent of the pressure down to the limits of measurement; at pressures less than 10^{-6} mm. the diffusion was as good as the molecular pump, and no practical limit to the pressure was set by the diffusion of gas from H against the vapour stream.

Moreover, it should be observed that there is nothing in the principle of the pump to limit its use to very low pressures, except the condition that $d=\lambda$: if openings as small as the free path could be obtained at atmospheric pressure the pump would work. Gaede has actually used the pump at atmospheric pressure, taking the pores of an earthenware pot as the openings and steam as the vapour; but since the pores are backed by very fine tubes, through which the gas has to flow before it arrives at the pump, the speed of such a pump is very slow; it is not generally of practical use.

§ (45) **Langmuir "Condensation" Pump.**—A simpler and more efficacious method of preventing the flow of vapour into L is to use the inertia of the stream to carry it past the opening. Thus in the modification shown in *Fig.* 30 (*b*), if the velocity of the stream of vapour issuing at C is as great as the velocity of the molecules in the stream, all the vapour will travel forward till it meets the walls of the outer tube or the gas in H; none will stream towards L and prevent the diffusion of gas from L, although the pressure in the vapour stream, as measured by its density, may be very much greater than the pressure in L. (It will be seen that the construction is similar to the gas injector pump Be, but the principle of action is different. The gas from L diffuses against the hydrostatic pressure; it does not flow with it.)

If the walls of the outer tube were heated by the vapour, the liquid condensing on them would have a vapour pressure greater than that in L; there would be a flow of vapour from the heated walls towards L, which is cool, and this stream would once more hinder the diffusion of gas from L. Accordingly Langmuir (20), who first used this arrangement, laid great stress upon the cooling of the walls struck by the vapour stream; he insisted that the vapour must be immediately condensed to the temperature prevailing in L, so that there should be no flow of the vapour back towards L. On account of the importance attributed to this condensation, he termed his pump a "condensation" pump to distinguish it from Gaede's diffusion pump; but it is equally a diffusion pump in the sense that the gas from L follows the gradient of partial pressure, not that of total pressure. Gehrts (21) has pointed out that Langmuir's principle was anticipated by Magnus (22), who did not see its applications.

It appears, moreover, that though the very efficient cooling of the walls and the complete condensation is necessary to the most efficient working of the pump, it is possible to make a pump of this type with much less efficient cooling. This is achieved in Crawford's parallel jet pump (24). But in its working characteristics this pump resembles the diffusion rather than the condensation pump, and has not the advantages of Langmuir's pump noted below.

§ (46). — The construction of Langmuir's pump in metal (25) is shown in *Fig.* 31; it can also be made without great complication in glass (20). The mercury M is maintained at a temperature of about 100° C. by the expenditure of about 300 watts, supplied electrically or by a burner. The baffle B deflects the vapour stream downwards and against the walls cooled by the water jacket J. The L.P.V. is connected to L; the auxiliary pump to H. If this pump maintains a pressure p_H of 0·01 mm. or less, S is as great as 3000-4000 cm.^{3}/sec. and is, as before, independent of p_L down to the lowest observable pressures. Higher pressures p_H decrease the speed, but the pump will work even if the pressure is nearly 0·1 mm. The speed is independent of the temperature of the mercury, so long as this is above a limit, which is greater the greater is p_H. The great speed of the pump—greater even than the maximum of the molecular pump—and the absence of any need for the accurate control of temperature, are the advantages that have caused condensation pumps to replace wholly the original Gaede type.

Many variations on the original Langmuir design have been made. In some of them (26, 27) the heating of the mercury is effected by an arc maintained between two mercury surfaces inside the pump; in fact this arrangement has been applied to large mercury-vapour current rectifiers (28), so that the rectifier acts as its own high-vacuum pump, only an auxiliary pump being needed. Again, it has been proposed (29, 30, 31) to combine in the same apparatus a mercury-vapour jet pump and a condensation pump, using the same stream of mercury vapour. The two act in series, and the combination will work with an auxiliary vacuum of 10-20 mm.; but the construction is complicated.

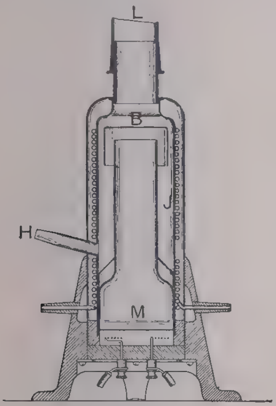


FIG. 31.

However, special reference need be made only to one type of this pump, remarkable for its simplicity. It is found possible to dispense altogether with the inner tube in *Fig.* 30 (*b*) and to make the arrangement of *Fig.* 30 (*a*) act as a condensation pump by merely cooling the walls of the horizontal tube. Since the mercury molecules striking the cooled walls do not rebound therefrom, if the cooled tube is made sufficiently long, all the molecules emerging from its end at M will be moving parallel to the length of the tube and will not enter the side tube. One form of such a pump is described in (32). An even simpler construction is shown in *Fig.* 32 adopted, the whole being made of sheet metal. The limit of p_H at which the pump will work is about 0·015 mm., and somewhat higher than that for the Langmuir type. But the value at which the maximum speed is obtained is not very different; this maximum is about 1500 cm.³/sec., and is set by the dimensions of the inlet tube (see below) rather than by the pump itself. The auxiliary vacuum of 0·01 mm. for this or the Langmuir pump can be obtained by oil-pumps, and presents no difficulty. The simple pump of *Fig.* 32, as well as the Langmuir and other more complicated pumps, is used on the industrial scale in the manufacture of thermionic valves and other high-vacuum devices.

§ (47) HIGH-VACUUM TECHNIQUE.—It has been pointed out that there must be some limit to the pressure reached by a diffusion or condensation pump, determined by p_H and the speed of the vapour stream. When a high-vacuum pump is used the pressure attainable and the speed of pumping are actually limited by factors other than the efficiency of the pump. In the first place, the tubes connecting the pump to the apparatus offer a resistance to the flow of gas. Knudsen (16) has shown that the volumetric speed of a perfect pump is given by

$$S = \frac{1}{\sqrt{\rho_0} \, . \, R}, \qquad (35)$$

where R is a constant dependent of the form of the connecting tube and ρ_0 is the density of the gas at a pressure of 1 dyne/cm.².

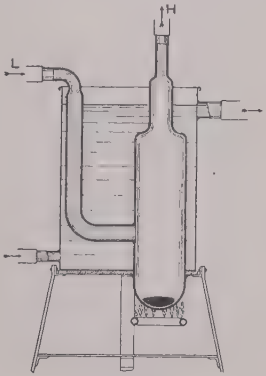

FIG. 32.

For a cylindrical tube of radius r and length L,

$$R = \frac{3L}{4\sqrt{2\pi}}. \qquad (36)$$

If r is expressed in millimetres, L in metres, then for air at 20°,

$$S = 1{\cdot}03\frac{r^3}{L}. \qquad (37)$$

S is 1000 cm.³/sec. for air flowing down a tube 1 metre long and about 1 cm. in diameter. Consequently to make full use of the speed of a condensation pump, connecting tubes not less than 2 cm. in diameter must be used;

if the evacuated vessel has to be sealed off eventually, the speed is often limited by the diameter of the sealing-off constriction. If this constriction is to be sealed off by a blowpipe it is difficult to make it more than 3 mm. in internal diameter; but it is possible by heating the tube very uniformly and by making the temperature gradient along it very steep (*e.g.* by a small electric furnace surrounding it) to seal off tubes 10 mm. or more in diameter.

§ (48).—Secondly, there is an evolution of gas from the apparatus being exhausted. Glass and metals in their ordinary condition give off large quantities of gas when exposed to a vacuum. The gas from glass is chiefly water and CO_2 which has been absorbed from the atmosphere and will be reabsorbed if the glass, having once been freed from gas, is exposed to the atmosphere once more. The gas from metals is largely hydrogen and carbon monoxide, absorbed from flame gases during manufacture and diffusing out from the interior. The evolution is greatly hastened by heat and, in metals at least, by making them the electrode of a discharge, even if it does not cause material heating.

To obtain a high vacuum, it is necessary to heat the glass while the vessel is exhausted to the highest temperature that the apparatus will stand without collapse; about half an hour at this temperature will liberate the gas from the surface, but there is a continual evolution at this temperature which is generally thought to result from an actual decomposition of the glass; this evolution stops when the glass is cooled, but if the cooling is too rapid some of the gas may condense on the glass during cooling and be evolved slowly again. For some purposes it is desirable to enclose the apparatus in a vacuum furnace, so that the external pressure of the atmosphere is removed and the glass can be heated for some time beyond the softening point without collapse. The metal parts must also be heated to near their melting point for several hours; this heating is effected in modern practice, either by making the metal the target of an electron bombardment from an incandescent cathode, or by exciting high-frequency eddy currents in the metal by coils surrounding the apparatus. Much time can be saved by heating the metals in a vacuum before they are introduced into the apparatus.

By long-continued treatment of this nature the evolution of gas can be stopped and a vacuum obtained which is perfect so far as the most delicate manometers can tell, and is maintained indefinitely if the vessel is gas-tight. But if the exhausted apparatus is sealed off from the pump, some gas is always introduced by this operation. For in order to soften the glass it must be heated above the temperature at which an inexhaustible evolution of gas starts. The gas thus introduced can be diminished by heating the sealing-off place to near its softening temperature for some time before sealing, and then completing the sealing as quickly as possible. Again much of the gas (chiefly water vapour) thus introduced disappears, being either absorbed by the glass, or "cleaned up" by a discharge subsequently passed through the vessel. But it seems that, whatever precaution is taken, the most delicate forms of manometer will always detect the presence of some gas in a vessel immediately after it is sealed off.

For further information on these points reference is made to (33), which is the best summary in English of the state of an art which is described in patents rather than in scientific journals. Some important devices are still kept secret.

D. MISCELLANEOUS METHODS OF EVACUATION

§ (49).—It remains to consider some other methods of evacuation which, though they do not satisfy any definition of a pump that would have been acceptable twenty years ago, satisfy, ideally at least, that given at the beginning of this article. Some of them are, and still more have been, of great practical importance; and they do not appear to differ more radically from the older conception of a pump (which implied a mechanical device with moving parts) than the diffusion pumps. Their chief modern use lies in the possibility they provide of evacuating a portable vessel sealed off from all fixed apparatus.

§ (50) CONDENSATION.—The pressure of the gas in a vessel can be reduced by cooling sufficiently any part of its walls. The limiting pressure obtainable by this means is, of course, the vapour pressure of the substance at the lowest temperature available. Savery, when he evacuated the cylinder of his steam-pump by condensing the steam with a jet of water, was using this principle. It has had some more modern applications, *e.g.* when a gas such as air has been removed by displacing it with CO_2 and then condensing the CO_2 in liquid air. The method is also used for compression. Chlorine, CO_2 and SO_2 have been compressed into containers by condensation in place of by compression pumps.

§ (51) CHEMICAL ACTION.—Gas can also be removed by causing it to react chemically with the formation of solid or liquid compounds. Gas analysis by "absorption" with liquid reagents employs this principle, but some developments of it need more special mention. Thus it has been shown (34) that metallic calcium heated to 700° C. will combine with most, if not all, gases, except those of the inactive group, to form solid compounds with low vapour pressures. But some of the compounds, especially the hydride, have considerable dissociation pressures at slightly higher temperatures, and the temperature of the metal must be carefully controlled. The method has its uses in special circumstances (*e.g.* where high vacua have to be maintained away from a laboratory or supply of liquid air). The alkali metals will also combine with all active gases; the combination is usually brought about by the electric discharge. It has long been known that a discharge passed with a cathode of sodium or potassium (more conveniently the alloy of the two) will remove the common gases down to the pressure where the discharge ceases. The latest development in this direction is absorption by heated thorium or zirconium (35).

§ (52) ABSORPTION.—But such chemical methods have been little practised since the discovery of the powerful absorption for gas of charcoal at low temperatures. From the discovery of the method by Dewar (36) to the invention of the molecular pump in 1913, it was the standard method of producing extreme vacua unattainable by liquid piston pumps. A glass or, preferably, silica tube containing a few grams of charcoal is attached to the vessel to be evacuated. The charcoal is heated during the preliminary exhaustion of the vessel, which should be carried to ·001 mm.; the vessel is then disconnected from the pump and the charcoal tube cooled in liquid air. If the vessel is large and the highest vacuum is required, two or more charcoal tubes may be attached, one being sealed off before the next is cooled.

Many experiments have been made on (1) the relative amounts of different gases which charcoal will absorb at different temperatures and (2) the absolute amounts absorbed by charcoal prepared in different ways. A full discussion of the results is beyond the scope of this article, and for fuller information reference may be made to a good summary in (37). As regards (1) it appears that, in general, gases are more absorbed the higher their boiling points, the exception being the inactive gases which are but slightly absorbed. The mass absorbed is proportional to the mass of the charcoal; it increases as the temperature is decreased and as the final pressure of the residual gas is increased; it is doubtful, therefore, whether a really perfect vacuum could be obtained by the method in ideal conditions, but, as with the diffusion pump, the actual limit lies beyond the range of measurement. The rate of absorption decreases greatly as the equilibrium pressure is attained, and, though the speed of evacuation is rapid compared with that of any piston pump down to ·0001 mm., it is probably slower than that of the Langmuir pump at lower pressures.

As regards (2), there is some conflict of evidence which has been only partially removed by the very complete study of the absorption by charcoal which resulted from its use in gas masks during the late war. In general the denser charcoal from the harder woods shows the greater absorption; the shell of the cocoanut and the kernels of some fruits are the best raw materials. The original coking should be at a temperature not exceeding 900° C., and must be followed by some process for the removal of residual hydrocarbons. For this purpose heating in a stream of chlorine at 800° followed by heating at the same temperature in hydrogen has been suggested; but the best modern practice appears to be alternate absorption of air or oxygen at atmospheric pressure and liquid air temperature with "out-gassing" of the absorbed gas by evacuation at 400°-500° C. Some writers maintain that all absorbed gases can be removed by heating to 600° C., others that heating to any temperature over 500° impairs the subsequent absorption. It has been found also that charcoal, activated by special processes, will produce high vacua even at atmospheric temperature.

Absorption, similar to that of charcoal, is displayed by other finely divided solids. In fact, all solids probably absorb some gas at all temperatures, the differences are merely of degree. Of the other solids proposed for practical evacuation, palladium black (which will absorb other gases as well as hydrogen) and finely divided copper may be mentioned. In addition reference may be made to the unusually great absorption of hydrogen by tantalum at atmospheric pressure. Here again reference may be made to (38).

§ (53) ABSORPTION IN THE ELECTRIC DISCHARGE.—In the early study of X-rays it was found that a hard tube often became "harder" by the passage of the discharge through it in consequence of a disappearance of part of the residual gas. This disappearance seems to be a normal accompaniment of the discharge; when it does not take place, or when the contrary process of an evolution of gas occurs, it is because the normal disappearance is obscured by an evolution of gas caused by heating or possibly by some other and distinct action of the discharge.

The facts concerning this absorption of gas are still obscure, and still more obscure the explanation of them. It is certain that the inactive gases are in general less absorbed than others, but whether and to what extent the nature of the electrodes and of the walls determine the absorption is not yet certain. Here reference will only be made to those actions of the discharge in "cleaning-up" gas which are of practical importance. A general reference may be given to (39).

The final evacuation of such apparatus as thermionic valves, rectifiers and X-ray tubes is probably effected by the discharge. However carefully the apparatus is evacuated by pumping, some gas is always introduced in sealing off from the pump. This gas is largely, if not entirely, absorbed by the walls and electrodes before any discharge passes; but during the first few moments of the discharge, which represents the normal function of the apparatus, some further change occurs which makes the "clean-up" more complete and more permanent.

It has long been known that the passage of the discharge between suitable electrodes would promote chemical actions which lead to the removal of gas. An instance is provided by the discharge between electrodes of the alkali metals, which has been already mentioned. Again, it has been found that a discharge passing to an electrode of charcoal would cause the charcoal to absorb at atmospheric temperature as it will absorb without the discharge at liquid-air temperature (40).

§ (54).—But the most practically important process of evacuation dependent on the discharge is that which involves the introduction of phosphorus vapour into the evacuated vessel. It appears to have been discovered first by Malignani (41); it was applied to the evacuation of electric incandescent lamps and has been used for the same purpose continuously since its discovery. At first it appears to have been thought that the action was chemical, but it is now known to be dependent on the passage of a discharge through the mixture of gas and containing phosphorus vapour.

The exact conditions which determine the disappearance of the gas are still obscure, but it may be stated generally that if a discharge is passed through any mixture of gas or vapours containing phosphorus vapour the pressure will be reduced more rapidly and to a lower limit than it would be if the phosphorus vapour were absent. The gas that has disappeared can be restored by heating the walls of the vessel to a temperature at which red phosphorus will evaporate. The latest theory of the action (42) is that the gas is deposited on the walls and covered with a "varnish" of red phosphorus produced by the action of the discharge from the phosphorus vapour, which prevents the re-evolution of the gas so long as the "varnish" remains; it is also supposed that the exceptional electrical properties of the phosphorus vapour are of importance. It is known that sulphur, iodine, and arsenic act in somewhat the same way as phosphorus in this matter.

In an incandescent lamp the necessary discharge passes between the opposite ends of the filament which act as electrodes; the cathode, being incandescent, gives a thermionic emission sufficient to abolish the cathode fall of potential and permit a discharge to pass even when the potential difference between the electrodes does not exceed fifty volts.

In Malignani's original method the phosphorus vapour was introduced by heating a small quantity of red phosphorus in the tube connecting the lamp to the pump just before sealing off. The later practice is to deposit the red phosphorus on the filament or the adjacent supports, whence it is evaporated as soon as the filament is heated. Nowadays it is also usual to deposit on the filament, together with phosphorus, salts such as fluorides or chlorides. Various benefits are attributed to the presence of these salts, but it seems to be agreed that their action is subsidiary to that of the phosphorus, and that the evacuation would not occur unless phosphorus (or one of the other elements mentioned) were present.

By this process of phosphorus evacuation, the use of high-vacuum pumps in lamp manufacture is rendered unnecessary. Even if the pump leaves residual gas at a pressure of 0·1 mm. in the lamp, almost all this gas will be removed in the first few seconds of "burning," and the pressure reduced to less than 0·001 mm. No mercury-pumps are now used in lamp-making; oil-pumps, usually of Class A*d*, are sufficient.

The same method has been applied to other commercial vacuum apparatus, *e.g.* rectifying valves of the old type without an incandescent cathode (43), and, more rarely, to the modern thermionic type.

BOMB CALORIMETERS

§ (1) **Introduction.**—The laboratory method of determining the calorific value of a fuel is to burn a known weight of a carefully dried sample in a vessel containing oxygen. From the temperature rise of the water in the calorimeter the heating value of the fuel is computed, taking into account certain corrections which are described later. Although the calorific value does not give all the information desired concerning a particular fuel, or determine its suitability for a specified purpose, yet it is generally accepted that the heating value is the most important property to be considered in estimating the value of fuel. Purchasers of large quantities of coal now adopt the heat-unit basis of evaluation, and the technique of combustion calorimetry has been so well developed that a skilled operator can average thirty-five determinations per day.

Two types of apparatus are employed for such tests. In one the fuel sample is burned under normal atmospheric pressure in a calorimeter of the "submerged bell" type,[1] whilst in the other the fuel is burned under high pressure in a "bomb" type of calorimeter. Some authorities prefer the "bell" type to the "bomb" because in it the combustion is carried out in oxygen at nearly atmospheric pressure and, consequently, the conditions resemble those obtained in steam boiler practice. With a "bomb" calorimeter the combustion is almost instantaneous and resembles an explosion in its violence and rapidity.

---

[1] See "Coal Calorimeter."

The decomposition products of coal vary somewhat, and it is generally found that the results obtained with the bomb calorimeter are slightly higher than those with the "bell." For scientific work, however, the bomb type is universally used, since under good working conditions the combustion obtained is practically complete. In skilled hands either method gives reliable and concordant results for solid fuels, but the "bomb" is the only method applicable to liquid fuels.

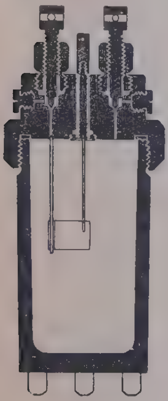

FIG. 1.

§ (2) DESCRIPTION OF A BOMB CALORIMETER OUTFIT.—The calorimetric outfit consists of the following elements:

(i.) The bomb.
(ii.) The calorimeter vessel, stirrer, and constant temperature jacket.
(iii.) The temperature measuring instrument.

(i.) *The Bomb.*—In one of the oldest forms of apparatus — the Mahler-Donkin — the bomb consists of a massive gun-metal cylinder provided with a cover held down by three studs. The cover is provided with a milled-head screw valve for regulating the inlet of oxygen to the cavity inside the bomb. The joint between the bomb proper and its cover is effected by means of a lead washer inserted in a circular groove. The inside of the cover has a projecting ring which registers with this groove when it is screwed down. The bomb is plated inside with gold in order to withstand the corrosive action of the nitric and sulphuric acids produced by the combustion of the fuel. The most satisfactory form of lining is that of platinum, but nowadays it is not much used on the score of expense. Porcelain enamel is also sometimes used for lining the bomb.

The Kroeker type of bomb has a cover screwed on to the bomb (see *Fig.* 1). The bomb is made of steel and has a fixed platinum lining, while the cover is of bronze.

Parr[1] has recently designed a bomb of an acid-proof base-metal alloy which appears very promising.

Some investigators employ a replaceable lining, but in practice it is found difficult to maintain a perfect fit and, consequently, difficulties arise owing to leakage of the products of combustion into the space behind the lining where it corrodes the metal of the body of the bomb.

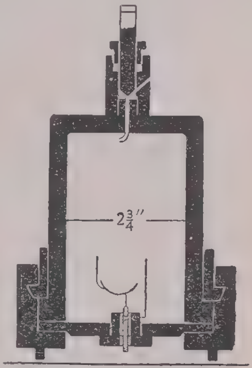

FIG. 2.

The staff[2] of the U.S. Bureau of Mines have developed a form of bomb (see *Figs.* 2 and 3) in which the lid is held in position by a novel form of sealing device. This consists of a tough steel receiving nut and lock so constructed that less than a one-eighth turn with the wrench suffices for sealing. A circular gasket of electrician's solder effects the seal. This locking device is an adaptation of the principle used in the breech locks of artillery. They claim for this design durability, ample strength, and facility of manipulation. Further, when the lock wears out a new one can be substituted without the expense of making and gold-plating a new shell. The shell of the bomb is made of Monel metal which is well adapted to gold plating.

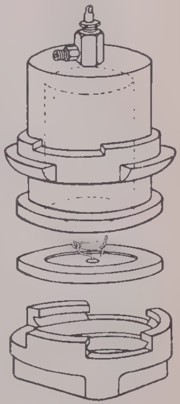

FIG. 3.

Féry has devised a bomb calorimeter in which the heat developed is shown on an indicator. See article on "Calorimetry, Method of Mixtures," § (13) (ii.), "Metallic Block Calorimeters."

(ii.) *The Calorimeter, Stirrer, and Constant*

[2] "A Convenient Multiple-unit Calorimeter Installation," by J. D. Davis and E. L. Wallace, *Bureau of Mines Technical Paper*, 91, 48 pp., Washington, 1918. Abstract in *Engineering*, Jan. 10, 1919.

Temperature Jacket.—In the outfits employed in this country the calorimeter, stirrer, and jacket are similar to those employed in apparatus for ordinary calorimetric experiments by the Method of Mixtures (see § (4)).

At the U.S. Bureau of Mines[1] a form of apparatus has been developed which is especially adapted for combustion calorimetry (see *Fig.* 4).

The calorimeter is made of heavy sheet brass reinforced at the top and middle by brass bands (see A). A tubular stirrer well is soldered to the calorimeter as shown in B. An electrode is fastened to the bottom of the calorimeter, but insulated from it, which makes contact with the bomb plug when this is placed in position.

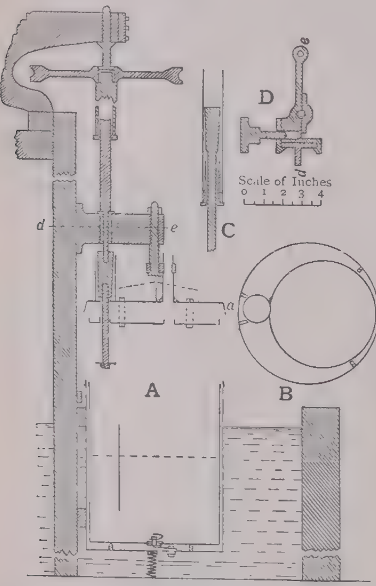

Fig. 4.

Details of Calorimeter: A, vertical section; B, horizontal section through *ab* showing tubular stirrer well; C, shaft clutch; D, horizontal section through *de* showing lid bracket.

The calorimeter is supported in its jacket on three ivory studs. The jacket is a cylindrical vessel provided with a cover of brass ground to a water-tight fit. This cover is provided with a thin sheet-brass water seal (see *Fig.* 4) fixed to the cover proper by means of three thin insulating rods of ivory in such a manner that when the calorimeter is in place and the cover brought down snugly the water seal is in contact with the surface of the water in the calorimeter, thus serving as an effectual seal against evaporation into the space between the calorimeter and its jacket.

Soldered to the jacket are two heavy brass lugs, by which it is held to the vertical brass T-bar of the frame in such a manner as to permit the jacket to slide vertically. The jacket is supported by a heavy helical brass spring bearing against the bottom of the tank, and of such strength that the jacket when charged is held vertical with its top slightly above the surface of the tank water against an adjustable stop fixed to the T-bar.

The stirrer shaft arrangement is also shown in *Fig.* 4. The upper part of the shaft on which the driving wheel is mounted consists of a thick-walled brass tube, into which the lower part of the shaft telescopes, the latter being provided with a conical piece (C) screwed to the end which engages a receiver at the lower end of the shaft tube after the manner of a conical friction clutch when the whole calorimeter is lowered into place. The lower bearing of the stirrer shaft is carried by the lid bracket (D), which is held to the vertical T-bar of the frame by a clamp which permits of raising and lowering the lid and clamping in any desired position.

The calorimeter cover has tubular outlets (not shown in *Fig.* 4) for the thermometer, the stirrer shaft, and electrical leads, so that the jacket and its cover may be totally immersed in the tank water during an experiment.

In the equipment of the Bureau six such outfits are mounted in one thermostatically controlled constant temperature bath.

(iii.) *The Temperature Measuring Instrument.*—With the majority of bomb calorimeter outfits mercury thermometers are employed for the measurement of the temperature rise of the water. Such instruments have the advantages of simplicity, cheapness, and moderate accuracy. They have the disadvantages of considerable lag and lack the sensibility required for work of the highest precision. The mercury thermometer, moreover, possesses the serious drawback that the mercury often sticks in the bore, particularly with a falling meniscus. This trouble can be somewhat alleviated by tapping the stem, and some observers utilise a miniature electric buzzer for this purpose.

The thermometer should preferably be a solid stem type with its scale divided to ·02° C., and the scale divisions should extend down to the bulb to avoid uncertainty as to the magnitude of the emergent column.

For work of the highest precision a calorimetric resistance thermometer is really essential, and a description of suitable instruments for the purpose will be found in the article on "Resistance Thermometers," § (6 (i.)).

---

[1] Davis and Wallace, *loc. cit.*

§ (3) METHODS OF CONDUCTING A TEST. (i.) *Calibration of the Apparatus.*—It is necessary to determine the heat capacity of the bomb and its fittings by experiment, since it is rarely possible to calculate this constant from the specific heat of the materials employed in its construction. There are two standard methods of effecting this calibration: (*a*) By an electrical method based on the input into the calorimetric system of a known amount of heat measured as electrical energy. (*b*) By burning substances of known heating value.

(*a*) The electrical method is capable of considerable accuracy, since electrical energy can be measured with high precision. In practice, however, the method suffers under the disadvantage that it involves elaborate equipment and is time-consuming. Further, it is by no means easy to reproduce with it the same conditions as prevail during a combustion test. The electrical method is generally adopted in standardising laboratories, but for the purpose of a works laboratory the second method is to be preferred.

(*b*) To calibrate a calorimeter by means of standard substances, such as naphthalene or benzoic acid, it is advisable to make about half-a-dozen combustions, sufficient amounts of the standard being used to produce about the average temperature rise obtained in tests with coal. This method, besides being simple and easy of application, tends to minimise errors such as those due to thermometer calibration, cooling correction, heat input from stirring, etc. Dickinson[1] has recently redetermined the heat combustions of the following substances: naphthalene, benzoic acid, and sucrose or cane sugar, with a view to their adoption as standards in calibration work. His results are summarised in Table I. together with those of previous observers.

It appears from a comparison of the values given by different observers for the same substance that benzoic acid is the most suitable in view of the close agreement of the results obtained.

Dickinson found naphthalene to be a convenient material to work with, but care was necessary in handling since a gram briquette would lose about 1 milligram in weight per hour by sublimation. Sucrose did not seem so well adapted as benzoic acid for standardisation purposes. It has a smaller heat of combustion and frequently fails to ignite.

Dickinson suggests that the higher results given by other observers for sucrose may be due to the fact that they may not have corrected for the heat generated in the firing wire before the sample ignites. With sucrose a greater length of fuse wire has to be used than with other materials on account of its lower inflammability.

Iron wire is frequently employed because it burns instead of only melting, and is therefore more certain to ignite the sample. The heat of formation of iron oxide is about 1600 calories per gram of iron. The sucrose specimens required about 3 cm. of wire weighing 132 mg. per metre. Hence the correction for the heat liberated in its combustion amounted to about 2 calories per centimetre. Naphthalene ignited readily with 1 cm. of wire.

He also corrected for the small amount of nitric acid formed from the nitrogen contained in the oxygen. The amount is nearly proportional to the heat liberated in the combustion and to the percentage of nitrogen present, and was determined by titration after each combustion. The heat of formation of HNO_3 from $N+O+H_2O$ is about 230 calories per gram of acid. As the oxygen employed contained from 0·3 to 0·5 per cent of nitrogen, the correction to be applied for the heat of formation of HNO_3 was usually about 1 part in 1000.

TABLE I

The data in the above table are expressed in terms of the 15° calorie.

§ (4) PREPARATION OF THE TEST SAMPLES.[1] (i.) *Solid Fuels.*—It is necessary to convert the coal into a small briquette or tabloid for the purposes of test. If the attempt is made to employ the sample in powder form the force of the explosion usually blows some of it against the internal walls of the bomb and it escapes combustion.

Bituminous fuels as a rule will form briquettes by pressure alone. In cases where insufficient tarry matter is present in the natural fuel, just sufficient of a 1 per cent solution of gum arabic may be used to make the particles of fuel adhesive. For half a gram of fuel, three drops of such solution are enough. The briquettes must be heated in an air bath to 110° C. for at least four hours to expel the last traces of moisture thus introduced before testing in the calorimeter.

---

[1] "Combustion Calorimetry," *Bull. Bur. Stds.*, 1915, xi. 253.

[1] *The Times Engineering Supplement*, Feb. 23, 1917.

(ii.) *Liquid Fuels.*—In weighing and transferring the liquid fuel to the bomb, carriers consisting of small cylindrical blocks of pure cellulose are used, one of these blocks being able to absorb several times its own weight of any ordinary fuel oil. The saturated block, after being weighed, is burned under the conditions and with all the precautions necessary for solid fuel, the only difference being that a rather higher pressure is used. in order to obtain a greater supply of oxygen gas in the bomb. A blank test with the cellulose alone gives the necessary data for the calculations. As liquid fuels contain only traces of acid-forming elements no trouble arises from corrosion, and a bomb provided with a gold lining will last for some hundreds of tests.

As regards the special precautions necessary to obtain correct results when testing liquid fuels, it must be pointed out that the absorbent cellulose blocks sold for this purpose absorb moisture as well as oil, and that it is necessary to dry them before use for one or two hours in the air-bath at 100° C. When saturated with heavy oils of high boiling-point they are also somewhat difficult to ignite, and it is advisable to place a little of the dry unsaturated cellulose in a loose condition around the platinum ignition wire in order to avoid failure of the test from this cause. As the cellulose blocks are large in proportion to their weight and absorbent capacity, a larger platinum dish will be required than for the tests with solid fuel, and the platinum ignition wire should be arranged to hold down the cellulose block lest the explosive violence of the combustion blows it out of the dish.

§ (5) QUANTITY OF OXYGEN REQUIRED.—The quantity of oxygen required is about three times that which will unite with the charge to give complete combustion. Dickinson found that, when the amount of oxygen was much less than two and a half times that required to unite with the combustible charge, there were often cases of incomplete combustion as indicated by a reduction in the total heat liberated, as well as by the occasional presence of a slight amount of soot and by the odour of the products of combustion.

Since the usual pressure employed in routine tests is 20 to 27 atmospheres, or 300 lb. to 400 lb., it is advisable to have a small back-pressure valve inserted in the milled-head screw in the bomb cover in order to avoid a great loss of gas when disconnecting the oxygen supply pipe and gauge from the bomb, after filling the latter with oxygen. At these high pressures the combustion of the coal is practically instantaneous, and the thin platinum wire used for ignition purposes will generally be found fused owing to the temperature momentarily attained. In order to protect the platinum capsule or crucible from the same effect, and from the action of the molten slag produced, it is necessary to line it with thin asbestos board, cut and shaped to fit the crucible or capsule. This asbestos board must be dried and ignited before use in order to remove all matter that might vitiate the results.

§ (6) CALORIMETRY BY COMBUSTION WITH SODIUM PEROXIDE.—Fusion with sodium peroxide is the only way known for finding the heat of oxidation of elements which do not burn in oxygen and which form oxides insoluble in acids. The method is adapted to the determination of the heat formation of the oxides of a metal and also the heat combination of metallic oxides with sodium oxide.

The method is indirect and the heat effect sought is not the observed effect; hence burning in compressed oxygen is preferable where possible. For example, when carbon is burned with sodium peroxide the observed heat (x) is the result of the following reaction:

$$2Na_2O_2 + C = Na_2CO_3 + Na_2O,$$

and x equals the heat of formation of carbon dioxide plus the heat of combination of carbon dioxide with sodium oxide, and less the heat required to separate two atoms of oxygen from two molecules of sodium peroxide; thus

$$x = C + 2O + (Na_2O + CO_2) - (2Na_2O + 2O),$$

so that

$$C + 2O = x - (Na_2O + CO_2) + (2Na_2O + 2O).$$

Moreover, many substances do not give with sodium peroxide sufficient heat to fuse the mixture, and hence some readily combustible substance, such as sulphur or carbon, must be added which gives in many cases the larger part of the total heat effect. Professor Mixter[1] of Yale University, who has made an extensive study of this method, gives the following results obtained by fusion with sodium peroxide for comparison with those by combustion in oxygen. They are:

Reaction.	Sodium Peroxide Method.	Combustion in Oxygen Method.	Reference.
$C+2O=CO_2$.	96·4	94·7	*Amer. Journ. Science*, xxix. 130; also xix. 434
$Ti+2O=TiO_2$.	215·6	218·4	*Ibid.* xxvii. 343
$3Fe+4O=Fe_3O_4$	267·5	265·2	*Ibid.* xxxvi. 55

Both values for $C+2O$ are for acetylene carbon. One reason for the higher value found in the sodium peroxide method is that the carbon and peroxide were mixed in a mortar, thus allowing the peroxide to absorb a little moisture which added to the heat of the fusion. The value 267·5 for $3Fe + 4O$ is derived from the results of fusions of iron, ferrous oxide, ferric oxide, and the mineral magnetite with sodium peroxide, and 265·2 was the result of burning iron in oxygen.

---

[1] *American Journal of Science*, 1917, xliii. 27.

Sodium peroxide absorbs water rapidly from the air, consequently it should be exposed as little as possible, as the hydrated peroxide will give more heat with a combustible than the anhydrous. One of two samples, that which gives off the less oxygen when fused, is the better one. The error from the water content is small in good peroxide. Its effect is further diminished when carbon, for example, is added to make a mixture fuse, because in practice the heat effect of the carbon is found for the carbon and peroxide actually used.

Various substances may be added to a peroxide mixture to increase the temperature of the fusion. Mixter has used acetylene carbon, sulphur, and lamp-black. Pure rhombohedral sulphur in fine powder would appear to be the best of the three, but it becomes electrified when shaken in the bomb with the other ingredients and sometimes sticks to the bomb and is not completely oxidised. Sulphide is formed, and occasionally free sulphur is left. When the bomb is much blackened by a fusion with sulphur the heat result is low. Acetylene carbon is the ideal substance to use, but difficult to obtain.

One part of the carbon requires 13 parts of pure sodium peroxide for combustion, and it is best to take about 20 parts in determining the heat effect of the carbon or lamp-black. For the combustion of sulphur double the calculated amount of peroxide should be used. Oxygen is often evolved in a combustion from the action of an acidic oxide on the sodium peroxide, and the heat required to set it free from the peroxide is added to the observed heat. This correction, 1·73 g.-cal. for 1 c.c. of oxygen at 0° and 760 mm., is derived from Beketoff's $Na_2 + O = 100{\cdot}26$ Cal. and de Forcrand's $Na_2 + 2O = 119{\cdot}8$ Cal.

Apparatus employed for the Tests.—The bomb is made of sterling silver whilst the top and fittings are of brass.

The mixture under test is contained in a cup of fine silver supported in the bomb by its upper edge. A fusion in the cup cools more slowly than when in contact with the cold bomb, and hence the reaction is more complete.

The general arrangement of the apparatus is identical with that employed in fuel calorimetry with the addition of bulbs for collecting any oxygen set free by fusion. E. G.

CALORIMETRY

Calorimetry is concerned with the measurement of energy in the form of heat. It constitutes one of the most difficult branches of exact measurements owing to the fact that a perfect non-conductor of heat does not exist.

The common method of measuring quantities of heat is by utilising the different effects of heat on materials such as the change of temperature or the change of state, but in recent years another method has come into extensive use, known as the Electrical Method. In this a definite and easily measurable amount of electrical energy is converted into heat, and the resulting change of temperature or state observed. The electrical method has many advantages when measurements of the highest precision have to be made on account of the facility with which the heat supply can be controlled.

In the brief review given in the following pages the appliances employed in heat measurements will be described, and then the theories which have been advanced to correlate the thermal data with other physical constants.

CALORIMETRY, ELECTRICAL METHODS OF

§ (1) **General.** — The electrical method of calorimetry was first employed by Joule with a view to the determination of the mechanical equivalent of heat (J). Subsequent work by Professors E. H. Griffiths, Schuster, Gannon, Callendar, and Barnes showed that the method was one capable of the highest precision for the determination of J. The article on the determination of the mechanical equivalent[1] of heat should be consulted for details of the method as applied to the determination of heat capacity of water and its variation with temperature.

In passing it might be mentioned that the calibration of bomb calorimeters is frequently carried out by electrical methods in which an equivalent amount of heat to that obtained in combustion is generated in the bomb and its amount measured by observations of the watts dissipated, the procedure being identical with that followed in methods for determining J.

In specific heat determinations the great convenience possessed by the electrical method lies in the fact that it permits of the determination of true specific heats, *i.e.* the specific heat over a very narrow range of temperature, and consequently it has been of immense service in determinations of the variation of atomic heats with temperature.

§ (2) **Specific Heat of Liquids by Electrical Methods.**—It is obvious that any of the appliances which have been devised for the evaluation of J are also applicable for the determination of the specific heat of liquids, and further that they would give data of the highest order of accuracy. There are, however, certain difficulties in practice.

Both Callendar and Griffiths applied their electrical methods for this purpose: the former determined the specific heat of mercury and the latter that of aniline.

§ (3) **Specific Heat of Mercury.**—The apparatus employed by Callendar,[2] Barnes, and Cooke for the determination of the specific heat of mercury is shown diagrammatically in *Fig.* 1. The calorimeter differs from that employed for the determination of J in that the flowing mercury is the conductor in which heat is generated electrically and not a fine platinum wire stretched along the axis of the tube as in the case of the J apparatus. A steady stream of mercury flows through the fine capillary tube and is heated by a carefully controlled electric current. The difference of temperature between the inflow and outflow is observed by means of a differential pair of platinum thermometers. The inflow and outflow tubes AB and CD are exactly similar, about 2 cm. internal diameter and 25 cm. long. They are connected by the fine flow tube BC of 1 mm. in bore and 1 metre in length, coiled up in the form of a short spiral 2·5 cm. in diameter. The inflow and outflow tubes are provided with two side tubes, one pair for conveying the current, and the other pair for the mercury flow.

A practical advantage possessed by the continuous flow method is the fact that the heat loss from the walls can be determined by making experiments with different rates of flow, but keeping the rise of temperature constant.

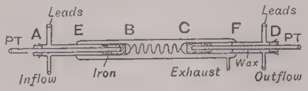

Fig. 1.

(i.) *Methods of determining the True Mean Temperature of Outflow.*—By far the most important practical detail in this method is the device adopted for obtaining the true mean temperature of the outflowing liquid. If a thermometer were merely inserted in the outflow tube, leaving a free space all round for the circulation of the liquid, it is evident that the heated liquid would tend to flow in a stream along the top of the outflow tube, and that the thermometer might indicate a temperature which had little or no relation to the mean temperature of the stream. It is easy to make an error of 20 per cent in this manner. A fairly uniform distribution of the flow might be secured by making the space between the thermometer and the outflow tube very narrow. But this leads to another difficulty in the case of mercury. As the space is narrowed the electrical resistance is increased, and an appreciable quantity of heat, which cannot be accurately estimated, is generated in the vicinity of the thermometers.

The difficulty was overcome in the mercury experiments by fitting the inflow and outflow tubes with soft iron cylinders, 6 cm. long, turned to fit the tubes and bored to fit the thermometers. The soft iron had a conduc-

530.9
A4638
E.

tivity about ten times that of mercury for both heat and electricity. The heat generated by the current in the immediate vicinity of the thermometer bulbs was so small that the watts might fairly be calculated from the difference of potential between the iron blocks at the middle points of the bulbs. The mercury stream was forced to circulate in a spiral screw thread of suitable dimensions cut in the outer surface of the blocks, which prevented the formation of stream-lines along one side of the tube, and secured uniformity of temperature throughout the cross-section of the outflow tube. The high conductivity of the iron also assisted in securing the same result.

A precisely analogous device for averaging the outflow temperature was applied in the water calorimeter. The bulb of the thermometer was fitted with a copper sleeve of high conductivity, on the outside of which a rubber spiral was wound to fit the outflow tube as closely as possible. The accuracy of fit was found to be much more important in the case of water than in the case of mercury. The reason of this is that the thermal conductivity of water being 10 or 15 times less than that of mercury the accurate averaging of the outflow temperature is more dependent on the uniformity of the spiral circulation and the complete elimination of asymmetric stream-lines.

In order to obtain a perfect fit for the sleeves with their spiral screws it was necessary that the bore of the outflow tube should be as nearly uniform as possible and accurately straight. It was most essential that there should be no constriction at the points of junction E and F with the vacuum-jacket, and that the external portions of the tubes AE, FD should not be of smaller bore than the portions inside the vacuum-jacket, though it would not matter much if they were a little larger.

(ii.) *Correction for Variation of the Temperature Gradient in the Flow Tube.*—The elementary theory of the elimination of the heat loss in the steady-flow method of calorimetry assumes that, if the electric current and the flow of liquid be simultaneously varied in such a manner as to keep the rise of temperature the same, the heat loss by radiation, etc., will remain constant. The experimental results of Callendar and Barnes show that this condition is very closely satisfied in the method, and they calculated all the results of the investigation on this assumption. It was noticed, however, that there were small systematic divergences in the experimental verification for the small flows which, though amounting only to a few parts in 10,000, received careful examination as possible indications of constant errors.

So long as the distribution of temperature throughout the apparatus is accurately the same for the same rise of temperature, whatever the flow, the heat loss must also be identical. But if there is any systematic change in the temperature distribution with change of flow, then there must be a corresponding systematic difference in the heat loss, which will lead to constant errors in the calculation if no account is taken of it. A possible source of error of this type is loss of heat by conduction along the outflow tube. When the flow is large, the heated liquid passing along the tube will keep it nearly at a uniform temperature, so that the gradient in the outflow tube will be small and the conduction loss correspondingly minute. As the flow is diminished, supposing the temperature of the outflow to remain the same, the gradient in the outflow-tube must increase in proportion to the reciprocal of the flow, since the radiation loss remains nearly the same. The conduction loss will vary directly as the gradient, or inversely as the flow, for a given rise of temperature.

A small error of this kind, due to conduction, was detected at an early stage in the mercury calorimeter, owing to the large mass of mercury in the flow tube, the small rate of the flow, and the relatively high thermal conductivity of the liquid. It was practically eliminated by filling the greater part of the outflow tube from the end of the vacuum-jacket with paraffin wax, leaving only a small passage for the outflow of mercury. This made the conduction loss very small, and nearly independent of the flow.

§ (4) Variation of the Specific Heat of Mercury with Temperature.—The value of the specific heat of mercury in terms of water was calculated from the experimental data, taking the value of J equal to 4·1891 for a thermal unit at 15·5°, which was the temperature recommended by Griffiths at the Paris Congress in 1900.

The experimental results lead to the expression

$$S_t = S_0 - 1{\cdot}074 \times 10^{-5}t + {\cdot}00385 \times 10^{-5}t^2,$$

or $$\frac{S_t - S_0}{S_0} = -{\cdot}000321t + {\cdot}00000115t^2,$$

where $$S_0 = {\cdot}033458.$$

This gives for the temperature coefficient at any temperature t the expression

$$\frac{d}{dt}\left(\frac{S_t}{S_0}\right) = -{\cdot}000321 + {\cdot}00000230t,$$

and for the average change per degree at 50° the value $-{\cdot}0000069$.

The data obtained in the experiments are summarised in Table I., p. 35.

§ (5) Specific Heat of Aniline.—Professor E. H. Griffiths [1] determined the specific heat of aniline over the range 15° to 50° C. by means of an apparatus similar in its essential features

---

TABLE I

SPECIFIC HEAT OF MERCURY AT DIFFERENT TEMPERATURES

Mean Temperature.	Specific Heat.	Mean Temperature.	Specific Heat.
2·85	·033435	32·41	·033141
2·93	·033440	36·59	·033121
4·42	·033405	45·00	·033050
18·37	·033291	53·39	·032997
24·52	·033224	65·22	·032929
31·68	·033156	83·89	·032818
32·14	·033151		

to that shown in *Figs.* 5 and 6 of the article "Heat, Mechanical Equivalent of."

For experimental work in calorimetry aniline has various points in its favour. It has a low vapour pressure at ordinary temperatures, is a good electrical insulator, and has a low heat capacity.

On exposure to light it becomes discoloured, but no information is available to show whether this affects the thermal capacity.

For the variation of the specific heat with temperature Griffiths obtained the following equation:

$$S_1 = 0{\cdot}5156 + (t-20)\times{\cdot}0004 + (t-20)^2\times{\cdot}000002.$$

The agreement between this formula and the experimental results will be seen from the table below:

TABLE II

Temperature.	S_1 Experimental.	S_1 Formula.
15°	·5137	·5137
20	·5155	·5156
25	·5175	·5176
30	·5198	·5198
35	·5221	·5221
40	·5244	·5244
45	·5268	·5269
50	·5294	·5294
52	·5304	·5305

In the course of this work it was observed that the volume heat, *i.e.* the specific heat multiplied by the density, was practically constant over the range of temperature investigated as shown by the following results:

TABLE III

Temperature.	Specific Heat, S.	Density, *d*.	S × *d*.

20	0·5156	1·0218	·5269
30	0·5198	1·0130	·5267
40	0·5244	1·0040	·5267
50	0·5294	0·9955	·5270

§ (6) SPECIFIC HEAT OF OILS.—In some experiments in which it was desired to determine the specific heat of oils over a wide range of temperature the apparatus shown below (*Fig.* 2) was employed by the writer.

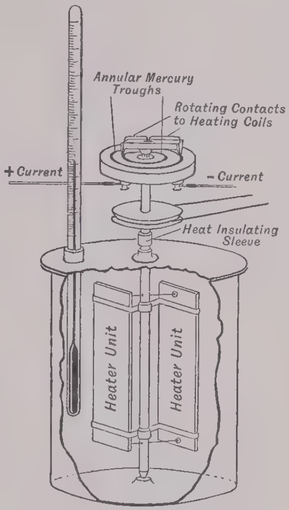

FIG. 2.

At room temperatures the oils were exceedingly viscous, and consequently it was necessary to employ somewhat unusual methods of ensuring that the contents were well mixed. The heating coils were arranged in the form of two flat paddles so that they were in continuous rotation through the oil; suitably disposed baffles further assisted the mixing of the contents of the calorimeter. It was necessary to lead the current in and out of the calorimeter by means of two annular troughs of mercury into which contact bars from the heating coil dipped.

§ (7) SPECIFIC HEAT OF LIQUIDS USED FOR REFRIGERATORS.—Osborn [1] has developed an apparatus suitable for the determination of specific heats and latent heats of the liquids commonly employed in refrigeration work, such as ammonia, CO_2, SO_2, methyl-chloride, and ethyl-chloride. Such determinations present greater experimental difficulties than are met with in work on liquids at ordinary pressure, since these materials have a vapour pressure varying from 1 to 70 atmospheres at the temperatures at which the thermal properties are of importance in engineering work. Consequently, in the design of apparatus for experiments of this character great attention has to be paid to details of construction.

(i.) *The Calorimeter.*—Briefly the arrangement is as follows: The material to be investigated is enclosed in a calorimeter with thick metallic walls of known thermal capacity (*Fig.* 3). Heat is applied electrically and the jacket is maintained at the same temperature by the usual adiabatic arrangement.

---

[1] *Bull. Bur. Stds.*, 1917, xv. 133.

An air space between the polished nickel surfaces of calorimeter and jacket furnishes thermal insulation. Two tubes extend from the top of the calorimeter through the jacket and liquid to the outside air, terminating in valves. One of these tubes is intended for connection to pressure-indicating apparatus and the other for the introduction and removal of the material to be investigated.

Care was taken to avoid having heavy metal connections across the air space and by suitably distributing those connections which are necessary over the calorimeter surface, the part of the thermal leakage due to lead conduction was considerably minimised. Thermoelements indicate relative surface temperatures of the jacket calorimeter, 10 junctions being distributed upon each surface. This permits of control over the thermal leakage and the correction for such leakage as could not be avoided.

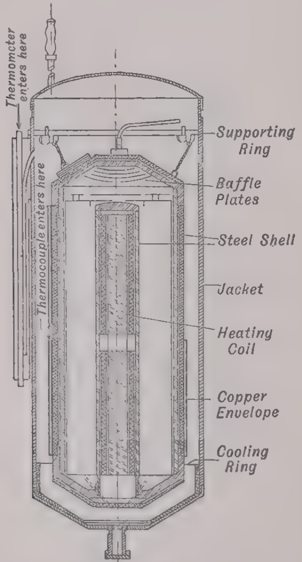

FIG. 3.—Section of Calorimeter and Jacket.

Thermojunctions placed upon the connecting tubes indicate the temperature of these tubes at several points relative to a point on the jacket and in this way the temperature of the vapour expelled during vaporisation experiments could be found.

The inside of the central tube in the calorimeter is accessible at the bottom for the introduction of the heating coil and thermometer. Upon the outside of this tube are fastened 12 radial vanes of tinned iron about 0·3 mm. thick, extending to within about 1 mm. of the surrounding cylindrical wall. These vanes are for the purpose of promoting the distribution of heat within the annular space containing the material under investigation. The vanes extend just above the top of the central tube. At this place are two flat circular baffle plates, separated about 2 mm. by three small steel studs. The lower plate is united to the tops of the radial vanes with tin. A central hole in the lower plate and several holes in the upper one between centre and outside furnish a tortuous passage for vapour coming from below. These two plates are intended to intercept any large drops of liquid which might be thrown up by vigorous boiling, should it occur, and also act as a thermal shield for the top of the calorimeter. A second set of four baffle plates of spherical contour separated by about 2 mm. are attached to the inside surface of the conical part of the calorimeter top. Each plate has a central hole and four slots at the edge so as to avoid trapping gas or liquid, but these passages are so sized and spaced that the main path through the plates is very tortuous, so as to make difficult the passage of liquid particles from below in a current of vapour being withdrawn through the outlets in the top. The entire inner surface of the steel shell and of the various plates within were all tinned, using pure block tin.

(ii.) *Method of Experiment.*—Two distinct methods of experiment were employed. In the first method the heat, added to a fixed amount of the substance under test confined in the calorimeter under saturation conditions, together with the resulting change in temperature, are measured. By using data for the specific volumes of the two phases and the latent heat of vaporisation, the heat lost in the vaporisation of the liquid is estimated and can be allowed for; thus the specific heat of the liquid when kept saturated is found.

In the second method the calorimeter is kept full of liquid at a constant pressure. The heat, added to the variable amount in the calorimeter, and the resulting change in temperature are measured. A correction for the heat withdrawn in the expelled liquid is determined by special experiments. By use of the data for variation with pressure of the latent heat of the liquid, obtained from separate measurements, made with the same apparatus and material, the corrections for pressure variation are applied, and thus a second determination of the specific heat of the saturated liquid is obtained.

As a final result, the specific heat σ, in joules per gram per degree centigrade, of liquid ammonia, kept saturated, at the temperature θ, is given in the range $-45°$ to $+45°$ C. by the equation

$$\sigma = 3{\cdot}1365 - 0{\cdot}00057\theta + \frac{16{\cdot}842}{\sqrt{133-\theta}}.$$

The two curves in *Fig.* 4 show the results graphically.

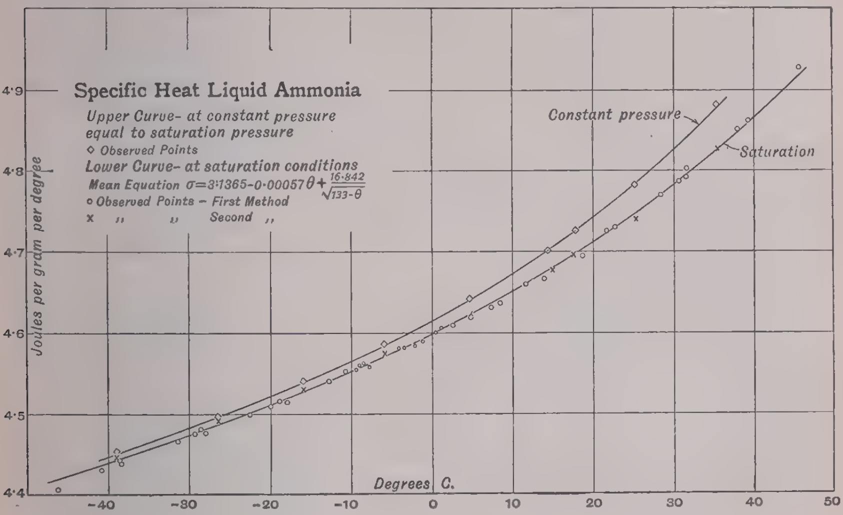

FIG. 4.

§ (8) SPECIFIC HEATS OF SOLIDS BY ELECTRICAL METHODS.—Very little work has been done on the determination of the specific heat of solid substances by the electrical method except for the metals. The method, of course, lends itself admirably to the determination of the specific heats of good thermal conductors, but with poor conductors special devices must be adopted to ensure uniformity of temperature throughout the material under test.

§ (9) GAEDE.—Gaede[1] appears to have been the first to measure specific heats in this manner. In his experiments the specimens formed their own calorimeters. These were machined to a cylindrical form and a deep central core bored out. Into this was thrust a copper core, wound with a properly insulated heater of constantan ribbon and a resistance thermometer of fine copper wire. Thermal contact between the core and the walls of the well was secured by filling the intervening space with mercury, using a thin steel shell when necessary to avoid amalgamation. This calorimeter was suspended in a thermostat and heated through an accurately measured temperature interval of about 15° by a measured quantity of energy supplied electrically.

Very few particulars of the investigation have been published, and the data obtained are summarised in Table IV.

§ (10) METALS.—Professor E. H. Griffiths and Dr. Ezer Griffiths studied[2] the specific heats of the metals aluminium, tin, copper, cadmium, zinc, lead, and silver over the range −160° to +100° C.

(i.) *Temperatures* 0°-100°.—The apparatus employed for determinations in the range 0° to 100° C. is shown in *Fig.* 5.

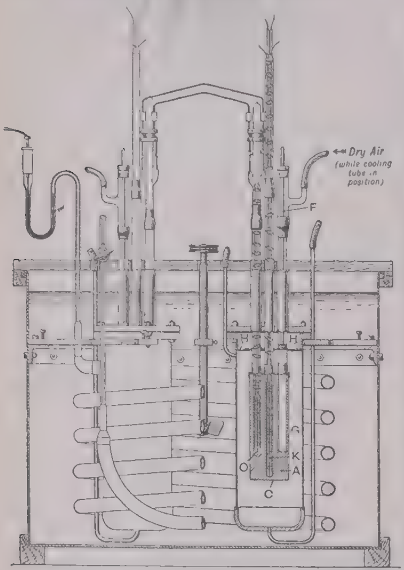

FIG. 5.

Two similar blocks of the metal under test were suspended in two brass enclosures immersed in a constant temperature bath. In the central hole of each block was a heating coil whilst the coaxial holes contained resistance thermometers connected differentially.

The third hole was used for the purpose of cooling the block below the surrounding temperature by the insertion of a thin-walled tube containing ether and connected to a water pump.

In the experiments one of the blocks was heated through a range from one degree below the temperature of the enclosure to one degree above the temperature of the enclosure by a measured supply of electrical energy.

This temperature interval was measured on a resistance bridge in the usual manner. Since the two resistance thermometers were adjusted to close equality and made of the same sample of wire, the balance point on the bridge wire was practically at the centre of the wire at all temperatures when the blocks were in temperature equilibrium with the enclosure. Hence no auxiliary coils were required in the Wheatstone's bridge circuit beyond the equal ratio arms.

The energy supplied to the heating coils was measured by balancing the potential difference at its ends against the E.M.F. of a series of cadmium cells in series, the current through the coil being adjusted until balance was obtained. The resistance of the heating coil was determined for the particular value of the current passing.

(ii.) *Low Temperatures.*—The experiments were continued at low temperatures but with a modified form of apparatus shown in *Fig.* 6, as it was very difficult to obtain any constant temperature baths in the region from −80° to −180° C.

In this apparatus a constant temperature enclosure was obtained by the use of a thick-walled copper box surrounded by a coil of piping through which cooled air circulated. The Joule-Thomson effect of cooling was utilised in a direct manner. Air was compressed to a pressure of 2000 to 3000 lbs. per sq. in., and then entered into the interchanger by the pipe A, *Fig.* 6. This interchanger BB was constructed of ordinary solid drawn copper tubing ⅛ in. bore coiled in the form of flat spirals. Successive layers of the coil were separated by strips of cardboard and the entire coil packed

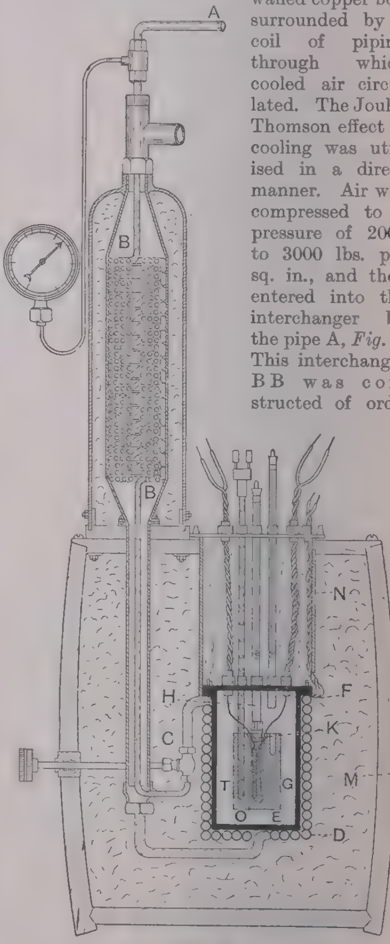

FIG. 6.

around with heat-insulating material. From the interchanger coils the air was carried to the valve C, by means of which an observer controlled the flow, excess of air being discharged at the safety-valve on the compressor. After expansion the air circulated through the coil of lead tubing D, and then back over the surface of the interchanger coils. On the exterior surface of the thick-walled copper enclosure E was wound a layer of insulated copper wire F, which served as a resistance thermometer. Variations in the temperature of the walls of this enclosure were rendered visible by the movements of a galvanometer spot. By controlling the flow of air the oscillations of the spot could be kept within narrow limits and, under normal conditions, the oscillations did not exceed a hundredth of a degree in amplitude.

The interior of the wooden vessel M was packed with slag wool,[1] the passage for the withdrawal of the copper enclosure being kept clear by a cylindrical tube of cardboard N. The space between the top of the enclosure and the outer lid was filled by wrapping felt matting around the glass tubes and leads.

The block of metal G was suspended within the enclosure by a single glass tube H. The centre hole contained the heating coil O, of manganin wire wound on a mica rack and immersed in a light paraffin, usually petrol. The heating coil was fixed to a short taper plug of copper K, which closed the central hole. The resistance of the coil was about 26 ohms. A platinum thermometer was inserted in the cylindrical hole T, the annular gap between the stem and the walls being closed by a packing of asbestos thread. The differential arrangement employed in the previous experiments was abandoned as it would have required too long a time to obtain the equilibrium conditions.

(iii.) *Method of Experiment.*—In these experiments the practice was to heat the material through a small temperature interval from below the surroundings to an approximately equal interval above, and observe the rate of rise during this period. The method of experiment was such that a direct determination of the temperature of the enclosure was not required. An experiment was conducted as follows:

The temperature of the enclosure was lowered progressively by utilising the full supply from the compressor and controlling the flow so as to produce a steady pressure drop through the valve of 120 to 150 atmospheres.

The temperature of the block would fall at a steady rate by radiation and convection to the enclosure walls, and when its temperature had nearly reached the desired point the cold air circulation around the enclosure was stopped.

Its temperature would then rise rapidly by conduction from without and soon pass that of the block which, in consequence of the slow transmission of heat by radiation and convection, would lag behind that of the walls. The temperature of the enclosure walls would then be maintained steady at about three degrees higher than that of the metal block.

Some time had to elapse before the conditions were sufficiently settled to justify the commencement of an experiment.

The first group of readings consisted of observations of the rate of rise of temperature of the block by radiation, etc., the transits of the temperature being observed across successive equal intervals (of about $\frac{1}{20}$th of a degree), the time between successive transits being of the order of 50 seconds.

The electrical supply was then switched on, and, after allowing a little time for the setting up of a steady gradient, transits every fifth of a degree were taken.

When the temperature had risen two or three degrees above the surroundings the electrical supply was switched off and observations of temperature and time continued.

The temperature would then fall steadily under the influence of radiation, etc., the rate of cooling being observed in precisely the same manner as the rate of rise of temperature before the electrical supply was switched on.

If σ is the rate of rise or fall due to radiation for 1° C. difference in temperature between the block and the surroundings, then assuming Newton's law to be valid for the loss or gain by "radiation" (an assumption which was fully justified by the experimental results), we have the expression

$$\frac{\partial\theta}{\partial t}=\sigma(\theta-\theta_0)$$

for the rate of rise or fall under the influence of "radiation" alone. Hence, plotting $\partial\theta/\partial t$ against θ, the straight line joining the two groups will cut the temperature axis at $\theta=\theta_0$ which determines the temperature of the surroundings.

For the rate of rise under the combined effect of the electrical supply and radiation we have the equation

$$\frac{\partial\theta}{\partial t}=\frac{E^2}{RMS}+\sigma(\theta-\theta_0),$$

where E^2/R is the electrical supply per second in thermal units, MS the thermal capacity of the block including that of the resistance coil, etc.

Plotting the observed rates of rise on the same scale as the "radiation" observations, it is obvious that the straight line thus obtained should be parallel to the line joining the two groups of "radiation" observations, since the tangent of the angle made with the θ axis is equal to σ. For $\theta=\theta_0$ the "radiation" term vanishes, hence, if $\partial\theta_N/\partial t$ denotes the value of the ordinate at this point, then

---

[1] It is probable that wool in its natural state would have been a better insulator at these low temperatures, since the grease in the wool prevents it from absorbing moisture.

$$\frac{\partial\theta_N}{\partial t} = \frac{E^2}{RMS},$$

from which S can be obtained. The results obtained are summarised in Table V. and shown graphically in *Fig.* 7, where T is the absolute temperature and C_p is the atomic heat, *i.e.* specific heat multiplied by the atomic weight:

§ (11) NERNST AND LINDEMANN.[1]—These observers made a series of point to point determinations at very low temperatures, using a calorimeter developed by Eucken.[2] A piece of metal of suitable size was shaped into a hollow cylinder and a loosely fitting core made for the same. On the core was wrapped a platinum wire, properly insulated, to serve as a resistance thermometer and also as electric heater. The core was placed in the cylinder and paraffin poured into the crevices to improve the thermal contact (see *Fig.* 8). The whole was suspended *in vacuo*, and the specific heat over small temperature intervals determined from measurements of energy supplied electrically and of the temperature rise resulting therefrom. Nernst and Lindemann applied the same method to poor heat conductors. For such materials the design of calorimeter is shown in *Fig.* 9. The wire was wound on a silver tube projecting into a silver vessel, the high conductivity of the silver assisting the equalisation of the temperature through the mass. Some of the data for pure metals obtained by Nernst are given in Table VI.

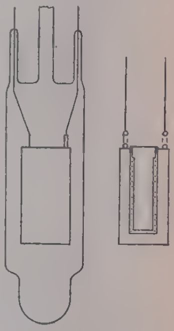

FIG. 8.

§ (12) COPPER.—Harper[3] studied (i.) the specific heat of copper over the range 15° to 50° C. The specimen was in the form of copper wire, which also served as its own thermometer and heater. The wire was 50 metres in length and 2·5 mm. in diameter; it was compactly coiled into a number of flat spirals separated by mica plates. The coil was suspended *in vacuo*, and heated with a measured quantity of energy supplied electrically, the resulting temperature rise being measured by the change of resistance. The

results of 27 determinations between 15° and 50° are represented by the equation

$$S=0{\cdot}0917+0{\cdot}000048(t-25)° \text{ calories}_{20} \text{ per gram degree.}$$

4·182 joules is taken as equal to one 20° calorie.

(ii.) *Comparison of Data by Various Observers.*—Harper[1] has tabulated the data given by various observers for the specific heat of copper. In order to compare the results at one definite temperature the coefficient 0·000044 has been used in reducing results obtained at the various temperatures to the 50° C. value, the formula

$$S=So+0{\cdot}000044t$$

being assumed as valid for values of t from 0° to 100°.

This coefficient is the mean of those given by recent observers employing electric heating and a point to point method as shown in Table VII.

* In the case of zinc the actual figures are not recorded, and the above figures have been obtained from the curves given in the paper.

It will be observed from a comparison of the data given in Table VIII. (p. 42) and shown graphically in *Fig.* 10 that there is substantial agreement between the results of observers using the electrical method both as regards the absolute value of the specific heat and its temperature coefficient. It is very improbable that there is any systematic error common to all since the three methods differ radically in detail.

§ (13) SPECIFIC HEAT OF GASES BY ELECTRICAL METHODS.—The method of electrical heating for the determination of the specific heat of gases at different temperatures has been developed by Callendar and his associates.

Gases present greater practical difficulties than either solids or liquids, since it is necessary to take great precautions to ensure uniformity of temperature in the gas stream

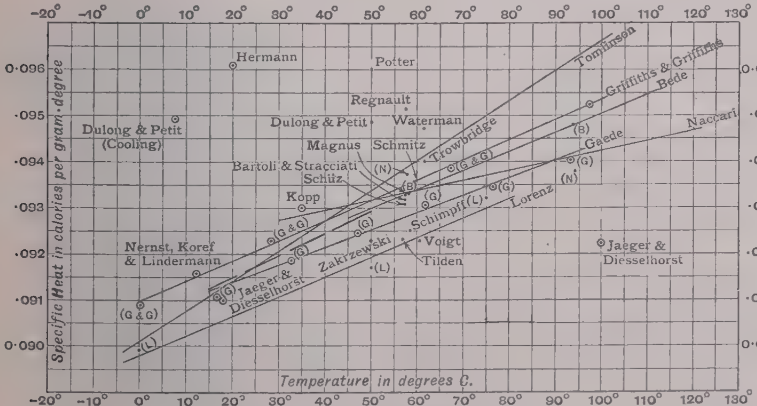

FIG. 10.—Specific Heat of Copper.

1914	Harper	15-50	..	0·0929	Results expressed by formula $c=0{\cdot}0917+0{\cdot}000048\,(t\text{-}25)$.

The units in terms of which the above results are expressed are not all the same, but the differences need not be taken into account in making comparisons. In every case the difference between the unit employed and the 15° calorie or the 20° calorie (which differ from each other by about one part in a thousand) is less than the probable experimental error.

Callendar and Swann[1] applied the continuous flow method to the determination of the specific heats of air and carbon dioxide at atmosphere pressure at 20° C. and 100° C.

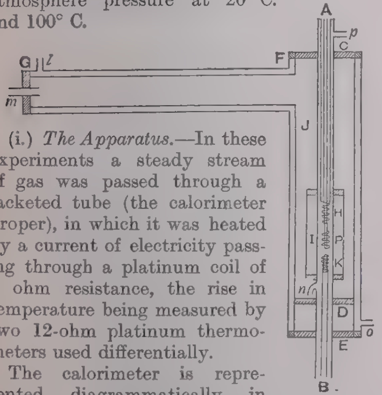

FIG. 11.

(i.) *The Apparatus.*—In these experiments a steady stream of gas was passed through a jacketed tube (the calorimeter proper), in which it was heated by a current of electricity passing through a platinum coil of 1 ohm resistance, the rise in temperature being measured by two 12-ohm platinum thermometers used differentially.

The calorimeter is represented diagrammatically in *Fig.* 11, the heating coil and platinum thermometers being situated in the tube AB, which is jacketed by the tube J. The tube FG formed the heater in which the gas attained the desired temperature, and being double-walled could be steam-heated or water-cooled. This tube was packed with tightly fitting discs of copper gauze. The gas under test entered at *m*, was heated up to the required temperature and entered the space round the calorimeter proper. It next passed through the tube *n*, into the calorimeter, and finally emerged by the tube *p*.

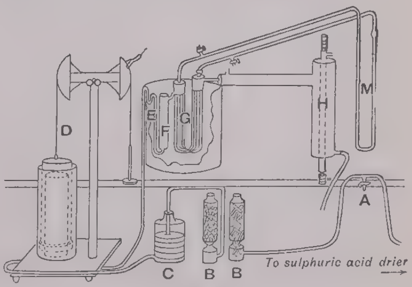

FIG. 12.

A, Teepiece open to atmosphere through constricted opening to allow excess of gas to escape; BB, towers containing solid KOH and $CaCl_2$; C, cotton wool dust filter; D, automatic pressure regulator; E, throttle; F, tube packed with gauze to bring gas to the desired temperature; G, fine metal tubes for measurement of flow; M, oil gauge.

The general arrangement of the apparatus will be understood from *Fig.* 12.

---

[1] *Phil. Trans.* A, 1910, ccx. 199.

(ii.) *Theory of Method.*—If C is the electric current, E the potential difference between the ends of the heating coil, $\delta\theta$ the rise in temperature of the gas, Q the rate of flow of the gas in grammes per second, J the mechanical equivalent of heat, and S the specific heat of the gas at constant pressure, the elementary theory of the experiment gives

$$CE = JSQ\delta\theta + h\delta\theta,$$

where $h\delta\theta$ is a term representing the heat loss by radiation, etc.

A similar experiment with a rate of flow about half the above value, and with the electric current adjusted so that the rise in temperature was about the same as before, gave a second equation, so that h could be eliminated and S determined.

The largest currents of gas through the apparatus were of the order of 0·5 litre per second. The rate of flow was kept constant by an automatic pressure regulator. It was measured by passing the gas through 16 fine metal tubes arranged in parallel, and observing the pressure difference between their ends, the mean pressure, and the temperature. The expression giving the rate of flow in terms of these quantities was found by a series of experiments in which the gas was pumped into a reservoir of about 50 litres capacity, and then allowed to discharge through the apparatus. By means of a special device, the times taken for certain quantities of gas to pass through the apparatus were recorded automatically while the gas was actually flowing, so that the initial fluctuations were avoided.

The value of the electric current was obtained by measuring the potential difference set up at between the ends of a standard resistance coil in terms of cadmium cells. The heating effects of the leads of the heating coil were determined by experiments made under the exact conditions of the main experiments.

The rise in temperature in the main experiments was about 5° C., and it was measured to 0·001° C. Thus the specific heats were measured practically at single temperatures instead of over large ranges.

The validity of assuming the heat loss for a given rise in temperature to be independent of the rate of flow of the gas was tested by experiment. The matter was also examined from a theoretical standpoint, and corrections were calculated and applied where the assumptions made in the elementary theory were such as to lead to errors of more than about one part in 10,000. The corrections were small, only amounting to one or two parts in 1000.

Full details of various other precautions are given in the original paper, and the mean of a large number of observations gave the following results:

Air

0·24173 cal. per gram degree at 20° C.
0·24301 „ „ „ 100° C.

Carbon Dioxide

0·20202 cal. per gram degree at 20° C.
0·22121 „ „ „ 100° C.

The several determinations agree in each case to about 1·5 parts per 1000, and the mean results are probably correct to one part in 1000.

The values of the specific heats obtained are greater by about 2 per cent than the corresponding values found by Regnault and by later investigators who have employed methods similar in principle to that of Regnault, but it has now been established that Regnault's method gives values which are low by about this amount.

§ (14) SPECIFIC HEAT OF STEAM.—Brinkworth[1] developed the same method for the determination of the specific heat of steam at atmospheric pressure between 104° C. and 115° C.

(i.) *Outline of the Method.*—Steam is generated in a boiler and thence led to one limb of a U-tube pressure regulator. The pressure of the steam forces the mercury down in this limb of the U-tube and up in the other limb in which the adjustment of the supply of gas to the large ring burner, used for heating the water in the boiler, is made. After passing the regulator the steam, now maintained at a constant pressure, is led between the walls of the jacket surrounding the calorimeter proper, thence through a separator and a throttle into the space enclosed by the double-walled jacket, whence it passes down the calorimeter flow-tube to a condenser. During the passage of the steam through the flow-tube it is heated by means of an electric current passing through a platinum heating coil, and its temperature is measured on a platinum resistance thermometer. Another temperature measurement is made when the supply of electrical energy is cut off, and the difference between these two temperatures gives the rise in temperature of the steam.

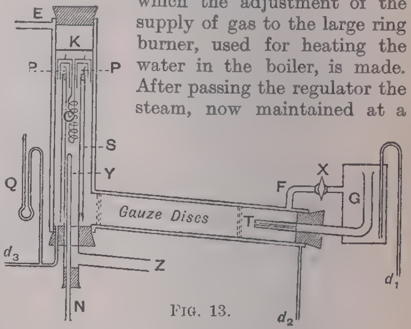

FIG. 13.

d_1, d_2, and d_3, drains for condensed water.

(ii.) *Calorimetric Arrangements* (*Fig.* 13).—The calorimeter proper consisted of a glass tube Y, about 50 cm. long, in which the heating coil C and the thermometer N were fixed. This tube was jacketed by another glass tube S, which enclosed the length occupied by the heating coil and thermometer.

The calorimeter flow-tube and its surrounding glass sheath were carried on a split rubber cork wound with omega tape and fixed, making a steam-tight joint, into a space enclosed by a double-walled brass jacket. The lower part of this jacket communicates with a double-walled side tube and the steam entering at E passes between the jacket walls to F, which communicates with the steam separator G. It then enters the inner portion of the side tube through the throttle T. This tube is tightly packed with gauze discs; thence the steam passes up the tube S into the top of the flow-tube at P, and descending past the heating coil C and the thermometer N flows away into the condenser at L.

---

[1] *Phil. Trans.* A, 1915, ccxv. 383.

On its passage through the tightly packed gauze discs in the side-heating tube the steam was heated up to the temperature of the jacket.

In *Fig.* 13, which represents diagrammatically the arrangement thus described, it will be noticed that the cylindrical space inside the double walls of the main jacket is divided into two compartments by a disc K. This disc of brass was soldered to the inner jacket tube about 5 cm. from the upper end. Its function is to prevent the steam in the tube S from impinging on the rubber cork closing the upper end of the tube, and thus being cooled.

Any slight cooling due to the steam striking the lower split cork is of no importance, since the steam would be warmed again during its passage up between the flow tube and the surrounding jacket. The whole of the jacket, the separator, and the connecting tubes were heavily lagged with felt. A novel feature of the apparatus is the "spiral" method of mixing the steam, in which use is made of a number of circular discs punched to fit the thermometer tube and then cut along a diameter, bent, and soldered together to form a continuous spiral round the thermometer (see *Fig.* 14). This method of mixing is found to be a great improvement on the gauze method previously employed.

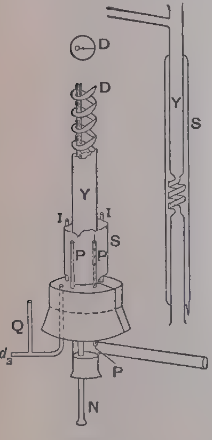

FIG. 14.

The usual equation for the continuous flow method is

$$EC = SQd\theta + hd\theta,$$

where EC is the electrical energy supplied, S the required specific heat if expressed in joules per gram C., Q the rate of flow of the steam, $d\theta$ the rise of temperature of the steam, and $hd\theta$ is a term representing the heat loss. If this loss is independent of the flow, then a linear relationship exists between the values of $EC/Qd\theta$ and $1/Q$. This is found not to be strictly the case, and another term depending on the flow is inserted in the fundamental equation which thereby becomes: $EC = SQd\theta + (h + k/Q)d\theta$. By the employment of three rates of flow, adjusting E in each case so that $d\theta$ remains the same, h and k can be eliminated and S measured.

The value obtained for the specific heat was 0·4856 cal. per gram degree at 104·5° C. and 760 mm. pressure; then, assuming a linear variation with temperature as experimentally determined, this corresponds to a value 0·4878 at 100°, both expressed in terms of the calorie at 20° C.

(iii.) *Effect of Impurities in the Steam.*—Steam in the immediate neighbourhood of the saturation point is liable to carry small particles of water in suspension, which cannot be evaporated completely by a moderate degree of superheat if any impurities, such as salt in solution, are present. Since 1 mg. of water requires more than half a calorie to evaporate it, and the heat required to raise the temperature of 1 gram of steam 10° C. is only 5 calories, it is necessary that the initial steam should not contain more than 1 in 100,000 of water if the specific heat is to be found correct to 1 in 1000 over a range of 10° C.

The rise of the boiling-point θ produced by x gram-molecules of salt per gram of water is approximately $1000x$° C. The proportion of suspended water remaining unevaporated at any degree of superheat θ' will be $1000x/\theta'$. The quantity evaporated in heating the steam from θ' to θ'' will be $1000x(\theta''-\theta')/\theta'\theta''$. This will produce an apparent increase of the mean specific heat of the steam over the range $\theta''-\theta'$ equivalent to $1000Lx/\theta'\theta''$, where L is the latent heat of evaporation. It was found that this extremely simple and convenient reduction formula fitted the results obtained over different ranges of temperature with extraordinary precision, and reconciled apparent discrepancies which had previously been attributed to errors of observation.

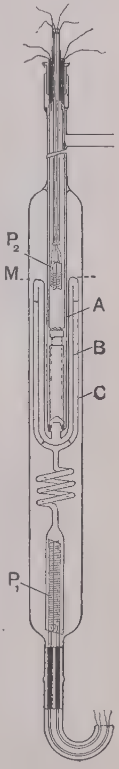

FIG. 15.

§ (15) DETERMINATION OF THE SPECIFIC HEAT OF AIR AND OTHER GASES AT ROOM AND LOW TEMPERATURES BY THE CONTINUOUS FLOW ELECTRICAL METHOD.—Scheel and Heuse[1] have determined the specific heat of air and other gases at +20°, −78°, and −183° by the continuous flow method. The air was directed in a steady stream through a pipe in which it received a known amount of heat by means of a heating coil.

Fig. 15 shows the glass calorimeter in the form in which Scheel and Heuse used it. The gas, which is brought to a steady temperature, enters the calorimeter from below and flows through a spiral, then through two glass jackets C and B, and finally reaches the inner tube A which contains the heating coil. The temperatures of the in- and outflowing gases are determined by the resistance thermometers P_1 and P_2. The whole is surrounded by a vacuum and a glass jacket silvered inside and is contained in a bath at constant temperature. As the air at first flows through the jackets C and B before it reaches the real calorimeter, it absorbs the greater part of the heat given off to the inner vacuum according to the principle of counter current and thus assists the insulating action of the jacket. This greatly reduces the loss of heat, but does not entirely prevent it. The temperature of the outflowing gas is measured in the transverse section M.

---

[1] *Ann. d. Phys.*, 1912, xxxvii. 79.

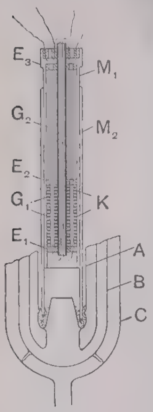

FIG. 16.

The heating coil is shown in *Fig.* 16 and consists of constantan wire K and is wound in two sections on a glass pipe.

In order to distribute the heat equally the wires are bound together and wound round the fine copper gauze G_1 as far as space permits. The wire coils are supported above and below by perforated ivory strips E_1 and E_2. In order to mix the gas thoroughly, the packing of copper wire gauze G_2 is introduced above the coil, which in its turn is fastened with an ivory strip E_3. The wires which conduct the current to the heating coil are led up through the inner glass tube and connected above E_3 with the wires to the source of the current and to the voltmeter. The heating coil and apparatus for mixing are contained in a brass pipe M_1 which fits into a second brass pipe M_2. M_2 is fastened with sealing-wax into an annular groove on the inner pipe A.

When working at room temperature the calorimeter was placed in a large water bath well stirred. At low temperature, on the other hand, it was placed in a vacuum vessel which contained a mixture of CO_2 snow and alcohol, or liquid oxygen. In each case the gas, before entering the calorimeter, passed through a pipe which was contained in the same bath as the calorimeter.

The same investigators,[1] when studying helium and some other rare gases to low temperatures, modified the apparatus so as to employ a closed circuit.

The results they obtained are summarised in Table IX. They also calculated out the corresponding values for the ideal gas state;

these results are inserted for comparison alongside the others.

The values at constant volume are obtained from the experimental numbers at constant pressure by means of the expressions deduced by a combination of the ordinary thermodynamical equations with D. Berthelot's equation of state.

§ (16) VARIATION OF THE SPECIFIC HEAT OF AIR WITH PRESSURE OVER THE RANGE 1 TO 1200 ATMOSPHERES.—In 1914 Holborn and Jacob[1] made a new series of measurements of the specific heat of air high pressures by an electrical method. The calorimeter employed is shown in *Fig.* 17. The castings used in this construction were made of nickel steel of high tensile strength. The air enters the calorimeter at the bottom through a small spherical piece c_1 and leaves at the top through a similar arrangement c_8. Between these two points there is a nickel steel pipe c_5 with semicircular ends c_3 and c_6, into which the wide pipes c_2 and c_7 lead for the entrance and exit of the current of air. Connections between the various pipes are made by flanges fitted with packing rings.

A heating coil q_1 through which the air flows is enclosed within the pipe c_5; from here the air passed through the annular spaces l_1 and l_2, its direction being changed twice before it leaves the calorimeter. The spaces l_1 and l_2 are enclosed within three nickel walls. The direction of the air current is indicated by the arrows in the figure.

FIG. 17.

The outer space of the calorimeter is also divided into two cylinders o_1 and o_2, through which oil from the small turbine r is driven in the direction of the arrows. The oil can be heated when desired by means of the resistance coil q_{11}. d is a steam jacket surrounding the calorimeter and the exit pipe, leaving the entrance pipe quite free. This latter pipe is protected against heat loss by a wrapping of twisted silk and from the action of the incoming air by a glass pipe inserted in it. The heater q_1 consists of a group of 60 split nickel tubes about 4 mm. inner diameter and 4·5 outer diameter. These are fastened to two porcelain plates and are held together, one behind the other, by clips. The air passes through and around the tubes; current is supplied to this heater by wires insulated with glass beads. In the diagram the black part represents metal and the shaded parts insulating material.

---

[1] *Zeitschr. Vereines Deutsch. Ing.*, 1914, lviii. 1429.

The results at a temperature of 59° are represented by the empirical formula

$$10^4 C_p = 2413 + 2{\cdot}86p + 0{\cdot}0005p^2 - 0{\cdot}00001p^3,$$

where p is the pressure in atmospheres.

The value 0·2413 obtained for the specific heat at 59° and one atmosphere pressure agrees very satisfactorily with those obtained by Swan (·2412 at 20°) and Scheel and Heuse (·2409). It of course differs from Regnault's value, which is now known to be low.

The following table gives the values obtained for the specific heat at a temperature of 59° C. and for various pressures measured in kilogram per sq. cm.:

TABLE X

p.	Holborn and Jakob.		Lussana.	Joule and Thomson.	Vogel.	Noell.
	(Obs.)	(Calc.)				
0	..	·2413	..	..	..	..
1	·2415	·2416	·2370	..	..	..
25	·2490	·2485	·2711	·2481	·2480	·2493
50	·2554	·2556	·3061	·2557	·2543	·2568

150	·2821	·2819	·4198	·2919	·2770	·2812
200	·2925	·2925	..	·3150	·2853	·2893

For comparison purposes the results of Lussana and the values calculated from the throttling experiments of Joule and Thomson, Vogel (1911), and Noell (1913) are inserted. These were obtained from Linde's formula

$$C_p = C_0\left(1 - \frac{d\delta}{dT}\right),$$

where C_0 is the specific heat at pressure 0 and δ the cooling when the pressure is reduced by throttling from p to a vanishingly small value.

E. G.

CALORIMETRY, METHODS BASED ON THE CHANGE OF STATE

§ (1) THE METHOD.—In this class of calorimetric appliances the quantity of heat to be measured is determined in terms of any one of the following: (i.) The mass of ice melted; (ii.) steam condensed; (iii.) liquid hydrogen or oxygen vaporised.

Such measurements do not require an accurate measurement of small temperature changes of the calorimetric fluid, and taking into consideration the state of thermometry half a century ago when this method was introduced, this fact was unquestionably of real advantage. Further, the temperature of the surrounding atmosphere can have but little effect upon the indications of the calorimeter since the initial and final temperatures are the same. In recent years calorimetric thermometers have been so highly developed that the measurement of small temperature changes presents no serious difficulty, and the technique of temperature control of the jacket has been greatly facilitated by the use of electrical heating, so that the inherent difficulties associated with the method of calorimetry now under consideration more than counterbalance the advantages it offers: consequently, it is very little used at the present day.

The Bunsen ice calorimeter and the Joly steam calorimeter are classical examples of this method of calorimetry.

Dewar has applied the same principle to specific heat determinations at very low temperatures, and obtained data concerning the mean specific heat of materials between liquid hydrogen and liquid nitrogen temperatures.

§ (2) BUNSEN'S ICE CALORIMETER.—In this instrument the heat given out by a body in cooling from some higher temperature to 0° C. is obtained by observing the contraction which takes place in the change from ice to water produced by the heat given by the body.

The observed volume change is converted into calories by assuming a value for the constant of the ice calorimeter, *i.e.* the mass of mercury drawn into the instrument by the addition of one mean calorie of heat.

Numerous determinations of this constant have been made and the values are summarised in Table I.

TABLE I

Dieterici . .	15·49	*Ann. Phys.*, 1905, xvi.
Griffiths (Ezer)	15·49	*Proc. Phy. Soc. London*, 1913, xxvi. I.

It might be remarked that many of the above values are based on observations of the heat imparted to the calorimeter by a small quantity of water contained in an envelope whose thermal capacity was comparable with that of the contained water. Since in the majority of cases no attempt has been made to vary the conditions and thus detect systematic errors, all the values are not entitled to the same weight. For example, the figure given by Bunsen is the mean of two experiments repeated under precisely similar conditions: the glass envelope weighed 0·2 gm., contained 0·3 gm. of water, and a platinum sinker (weight 0·5 gm.) was also attached.

Dieterici varied the quantity of water from 0·6 gm. to 2 gm., and consequently his determination is entitled to greater weight than the others. Griffiths' value was obtained by supplying a known quantity of heat measured as electrical energy. The heat was supplied by a manganin coil wound on a mica rack which fitted the interior tube of the calorimeter (see *Fig.* 2), and the results are based on the electrical units of E.M.F. and resistance. The conditions were varied. Thus the rate of energy supply in the fastest experiments was more than seven times that in the slowest, and the probable error by the method of least squares was less than 0·1 per cent.

Bunsen employed his ice calorimeter to determine the latent of fusion of ice as follows:

Known weights of water at a known boiling temperature were introduced into the inner tube of the calorimeter and the contractions observed.

In a separate experiment a known weight of ice at 0° C. was contained in a bulb, the rest of the space being filled with mercury. The ice was melted to water, the temperature being maintained at 0° C. Mercury was drawn into the bulb to occupy the space left by the ice in melting, and from the additional weight of mercury the contraction was obtained. He found that the melting of 1 gram of ice caused a contraction of 0·0907 c.c.

From the results of the two sets of experiments he calculated the latent heat of water to be 80·025 calories, which is 0·3 per cent higher than the value obtained in recent direct determinations.

The method is not a good one for determining the latent heat of water, since the calculations depend on the difference of the specific volumes of ice and water.

§ (3) BUNSEN'S CALORIMETER AND ITS MODIFICATIONS. (i.) *Description.* — A cylindrical test-tube A is fused into a larger glass bulb B, as shown in *Fig.* 1. The bulb B is furnished with a glass stem CD, which terminates in an iron collar D. This stem is filled with pure boiled mercury, which occupies the bulb to the level β. The remainder of the bulb above β is filled with pure boiled water. A calibrated narrow glass tube S, furnished with a millimetre scale, is fitted into a cork with fine sealing-wax, and then passed through the mercury in the collar D, and made fast in the mouth of the tube CD, so that it becomes filled with mercury; and by adjusting the cork in the mouth of the tube CD the extremity of the mercury column in the scale tube S can be placed at any convenient point. By methods, which are described in most text-books on practical physics, a mantle of ice is formed around the lower part of the tube A.

(ii.) *Precautions in Use.*—In the original manner of performing the experiment the instrument, as described above, was placed in a vessel containing pounded ice or snow, the top of the tube A and the tube S alone projecting above the ice. It is, however, generally found that there is always a small difference in the freezing-point of the ice in the instrument and that of the ice outside. If the temperature of the outside ice is higher, then there will be a slow melting of the ice in the instrument, which will cause a continuous creep of the mercury meniscus towards the instrument. If the freezing-point of the ice outside is lower than that of the ice in the instrument, then there will be a slow freezing of the water, causing the meniscus to creep away from the bulb. This creep generally amounts to 2 or 3 centimetres per hour, and is sufficient to make it very difficult to obtain trustworthy measurements. A slight addition to the instrument will almost eliminate the creep, reducing it to about a tenth its normal value. This addition, suggested by Boys, consists in placing the instrument in an empty vessel, the top of which is closed by a cork through which the tubes A and S pass. This vessel is surrounded by the pounded ice. Owing to air being a bad thermal conductor, heat can now only very slowly pass between the instrument and the surrounding ice. Another method of securing the same conditions has been employed by Callendar, who constructed the bulb B in the form of a vacuum vessel. The vacuum being a worse conductor of heat than air, the passage of heat from the surrounding ice to the instrument is in this way reduced yet more. When this device is used, the process of cooling the instrument down to zero will take a considerable time, unless a stream of ice-cool water is passed through the tube A.

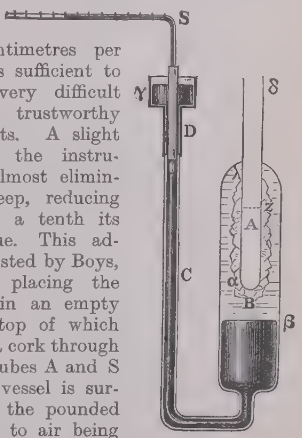

FIG. 1.

The writer adopted the plan illustrated in *Fig.* 2, which shows the instrument as set up for the determination of the constant of the calorimeter by the electrical method. The calorimeter is suspended within a transparent cylindrical vacuum vessel, the mouth of which is closed by a rubber cork as shown.

(iii.) *Variable Density of Ice.*—The objection most frequently quoted against the use of the ice calorimeter for work of precision is that the density of ice is not a constant quantity.

The experimental evidence on this point is briefly summarised below:

Nichols[1] reviews the work of previous investigators on the density of ice and describes his own experiments. He concludes that the density of ice mantles, determined by weighing in petroleum, is 0·91615 ± 0·00009. This result agrees with the mean value deduced from different methods by Plücker and Geissler, Kopp and Bunsen (for a similar variety of ice) to four places of decimals.

His experiments on the causes of the variations in density of artificial ice were not completed. The method was to freeze the ice mantle around the inner tube of a calorimeter by pouring in a mixture of CO_2 and ether. The unfrozen water was shaken out as completely as possible, and the adhering water frozen, the remaining space being then completely filled with mercury. The weight of the mercury, together with that of the ice, gave the data for the computation of the density of the ice mantle.

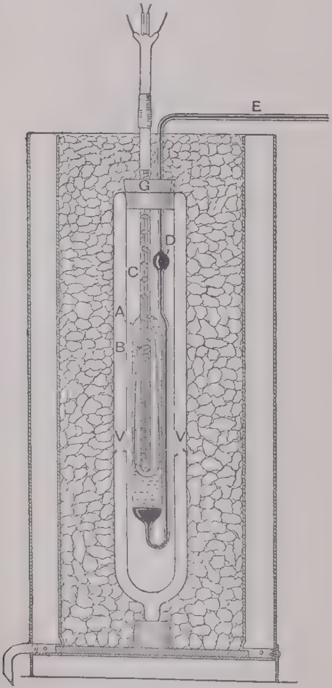

FIG. 2.

Although the results were consistent among themselves the absolute value was subsequently found to be erroneous on account of the deformation of the glass vessel under the weight of the contained mercury.

Nichols at first thought the discrepancy—amounting to 1 per cent—between his value and Bunsen's was due to the much lower temperature at which the mantle was formed in his own experiments. He therefore made some determinations with mantles frozen by means of alcohol at −5° to −10° as refrigerant in the manner devised by Bunsen. The measurements appeared to indicate that the mantles formed by the use of alcohol at −5° to −10° were less dense than those formed by means of CO_2 and ether at −70° by at least 1 part in 1000, and further that one of the latter mantles decreased in density by nearly this amount after standing 24 hours in an ice bath.

The use of CO_2 and ether resulted in a very rapid formation of ice, and the mantle, when a certain size was reached, invariably became filled with a network of fine cracks.

Vincent[2] later took up the subject, and also investigated the coefficient of cubical expansion of ice.

He prepared the ice by means of a freezing mixture, and appears to have obtained a different density for each sample prepared. Table II. summarises all his results:

TABLE II

Experiment.	Density Ice at 0°.	Weight assigned to the Experiment.
1	0·916335	3
2	0·915460	2
3	0·916180	2
4	0·915540	1
	0·916060	2
Weighted mean	0·9160	

His values for the coefficient of expansion of the above samples are consistent, and no connection between variation in density and expansion can be traced. Vincent's mean value for the density is 1 part in 5000 less than the mean of the results of Plücker and Geissler, Bunsen and Nichols.

The experiments of Leduc in 1906 suggest one cause of the variations in density which had been observed by previous workers. Leduc took extreme precautions to get rid of all traces of dissolved air in the water used for manufacturing the ice samples. He condensed the steam from boiling water under oil to obtain air-free water.

The results of these experiments indicated that the density of ice at 0° was not less than 0·9172, and as greater efforts were made to remove traces of gases the values obtained for the density increased. He concluded that the density of gas-free ice at 0° would probably be 0·9176.

It is of interest to note that Leduc considers that ice made from water which has been merely boiled, as in the case of the Bunsen calorimeter, still contains about 1 c.cm. of gas per litre at atmospheric pressure.

Another possible cause of the variations in density is the strains set up in the ice block on formation and which disappear in the course of time.

§ (4) JOLY'S STEAM CALORIMETER. (i.) *The Method.*—In the steam calorimeter devised by Joly[3] in 1886 the heat necessary to raise the temperature of a body from the air temperature to 100° is measured by determining the weight of steam which must be condensed into water at 100° to supply this heat.

---

[1] *Phys. Rev.*, 1899, viii.

[2] *Phys. Rev.*, 1902, xv.

[3] *Proc. Roy. Soc.*, 1886, xli. 352.

The instrument, especially in its differential form, has been found very useful for special purposes. But the experience of most users indicates that the condensation method is more troublesome to use than the method of mixtures for the determination of the specific heats of solids and liquids. In the hands of Joly, however, the steam calorimeter has produced data of fundamental importance concerning the specific heat of gases at constant volume.

One disadvantage of the condensation method is the fact that less than 2 milligrams of water is deposited per calorie, and consequently it necessitates accurate weighing.

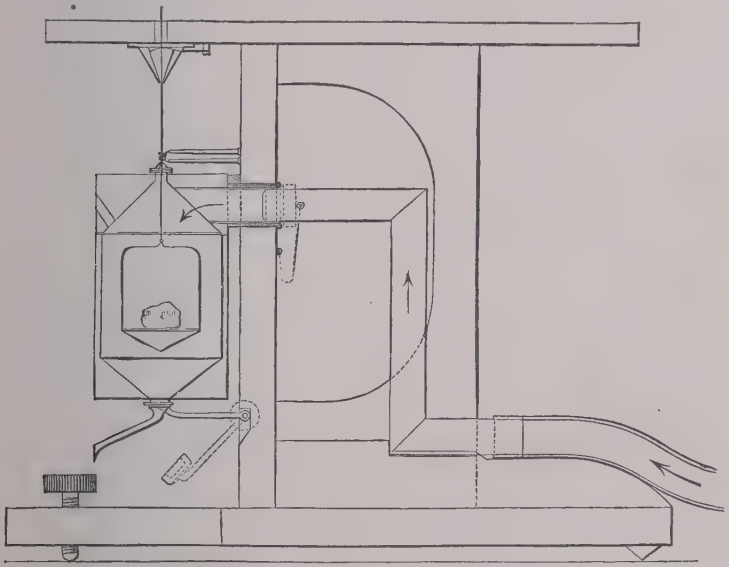

FIG. 3.

(ii.) *The Apparatus.*—The simplest form of Joly's apparatus consists essentially of a steam chamber of thin metal in which is suspended from the arm of a balance a small platinum pan (*Fig.* 3), carrying the substance under test.

Steam can be turned on to this chamber, as indicated, and escapes through a pipe at the base.

It is essential to arrange the inlet valve so that the steam can be admitted rapidly for reasons which are explained later.

(iii.) *Method of Experiment.*—The substance is weighed with air in the chamber and the temperature carefully noted. Steam in the meantime is got up in the boiler, and is suddenly admitted, so that the whole chamber becomes at once filled with saturated vapour. Condensation immediately begins on the substance and the resulting water is caught in the pan, weights being added to the other pan of the balance so as to restore equilibrium. During the process of weighing, the steam is passed through very slowly (by opening an escape tube leading from the boiler) into the calorimeter, so as to avoid disturbance of the pan.

After four or five minutes the substance has generally attained the temperature of the steam, and the condensation is completed. The pan then ceases to increase sensibly in weight, and the equilibrium of the balance is maintained permanently. A very slow increase of three or four milligrammes per hour (due to radiation) is, however, noticed. Let θ_2 be the temperature of the steam and L its latent heat. If w is the increase of weight the quantity of heat given out by the condensation is wL, and this is expended in raising the substance and the pan from θ_1 to θ_2. If W be the weight of the substance, and s its specific heat, the heat acquired by the substance will be $Ws(\theta_2 - \theta_1)$, and that acquired by the supporting pan will be $k(\theta_2 - \theta_1)$, where k is the thermal capacity of the pan, that is, the quantity of heat necessary to raise its temperature 1° C. Hence we have

$$Ws(\theta_2 - \theta_1) + k(\theta_2 - \theta_1) = wL.$$

The quantity k is determined by a previous observation, and the temperature θ_2 is found either directly, by a thermometer inserted in the steam-chamber, or by means of Regnault's tables and a reading of the barometer.

For extreme accuracy a small correction is still necessary. The weight W of the substance is found in air at θ_1, and the weight w is found when the substance and pan are in steam at θ_2. The weight of steam per cubic centimetre at 100° is little more than half that of air at ordinary temperatures; for this reason the weight w is greater than the weight of vapour condensed by excess in weight of a volume v of air at θ_1 over the same volume of steam at θ_2, where v is the volume of substance and pan together. The difference of weight of a cubic centimetre of air at 15° C. and a cubic centimetre of steam at 100° is ·000636 gram, according to Regnault; hence the correction to be applied to w is ·000636v.

This correction being applied, the weight of water condensed is determined, but it must be remembered that the weighing is made in steam; and, if extreme accuracy be desired, it is still necessary to multiply by the factor 1·000589, in order to reduce the weighing to vacuum. The actual weight in a vacuum of the water condensed will therefore be

$$1{\cdot}000589(w-0{\cdot}000636v),$$

so that s is determined from the equation

$$(\mathrm{W}s+k)(\theta_2-\theta_1)=1{\cdot}000589(w-0{\cdot}000636v)\mathrm{L}.$$

Reference should be made to § (6) of the article on "Latent Heat" for values of L.

In order to avoid the condensation of steam on the suspending wire, where it leaves the steam chamber, it passes, not through a small hole in the metal, but through a small hole pierced in a plug of plaster of Paris. Without the plaster the steam condenses on the metal and forms a drop at the aperture through which the suspending wire passes, and destroys the freedom of motion of the wire and prevents accurate weighing. With the plaster of Paris plug no such drop collects, and the weighing can be performed with accuracy. In his later experiments, Professor Joly placed a small spiral of platinum wire around the suspending wire just outside the aperture, and by passing an electric current through the spiral, sufficient heat is produced to prevent condensation on the suspending wire in the neighbourhood of the aperture. Besides accuracy in weighing, a point of prime importance is the rapid introduction of the steam at the beginning of the experiment. When the steam first enters the calorimeter, partial condensation occurs by radiation to the cold air and the walls of the chamber. Some of the condensed globules may fall upon the substance and lead to an error in the value of s. If the steam enters slowly this error may be large, and it is therefore important to fill the chamber at once with steam. This necessitates a good supply of steam and a large delivery tube, but when the chamber is well filled with steam a very gentle afterflow suffices. If the steam supply be cut off, the weight of condensed vapour slowly diminishes. This arises from the distillation over to the colder walls of the chamber, and if the steam be again turned on the weight increases.

The error arising from the deposition of condensed globules on the pan during the initial stages of the experiment is somewhat counterbalanced by radiation from the steam to the substance.

§ (5) The Differential Steam Calorimeter for the Determination of Specific Heats of Gases at Constant Volume.—In the differential[1] form of the steam calorimeter the correction for the weight of steam displaced by the pan is eliminated. In this form (*Fig.* 4) two similar pans hang in the steam chamber, one suspended from each arm of the balance so as to counterpoise each other. The thermal capacity of the pans can be made equal, so that the term with k as a coefficient does not appear in the equation, and the radiation error will also disappear, as it will cause equal condensation on the two pans.

The chief use of the differential form is, however, its application to the calorimetry of gases. For this purpose the pans are replaced by two spherical shells of copper, one containing the gas at a known temperature and the other empty. The spheres are furnished with small pans, or "catch-waters," to collect the water resulting from condensation. Greater condensation occurs on the sphere which contains the gas, and the excess gives the quantity of heat required to heat the contained mass of gas from θ_1 to θ_2. This determines the specific heat of the gas at constant volume. The great advantage of the differential calorimeter is that any source of error common to the two spheres is eliminated, and the gas or other substance enclosed in one of them merely bears its own share of error and not that also of the containing sphere. Thus the effect is practically the same as if the gas were contained in a vessel of zero thermal capacity in the single steam calorimeter form.

The spheres employed by Professor Joly were of copper and about 6·7 cm. in diameter, the one containing the gas being made to stand a safe working pressure of about 35 or 40 atmospheres. If at the beginning of the experiment this space is filled with air at about 22 atmospheres at θ_1 the pressure will rise to about 30 atmospheres at θ_2. In one experiment[2] the weight of air contained was 4·2854 grams. The condensation observed as due to the air was 0·15217 grams. This required a correction to compensate for the difference in weight of the spheres. The corrected value was 0·11629, the range of temperature, $\theta_2-\theta_1$, being 84·52° C. In a series of six experiments the mean precipitation per degree centigrade was 0·018004.

The following corrections are also necessary:

(*a*) Correction for the thermal expansion of the vessel, and the consequent work done by the gas in expanding to this increased volume.

---

[1] J. Joly, *Proc. Roy. Soc.*, 1889, xlvii. 218.

[2] *Phil. Trans.* A, 1891, clxxxii. 98.

(*b*) Correction for the dilatation of the sphere under the increased pressure of the gas as the temperature rises.

(*c*) Correction for the thermal effect of stretching of the material of the sphere. (Wires are generally cooled by sudden extension, but the cooling of the copper in this case is too small to merit consideration.)

(*d*) Correction for displacement or buoyancy arising from the increased volume of the sphere, both in the air at θ_1 and in the steam at θ_2.

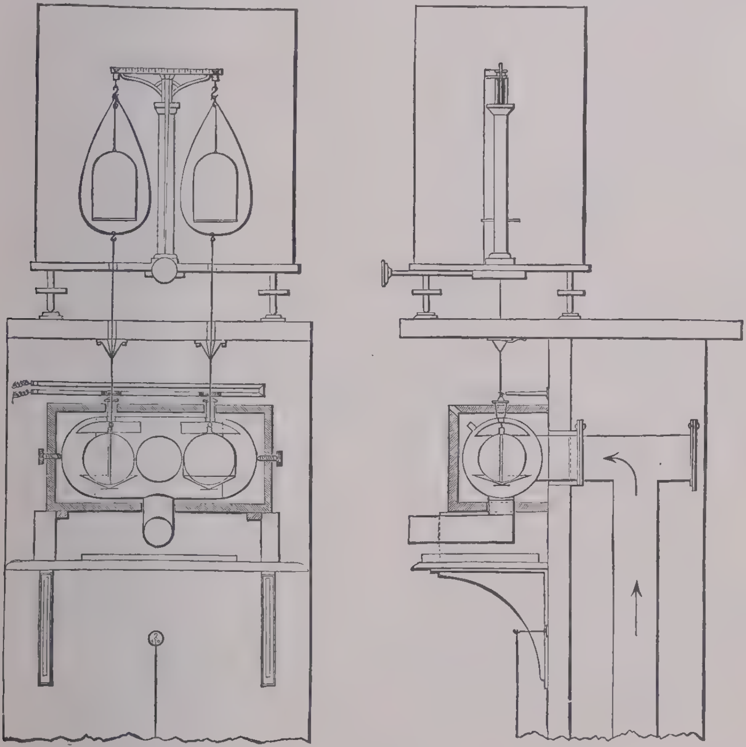

FIG. 4.

(*e*) Correction for unequal thermal capacities of the spheres.

(*f*) Reduction of the weight of the precipitation to vacuum.

Professor Joly's experiments show that in the case of air and carbonic acid the specific heat increases with the density, but with hydrogen the opposite seems to be the case.

For air the specific heat at constant volume at a mean pressure of 19·51 atmospheres, and a mean density of 0·0205, was found to be 0·1721. For carbon dioxide, the change with pressure is shown by the following table:

TABLE III

Pressure in Atmospheres.	Density.	C_v.
7·20	0·011530	0·16841
12·20	0·019950	0·17054
16·87	0·028498	0·17141
20·90	0·036529	0 17305
21·66	0·037802	0·17386

The mean result of the experiments on hydrogen gives a specific heat 2·402.

§ (6) DEWAR'S LIQUID AIR AND HYDROGEN CALORIMETER.—Dewar [1] has devised a calorimeter based on an analogous principle to the steam calorimeter in which he employs one of the liquefied gases as calorimetric substance. Whilst Joly's calorimeter depends upon condensation on a cold object, Dewar's calorimeter depends on the evaporation as a means of absorbing heat from the hot object. Instead of weighing the quantity of gas evaporated, he determines the volume of gas given off from the liquid which, of course, is at its boiling-point. Now the choice of liquefied gas to be employed as calorimeter substance is determined mainly by two considerations:

---

[1] *Proc. Roy. Soc.* A, lxxvi. 325; *Roy. Inst. Proc.*, 1904, xvii. 581.

(*a*) The quantity of gas given off by evaporation on the absorption of one calorie of heat, and

(*b*) The range of temperature available through which substance is cooled.

The table below summarises the data for some of the possible gases:

TABLE IV

Liquid Gases.	Boiling-point.	Liquid Volume 1 Gram at Boiling-point in c.c.	Latent Heat in Gram-calories.	Volume of Gas at 0° and 760 mm. per Gram-calorie in c.c.
Sulphurous acid	+10·0°	0·7	97·0	3·6
Carbonic acid .	−78·0	0·65 (solid)	142·4	3·6
Ethylene . .	−103·0	1·7 ,,	119·0	7·0
Oxygen . .	−182·5	0·9 ,,	53·0	13·2
Nitrogen . .	−195·6	1·3 ,,	50·0	15·9
Hydrogen . .	−252·5	14·3 ,,	125·0	88·9

It will be observed that oxygen gives off 13·2 c.c. per calorie whilst ethylene gives only 7. Hydrogen gives off 88·9 c.c. and is particularly advantageous but for the fact that the manipulation is difficult. Although nitrogen is a little better than oxygen, it is preferable to use the latter for the following reason. The boiling-point of air is below that of oxygen. Even if there is no layer of cold oxygen or gas on the surface of the liquid oxygen, the air coming in contact with it through the neck of the calorimeter would still remain gaseous; but if liquid nitrogen is used as calorimetric substance, air, being heavier than nitrogen but having a higher boiling-point, would, in falling down the neck of the calorimeter, come in contact with the cold gaseous nitrogen and be condensed.

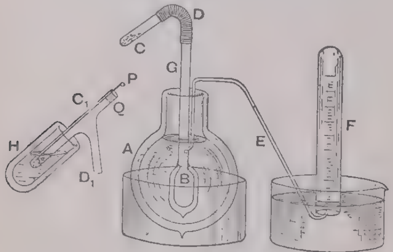

FIG. 5.

§ (7) THE LIQUID OXYGEN CALORIMETER.—It consists essentially of a large vacuum vessel A (*Fig.* 5) capable of holding two or three litres, into which is inserted the calorimeter, a smaller vacuum vessel B of 25 to 50 c.c. capacity, which has been sealed on to a long narrow tube G, projecting above the mouth of A, and held in its place by some loosely packed cotton-wool. From the side of this narrow tube, either before or after passing out of A, a branch tube E is taken off to enable the volatilised gas from the calorimeter to be collected in the receiver F, over water, oil, or other suitable liquid. To the extremity of the projecting tube G a small test-tube C, to contain the portions of material experimented on, is attached by a piece of flexible rubber-tubing D, thus forming a movable joint, which can be bent so as to tilt a few of the small pieces of substance contained in C into the calorimeter, and which afterwards assumes a position of rest somewhat like that in the diagram.

With care it is possible to tilt a single piece at a time from C into B, but an improved form of this receptacle is shown at C_1D_1. In it, P is a wire movable through the cork Q, fitted into the mouth of the test-tube C_1, attached by a branch through the stiff rubber tube D_1 to the end of G, as before. At the end of the wire P is a hook, by which one piece of the substance at a time can be pulled up and dropped into B. When no other arrangements are made, the portions of matter experimented on are at the temperature of the room; but when lower temperatures are required initially, a vacuum vessel H, containing either solid carbonic acid, liquid ethylene, air, or other gas, can be placed so as to envelop the test-tube C or C_1; or if higher temperatures are required, the surrounding vessel may be filled with the vapour of water or other liquids.

Now, when a quantity of liquid air has been undergoing volatilisation for a time, as the nitrogen evaporates more quickly than the oxygen the boiling-point rises slightly. Two points require attention in consequence of this: first, the maintenance of a constant temperature of the liquid air during any one series of experiments; next, the prevention of a tendency for the calorimeter B to "suck back" some of the already volatilised gas. Hence the exterior vessel A should be filled with a large quantity—some two litres—of *old* liquid air, containing a high percentage of oxygen, and the calorimeter itself should be filled with some of the *same* fluid. This will maintain very closely the constant temperature required. When any "sucking back" seems to be taking place, the calorimeter should be emptied and filled anew from the larger flask A. The tube between the calorimeter and the gas receiver should be of the size of wide quill tubing, and its lower end should be so arranged below the surface of the liquid in the collecting vessel as to give no resultant pressure. With such precautions, results may easily be obtained correct to within 2 per cent.

The instrument having been set up and filled with liquid air, an experiment is conducted by tilting up the little test-tube, previously cooled or heated, thereby dropping into the calorimeter a portion of any substance previously weighed. The substance in this way falls from the temperature of the room to that of liquid air. The heat given up by it volatilises some of the liquid, which is carried off by the branch tube and measured in the graduated receiver F. Immediately preceding or following this observation, a similar experiment is made with a small portion of a selected standard substance, usually lead. The quantity of lead is so chosen as to produce about the same volume of gas in the receiver as that supplied by the portion of substance experimented on. By this means the circumstances of the two observations are made as similar as possible, and thereby many sources of error are eliminated.

§ (8) **Liquid Hydrogen Calorimeter.**—In 1913 Dewar[1] further developed the method so as to adapt it to the range of temperature between the boiling-points of liquid nitrogen and hydrogen: from −196° to −253° C., a range of only 57°.

The liquid hydrogen calorimeter is a glass cylindrical bulb vacuum vessel A (*Fig.* 6) of 50 c.c. capacity, silvered, with $\frac{1}{2}$ cm. slit. On the neck is sealed a glass tube B. This projects through the brass coned fitting cap F of an ordinary slit silvered vacuum vessel in which it is supported. A side delivery tube, provided with stopcock D, is sealed near the top of B. A short length of rubber tubing on the neck of F makes a gas-tight joint with B. To minimise splashing, and to reduce the impact of the falling pieces, a thin strip of German silver or lead E, bent out near the top into a shoulder about 1 cm. square, stands centrally in the calorimeter A. The strip is cut from a thin tube of about the same diameter as the calorimeter neck. A short length of the tube is left above the shoulder, and supports the strip by fitting loosely into the neck of A. Some such device is essential in the use of this form of the liquid hydrogen calorimeter.

The calorimeter in its turn is immersed in liquid hydrogen in the supporting vacuum vessel C, the neck of the calorimeter being 8 to 10 cm. below the liquid hydrogen surface. The vacuum vessel C is only slightly wider than the lower part of A, and is provided with a coned cap F, whereby it is also supported and completely immersed in a wider vacuum vessel G containing liquid air. G is also fitted with a brass coned cover, fitting vacuum-tight on to the cap F on C. Both caps are pierced by two thin tubes, one for fitting on to the filling syphons, the other, bent at right angles, serving for connecting to the exhaust in the case of the liquid air vessel, and in the case of the liquid hydrogen to the stopcock leading the evaporating hydrogen through the upper part of the apparatus.

This arrangement thus charged only needs a little liquid air sucked in every one and a half hour. The liquid hydrogen vessel will not need replenishing for at least four hours. The level of the liquid hydrogen in the calorimeter does not fall 1 cm. in six hours with constant use. The bulk of the materials added roughly compensates for the volume of the liquid hydrogen evaporated.

It is important that this level should not materially change, since, after striking the shoulder, bodies move more slowly, are deflected on to the cold wall, and low results are obtained due to the longer cooling of the materials in the vapour before being immersed in the liquid hydrogen.

Fig. 6.

The isolation of the calorimeter was such that less than 10 c.c. of hydrogen gas was evaporated from it per minute. The whole apparatus is supported between the cork-lined spring jaws mounted on a heavy metal base on which the outer vacuum vessel rests.

The cooling vessel H is connected by an india-rubber tube to the top of the calorimeter. It consists of an ordinary cylindrical silvered vacuum vessel, 20 cm. long and 7 cm. wide, with a central axial open tube K sealed in below. This tube passes through the liquid in the vacuum vessel. It has the same diameter below as the neck tube of the calorimeter. Near the top of the central tube a side tube J, of about the same diameter and some 3 cm. long, serves for the introduction of the weighed pieces of material, which are all cooled previously to the temperature of liquid air, and then fall on to a thin metal disc P fitting loosely the tube K, where they remain about 15 minutes. P is supported by being hinged to two thin ebonite rods, L and M, fixed to a brass fitting cemented on to the top. The rod L is not fixed directly to the disc but to a metal ring R. From the ring R two thin vertical steel wires are connected freely to two points on the circumference of the pan below. This rod and the attached ring can be given a vertical motion by a crank N in the top fitting, thereby tipping the pan and releasing the piece of material, which then falls freely down into the calorimeter. A high vacuum is maintained by a cross-tube S, opening to the annular space, filled with charcoal.

---

[1] *Proc. Roy. Soc.*, 1913, lxxxix. 158.

At the temperature of boiling nitrogen, the convection currents in the central tube of such a vessel, when connected to the calorimeter below, have no serious effect on the temperature in the tube at a reasonable distance from the bottom, provided the central tube be not wide. With a larger pattern vessel the width of the central tube was increased to 2·2 cm., and even here the difference was under 3° at the level of the pan. These temperatures were measured by a small helium thermometer, consisting of a 4-c.c. bulb to which was sealed a small mercury manometer of fine capillary tubing.

The hydrogen evaporating from the liquid in the vacuum vessel C, in which the calorimeter is immersed, is employed in the interval of observations to maintain a hydrogen atmosphere through the neck of the calorimeter and the connected measuring tubes. Risk of solid air in the calorimeter neck is thus obviated. A simple arrangement of a three-way cooling vessel allows this to be manipulated.

The vessel V consists of a glass tube 8 cm. in diameter and 40 cm. long, open at the bottom and provided with a wide T-piece at the top. The tube is immersed to the neck in water in a glass cylinder, and is counterpoised by a weight and cord running over a pulley just above. It is thereby readily raised during the time gas is being evaporated from the calorimeter; this ensures that no back pressure is produced. One arm of the T-piece is open and connects to the stopcock D on the calorimeter neck; the other is provided with another small stopcock and connects to a 200-c.c. gas burette W similarly immersed in water. This latter stopcock is closed while the gas evaporated during an experiment is collected.

These arrangements are necessary to secure the minimum impediment to the evaporating hydrogen, which is usually evolved in less than 10 seconds, any temporary back pressure being fatal to concordant results. At least 15 seconds are allowed for collecting the gas given off, and even longer, in some cases, with badly conducting bodies.

As far as possible the materials used were cast in the forms of spheres about 8 mm. diameter.

In the case of liquid bodies, the mould was first cooled by liquid air. Frequently liquids were frozen into solid cylinders in thin glass tubing, and pieces cut off after removing the glass mould. The metallic materials were in some cases fused into buttons of convenient weight in an exhausted quartz tube. The lead, however, of which many pieces were required, was cut from rod, and subsequently squeezed in a small spherical mould.

Volatile bodies were weighed at a low temperature on a light German silver pan supported by a thin platinum wire suspension from the balance pan about 2 cm. above the level of liquid air contained in a wide deep vacuum vessel. Some materials would not make coherent bullets or cast sticks, and these were filled into very thin-walled cylindrical metal capsules.

In order to obtain consistent results it is necessary to employ exactly the same procedure in each test, but with this apparatus Dewar was able to obtain results which rarely varied among themselves by more than 2 or 3 per cent.

The data thus obtained for the mean specific heats of 53 elements at about 50° abs. are summarised in Table V.

The interesting fact discovered in the course of this investigation was that the atomic heats were periodic functions of the atomic weight, and the curve resembled, generally, the well-known Meyer atomic volume for the solid state.

E. G.

CALORIMETRY, METHOD OF MIXTURES

§ (1) INTRODUCTION.—Calorimetric apparatus assumes the most diverse form, each type characterised by certain features, which adapts it especially for a particular class of measurement.

For the determination of the mean specific heat of a substance over a range of temperature or for the determination of the heat of combustion of a fuel the Method of Mixtures is a convenient one to employ and is probably the best known of all calorimetric methods.

§ (2) THE METHOD OF MIXTURES.—The principle of this method is to impart the quantity of heat to be measured to a known mass of water contained in a vessel of known thermal capacity, and to observe the rise of temperature produced; from which data, as explained in detail farther on, the quantity of heat can be calculated. This method is the simplest of calorimetric methods, but is not the most accurate. Heat is lost in transferring the hot object to the calorimeter, and although it can be minimised by arranging that the transfer takes place rapidly, it cannot be eliminated or even accurately allowed for. Some heat is lost when the calorimeter is raised above the temperature of its enclosure and before the final temperature is reached. This can be roughly estimated by observing the rate of change of temperature and assuming that the heat loss is directly proportional to the duration of experiment and to the average excess of temperature. The accurate determination of this correction is of fundamental importance in this method and a detailed discussion of it will be given. It is always desirable to diminish the loss of heat as much as possible by polishing the exterior of the calorimeter to diminish radiation, and by suspending it by non-conducting supports inside a polished case to protect it from draughts. It is also very important to keep the surrounding conditions as constant as possible throughout the experiment. This may be secured by using a large water-bath around the apparatus, but in experiments of long duration it is advisable to use an accurate temperature regulator. The method of lagging the calorimeter with cotton-wool, which is often recommended, diminishes the heat loss considerably but renders it very uncertain, and should never be used in work of precision, since the bad conductors take so long to reach a steady state that the rate of loss depends on the past history more than on the temperature of the calorimeter at the moment. A more serious objection to the use of lagging of this kind is the danger of its absorbing moisture. The least trace of moisture in the lagging may produce serious loss of heat by evaporation.

Regnault about 1840 made a careful study of the Method of Mixtures, and by skill and attention to detail he obtained by means of it a valuable series of thermal data. It is only within comparatively recent years that any material improvements on Regnault's apparatus have been effected.

§ (3) THEORY OF METHOD OF MIXTURES.—It will be assumed that the cases under consideration are those of solids and liquids. The determination of the specific heats of gases requires especial consideration and is dealt with in a separate section.

Let M = mass of heated body,
θ = temperature of heated body at the moment of its immersion in the water of the calorimeter,
W = mass of water employed,
t = temperature of water when the body is immersed in it,
T = temperature when the thermal equilibrium is established between the body and the water, *i.e.* when temperature of water ceases to rise (or sink if the body was cooler than the water).

Now if s = mean specific heat of water between T and t, and S = specific heat of the body between θ and T, we get

$$MS(\theta - T) = Ws(T - t),$$

and

$$S = \frac{Ws(T-t)}{M(\theta - T)}. \quad . \quad . \quad . \quad (a)$$

This gives the calorimetric equation for the method of mixtures in its very simplest form; for practical working several corrections are necessary.

(i.) For W we must substitute another magnitude W_1 such that $W_1 = W +$ mass of water, having the same heat capacity as containing vessel, stirrer, and all parts whose temperature is seriously affected:

I.e. if μ = mass of metal reservoir, stirrer, etc.,
and s_1 = mean specific heat of this metal between T and t,

$$W_1 = W + \mu\frac{s_1}{s},$$

and in this case equation (a) becomes

$$S = \frac{W_1 s(T-t)}{M(\theta - T)}. \quad . \quad . \quad . \quad (b)$$

Sometimes the substance has to be supported in a receptacle, and if we put a = water-equivalent of such receptacle and taking $s = 1$ within the limits of the experiment, we get

$$S = \frac{W_1(T-t)}{M(\theta - T)} - \frac{a}{M}. \quad . \quad . \quad . \quad (c)$$

Where the results are to be as accurate as possible, equation (c) takes a more complicated form. In addition to the magnitudes already represented, we have to take account of the thermal capacity of the thermometers, etc.

In addition to these corrections dependent on the nature of the various parts of the apparatus, there is the cooling correction for the loss of heat from the calorimeter to its surroundings.

§ (4) MODERN APPARATUS FOR THE METHOD OF MIXTURES.—The complete outfit required for experiments with the method of mixtures consists of the following elements, which will be considered individually:

(i.) The calorimetric vessel and the device for mixing the contents.

(ii.) The jacket enclosing the calorimeter.

(iii.) The thermometer for measuring the temperature rise of the water.

(iv.) The appliance for heating or cooling the charge (in specific heat determinations).

§ (5) CALORIMETER AND STIRRER. (i.) *The Calorimeter.*—The calorimeter is usually made of pure copper, nickel plated and polished so as to reduce radiation to a minimum.

The use of a vacuum jacket as a calorimeter is not to be recommended for ordinary work. Undoubtedly it is possible by means of it to reduce the magnitude of the cooling rate, but this advantage is more than counterbalanced by the disadvantages of this form of container due to its brittleness, the lag of the portions of the glass walls above the surface of the water, the difficulty of ascertaining its heat equivalent and of keeping it constant.

Under certain circumstances the use of water or other calorimetric fluid becomes impracticable. Hence some investigators have employed as calorimeter thick-walled metallic cups and trusted to the high coefficient of heat conductivity of the metal to equalise the temperature. These specialised forms of calorimeters are described later.

(ii.) *The Stirrer.*—Stirrers vary considerably in design according to the specific purpose for which they are required. A typical form is illustrated in *Fig.* 1; here a screw is employed for stirring the contents. The vessel is constructed with an ∞-shaped cross-section, the stirrer being contained in a tube which is connected with the main tube at the top and bottom. By this arrangement it is possible to ensure a steady circulation through the calorimeter, and it is advisable to direct the stream as smoothly as possible by suitably curved passages.

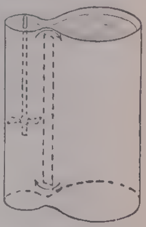

FIG. 1.

In the design of such a calorimeter particular attention must be given to the provision of wide passages for the circulation of the water and care taken to avoid as far as possible dead spaces. It might be remarked that this method of stirring has been found to be the most reliable for comparison baths for mercury thermometers and is much superior to a plain screw in a vessel of liquid.

White [1] adopted a somewhat similar form of calorimeter for his experiments on the specific heat of silicates at high temperatures. The charge, contained in a platinum crucible, was dropped directly from the furnace into the calorimeter.

It will be observed from *Fig.* 2 that the cover W is in actual contact with the water to ensure temperature equilibrium. The annular space under the cover permits the water to vary somewhat in amount without overflowing or failing to wet the cover, while the weight of the cover (70 grm.) prevents it from being floated out of the place when the water is high. An approximate preliminary adjustment of the amount of water is of course necessary, and is very easily obtained. Evaporation through the joint is about 7 mg. an hour, which is not likely to produce appreciable error. An oil seal gives very little trouble, and is used where maximum accuracy is desired.

---

[1] "Some Calorimetric Apparatus," *Phy. Rev.*, Dec. 1910, xxxi. No. 6.

Complete enclosure of the calorimetric vessel, with the possibility of quick opening and closing, and thorough circulation without much heating, are the main requirements.

In *Fig.* 3 a totally different type of stirrer is shown where the contents are mixed by a flat paddle of annular form which has a reciprocating motion in the liquid. In order to avoid pumping air in and out of the calorimeter by the reciprocating motion two small rubber bellows are fixed as shown with the end of the stirrer rod attached to the mid-point. The compression of the one bellows is compensated for by the extension of the other. This device is due to Professor E. H. Griffiths.

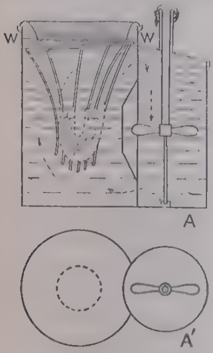

FIG. 2.

A, vertical section; A′, horizontal section. The position of the crucible is shown by the dotted lines.

The method of stirring demands the most careful consideration in any arrangement that may be adopted. Vigorous stirring of the water is necessary to keep the calorimeter at a uniform temperature throughout while the heat is being rapidly supplied to it. There are two distinct functions of a stirrer, mechanically more or less incompatible: First, the whole mass of liquid in a calorimeter must be circulated, so that there are no stagnant portions; and second, there must be thorough mixing of the different portions of the liquid in order that a measurement of its mean temperature may be obtained with a thermometer of convenient size.

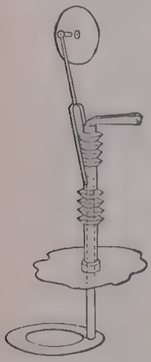

FIG. 3.

The reciprocating paddle form of stirrer mixes thoroughly the smaller portions of the liquid but produces little positive circulation, so that certain portions of the liquid may be left nearly stagnant. The screw propeller type of stirrer, on the other hand, properly applied, produces a rapid circulation of the whole mass of liquid, but may not mix so thoroughly the different portions, *i.e.* it permits of definite stream lines. Such a stirrer can be mounted on a very small shaft and in such a way as not to promote evaporation.

The tendency at the present day is to employ a small propeller driven continuously by a belt from a small electric motor, but for occasional work a hand-operated stirrer is preferred on account of its simplicity.

The common type of stirrer, which is standard on combustion outfits, consists of a copper annulus of such diameter that it loosely fits the inside of the calorimeter and is oscillated up and down by a rod. This form of stirrer is not to be recommended for the stem moves in and out of the liquid, promoting evaporations, which may be a serious source of error.

The paddle form of stirrer shown in *Fig.* 3 avoids this defect. Another simple paddle form of stirrer is illustrated in *Fig.* 4.

In the top edge of the calorimeter two small notches are cut at opposite ends of a diameter. The stirrer consists of a thin horizontal copper rod bent to the form shown and resting in the notches. Two thin copper plates are soldered to the rod while a small glass rod is cemented to form a handle. By giving the handle a to-and-fro motion the paddles move backwards and forwards through the liquid and thus mix it up fairly thoroughly.

(iii.) *Evaporation from Exposed Liquid Surface.* Experience has shown that one of the greatest sources of error in the Regnault form of calorimeter is the heat loss by evaporation from the exposed water surface. The evaporation of 10 milligrams of water consumes 6 calories, and since a calorimeter determination seldom involves a quantity of heat greater than 6000 calories an irregularity in the evaporation rate amounting to 10 milligrams introduces an error of one part in a thousand.

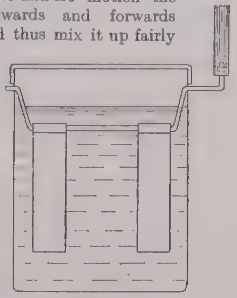

FIG. 4.

Observations with an open calorimeter of standard form have shown that a rate of evaporation of 10 milligrams per minute is not unusual, and this involves a heat loss as great, on the average, as that from the cooling by radiation, etc., besides being far more uncertain.

Consequently, in all precision work the calorimeter should be closed by a fairly tight-fitting cover so as to check the loss by evaporation.

Another precaution to be observed in this connection is to prevent the possibility of the evaporation of small amounts of water from the outside of the calorimeter during the course of the experiment, as the error due to this cause may be especially serious on account of the fact that the evaporation may be completed before the cooling correction is determined and consequently no allowance made for this heat loss. Two possible sources of such error should always be guarded against.

(*a*) The presence of a minute drop of water on the outside of the calorimeter due to lack of care in filling.

(*b*) Absorbed moisture if the surface is hygroscopic. A tarnished copper surface 100 cm. square in area will absorb 7 milligrams of water in a saturated atmosphere at ordinary temperature, whilst a surface of polished nickel of the same size and under the same conditions will not absorb as much as 0·1 milligram. Hence it is always advisable to provide the calorimeter with a lid, although it will be found that to close the calorimeter effectively the addition of a lid complicates the construction.

Even with the simplest form of apparatus a substantial improvement is produced by providing a lid of very thin metal having a slot to allow of its being removed for the introduction of the hot body without disturbing the thermometer.

§ (6) THE JACKET SURROUNDING THE CALORIMETER.—White[1] during the course of his extended researches on the specific heats of the silicates has devoted much attention to the design of the calorimetric apparatus employed.

One form of jacket for maintaining a constant temperature enclosure around the calorimeter which he has described is shown in *Fig.* 5. The jacket is shown in section and also in top view, partly open. Water is held up in the two halves of the cover, and in the upper section of the chamber wall, by atmospheric pressure. On leaving the propeller the water divides and passes across through the three upper passages, and then returns through the lower space. Its circulation is directed by the partitions P and Q, of which Q runs nearly the whole length of the tank outside the chamber, as shown by the dotted line. The chamber is opened by moving the covers aside; their down-turned ends then move in the troughs left at the ends of the tank. The covers slide upon the stout rod T. The pulley for the calorimeter stirrer, and the whole jacket stirrer, are borne on one half cover. This half is clamped firmly in place during an observation; moving aside the other fully exposes the calorimeter opening.

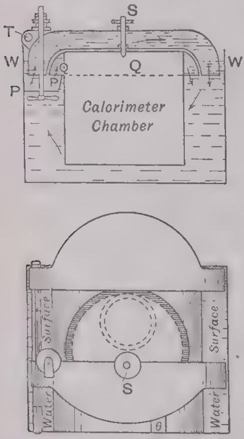

FIG. 5.

T, rod on which the top slides; S, stirrer pulley; *θ*, groove for passage of thermoelectric thermometer; W, water level.

(i.) *Method of supporting the Calorimeter.*—Heat transfer between the calorimeter and its jacket may take place in four ways—by conduction, convection, radiation, and evaporation. The object of applying the cooling correction is to eliminate this heat loss from the final result.

Whilst in practice it is not necessary to study these effects separately, it might be remarked that under ordinary conditions the greater portion of the heat transfer is due to convection and air conduction, the two together constituting about 80 per cent of the total.

It is advisable to reduce the transfer by thermal conduction through the supports of the calorimeter to a minimum since it constitutes an uncontrollable source of error.

Consider, for example, the case of a calorimeter supported within the enclosure on a sheet of cork or rubber. When the calorimeter and enclosure are at two steady temperatures the heat transfer is, by the laws of conduction, proportional to the temperature difference; if, however, the temperature of the calorimeter is changing rapidly the rate of transfer is not even approximately proportional to the temperature difference.

The following is a discussion of this source of error by Dickinson:[2]

Since the conductivity of such materials is always small, compared with that of the metallic sheets in contact with them, the temperatures of the surfaces may be taken, for the purposes of this discussion, as approximately the same as the measured temperatures of the calorimeter and the jacket respectively. The distribution of temperature in such a layer and the rate at which heat is leaving the calorimeter at any time may be then determined from the following considerations:

A sheet of material of thickness c bounded by plane surfaces x_0 and x_1 is initially at temperature θ_0. If x_0 and θ_0 are each taken as 0 for convenience, and the temperature of one of the surfaces x_1 is then caused to rise from θ_0 to θ' in such a way that $\theta=\theta'(1-e^{-\alpha t})$, the temperature distribution in this plate is given by the following equation:[3]

$$\theta=\frac{x}{c}\mathrm{F}(t)+\frac{2}{\pi}\sum_{1}^{\infty}\left[\frac{(-1)^m}{m}\sin\frac{m\pi x}{c}\left(\mathrm{F}(t)-\frac{m^2a^2\pi^2}{c^2}\int_0^t\mathrm{F}(\lambda)e^{\frac{-m^2a^2\pi^2}{c^2}(t-\lambda)}d\lambda\right)\right].$$

Where a^2 is the thermometric conductivity of the material, F(t) is the temperature of the face $x_1=c$, taken here as $\theta'(1-e^{-\alpha t})$.

The point of interest in this discussion is the rate at which heat is leaving the calorimeter at any time, as this determines the value of the emissivity for the portion of the surface in question. If θ' and c are each made unity, and the above expression for θ is differentiated with respect to x, the following expression for the temperature gradient at any point in the material is found :

---

[1] *Loc. cit.*

[2] "Combustion, Calorimetry, and the Heats of Combustion of Cane Sugar, Benzoic Acid, and Naphthalene." *Sci. Paper Bur. Stds.*, 1914, No. 230.

[3] Byerly, *Fourier's Series and Spherical Harmonics*, p. 110.

$$\frac{d\theta}{dt}=1-e^{-\alpha t}$$

$$+2\sum_{1}^{\infty}(-1)^m \cos m\pi x(e^{-\alpha t}-e^{-m^2\pi^2a^2t})\frac{\alpha}{m^2\pi^2a^2-\alpha}.$$

The surface $x=1$ is the surface in contact with the calorimeter, so that substituting this value of x and the appropriate values for a^2 and α, the above expression gives the temperature gradient in the material in contact with the calorimeter, which is proportional to the factor k for this portion of the surface.

As an example showing the effect of this kind of distribution of material, suppose that the calorimeter rests on a sheet of ebonite 1 cm. thick and that the temperature in the calorimeter rises quite approximately according to the relation $\theta-\theta_t=(1-e^{-\alpha t})(\theta_1-\theta_i)$, where $\alpha=0{\cdot}03$[1] and θ, θ_i, and θ_1 represent, respectively, the temperature at any time, the initial, and the final temperature. The value of a^2, the thermometric conductivity, for ebonite is approximately 0·001 in C.G.S. units. These quantities substituted in the above equation show that after 60 seconds the rate of heat loss is 2·75 times its final value, after 5 minutes the rate is 1·13 times the final value, and only after 10 minutes does it come to within 1 per cent of its final value. If the area in contact with such a sheet were a considerable part of the whole area of the calorimeter, the error introduced from this cause evidently would be a very serious one. Such a distribution of material as here discussed will also have an effect on the heat capacity of the calorimeter.

This discussion shows that all non-conducting supports should be negligibly small, or, since the thermometric conductivity $a^2=\mathrm{K}/c\rho$, the absolute conductivity K divided by the specific heat (c) and density (ρ), the material used for them should have a small density and specific heat. A form of support should therefore be employed, in which the smallest possible mass of insulating material is used, with the smallest possible area in contact with the calorimeter. The mass of such supports can readily be made negligible compared with that of the calorimeter.

(ii.) *Supports and Space between Calorimeter and Jacket.*—To reduce errors due to the above cause to a minimum Dickinson[2] employed the following arrangement of supports for his calorimeter. The supporting pieces (three in number) are each made up of a brass cone soldered to the bottom of the jacket, and a small ivory tip about 2 mm. in diameter cemented into the end of the cone and resting against small plates (one with a hole, one with a slot, and the third plane) on the bottom of the calorimeter. The thermal conductivity of the ivory tips is small, and their total mass is not over 0·1 gm., so that their effect on the cooling rate is too small to be significant. The brass cones, while they have a considerable mass, have a heat conductivity so great compared with the amount of heat which they can receive by radiation, convection, etc. (about 0·0001 calorie per square centimetre per second per degree temperature difference), that their temperature is at all times measurably that of the jacket, hence their effect is entirely negligible, both as regards cooling rate and heat capacity.

(iii.) *Heat Conduction along the Stirrer.*—The steel stirrer shaft which enters the calorimeter should end just above it in a thin rubber sleeve, which should fit tightly over it and tightly within a larger steel piece coupled to the driving shaft. It is evident that since the heat conductivity of steel is many times greater than that of the hard rubber sleeve, the temperatures of the two metal parts will remain very nearly the same as the temperatures of the calorimeter and the jacket respectively. The heat capacity of the rubber sleeve, some of which should be added to that of the calorimeter, is insignificant.

§ (7) METHOD OF CALCULATING THE COOLING CORRECTION. (i.) *Rumford.*—Rumford was the first to introduce a method of correcting for the heat loss from the calorimeter. His procedure was to make a preliminary experiment to ascertain approximately what the rise of temperature would be and then to cool the calorimeter half this number of degrees below the temperature of the surrounding atmosphere before the next experiment.

For example, let

$$\text{Temperature of atmosphere}=t^\circ,$$
$$\text{Approximate increase}=2\theta.$$

The calorimeter is cooled to $(t-\theta)^\circ$, and the heated body then introduced : the maximum temperature will be approximately $(t+\theta)^\circ$, and Rumford's idea was that the amount of heat gained by the calorimeter during the time its temperature was below t° will exactly compensate for the amount lost by it while its temperature was above t°. This is approximately true, but not quite so, owing to the fact that the rate of increase of temperature diminishes very rapidly as the heated body and the water approach thermal equilibrium : thus, it may happen that the rise of temperature from $(t-\theta)^\circ$ to t° will occur in less than 20 seconds, while the rise from t° to $(t+\theta)^\circ$ will occupy over 100 seconds.

(ii.) *Arithmetical Method of computing Heat Loss.*—A far more accurate, but not nearly so easy a method of correction is the following: Cool the calorimeter several degrees below the enclosure and take very careful readings at intervals of about 20 seconds before and after the introduction of the hot body, and also after the establishment of thermal equilibrium between the hot body and the water. Let θ, θ_1, θ_2, . . . θ_n be the temperatures of the calorimeter at the beginning and at the end of m periods of, say, 20 seconds each before the introduction of the hot body.

Let t, t_1, t_2 t_3, . . . t_n be the temperatures for n periods of equal duration after the introduction of the hot body up to the establishment of thermal equilibrium between the hot body and the water.

Let T, T_1, T_2 . . . T_r be the temperatures for r similar periods after the establishment of thermal equilibrium : t_n and T are virtually the same. The temperature t should not be taken from the reading of the thermometer, but should be calculated as follows:

---

[1] Value found by experiment by Dickinson for his calorimeter.

[2] *Loc. cit.*

$$i = \theta_m - \frac{\theta_m - \theta}{m}.$$

During the first interval after the introduction of the heated body the mean temperature of the calorimeter has been $t+t_1/2$, and if we put v for the change in the temperature of the calorimeter due to its surroundings we get for the first interval

$$v_1 = a\left(\frac{t+t_1}{2} - x\right),$$

where a and x have to be calculated. For the second interval we have

$$v_2 = a\left(\frac{t_1+t_2}{2} - x\right),$$

where a and x have the same values as in the expression for v_1. Finally,

$$v_n = a\left(\frac{t_{n-1}+t_n}{2} - x\right),$$

so that between t and t_n

$$\Sigma v = a\left(\frac{t+t_n}{2} - t_1 + t_2 + \ . \ . \ . \ t_{n-1} - nx\right).$$

The values of a and x are found in the following way: Let ϕ represent the mean temperature of the calorimeter before the introduction of the hot body,

$$\therefore \phi = \frac{\theta + \theta_1 + \theta_2 + \ . \ . \ . \ \theta_m}{1+m},$$

so that the mean value of $v = a(\phi - x)$ between θ and θ_m; and putting ϕ_1 for mean temperature after establishment of thermal equilibrium,

$$\therefore \phi_1 = \frac{\mathrm{T} + \mathrm{T}_1 + \mathrm{T}_2 + \ . \ . \ . \ \mathrm{T}_r}{1+r},$$

and the mean value of $v^1 = a(\phi_1 - x)$.

$$\text{Now } v = \frac{\theta - \theta_m}{m}, \text{ and } v' = \frac{\mathrm{T} - \mathrm{T}_r}{r}.$$

From the two equations $v = a(\phi - x)$ and $v' = a(\phi_1 - x)$

we get
$$a = \frac{v - v'}{\phi - \phi_1}$$

and
$$x = \frac{v\phi_1 - v'\phi}{v - v'},$$

from which Σv can be calculated, and hence the corrected value of the change of temperature of the calorimeter.

(iii.) *Graphical Method of deducing the Heat Loss.*—A graphical method of computing the cooling correction is due to Rowland.

(*a*) *Rowland's Method.*[1]—Instead of finding the number of heat units lost by the body while the temperature of the body is rising to its maximum value, the heat loss can be accounted for if the temperature is determined which the body would have attained if there had been no loss. The correction is obtained as follows: First make a series of measurements of the temperature of the water of the calorimeter, before and after the charge is dropped in, together with the times. Then plot them graphically on a large scale as in *Fig.* 6. Five or ten centimetres to a degree are sufficient. *nabcd* is the plot of the temperature of the water of the calorimeter, the time being plotted horizontally and the temperature vertically. Continue the line *dc* until it meets the vertical line *la*. Draw a horizontal through the point *l*. At any point *b*, of the curve, draw a tangent and also a vertical line *bg*; lay *lf* equal to *eg*, and draw the line *fhk* through the point *h*, which indicates the temperature of the atmosphere of the vessel surrounding the calorimeter. Draw a vertical *jk* through the point *k*. From the point of maximum *c* draw a line *jc* parallel to *dm*; where it meets *kj* will then be the required point. Hence, the rise of temperature, corrected for all cooling errors, will be *kj*.

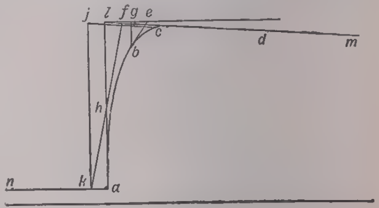

FIG. 6.

This method, of course, only applies to cases where the final temperature of the calorimeter is greater than that of the air; otherwise there will be no maximum.

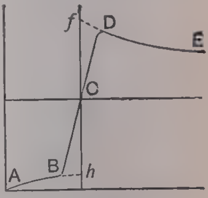

FIG. 7.

(*b*) *Ferry's Method.* — In the following modification by Ferry of Rowland's method this temperature can be obtained to a fair approximation by a simpler graphical construction.

Let C represent the temperature of the surroundings, and let a body at a temperature below these be given a quantity of heat H such that its temperature rises to a value above C. The way in which the temperature changes before the heat H is added is represented by the line AB in *Fig.* 7. The line BD shows how the temperature changes while the body is absorbing the heat H. From B to C the body is, in addition, receiving heat from the surroundings, and from C to D is losing heat to the surroundings. The line DE indicates the temperature changes due to radiation, etc., alone.

---

[1] "On the Mechanical Equivalent of Heat, with Subsidiary Researches on the Variation of the Mercurial from the Air Thermometer, and on the Variation of the Specific Heat of Water," *Proceedings of the American Academy of Arts and Sciences*, 1880, xv. 75-200; also *Physical Papers*, p. 402.

Through C draw a vertical line. Prolong ED backward until it cuts this vertical in *f*. Prolong AB forward till it cuts the vertical line in *h*. Then the temperature changes are given by *hf*.

To see that the above method of finding the desired temperature is reasonable, consider the following: If the heat H had not been given to the body, it would have continued to rise in temperature in the same way that it was rising from A to B, so that by the time it really attained the temperature indicated by C it would have reached the temperature indicated by *h*; that is, while the body really rose in temperature from B to C the rise in temperature from B to *h* was due to heat from the surroundings, and the rise from *h* to C was due to a part of the heat H. Again, if the body had not been given the heat H, but if it had been at first at such a temperature that as it cooled it reached the temperature indicated by D at the same instant that it really reached that temperature—and thereafter cooled as shown by DE—it would have been at a temperature *f* at the instant when it really was at the temperature C; that is, while the body really rose in temperature from C to D the fall in temperature due to radiation was the fall from *f* to D, so that if there had been no loss of heat by radiation the rise of temperature during this time would have been from C to *f*. If, then, there had been no gain or loss of heat by radiation the body would have risen in temperature the amount indicated by the distance from *h* to *f*.

While the temperature of the body rose from C to D it was really at a lower temperature than if it had been cooling from *f* to D, and so did not really lose as much heat by radiation as has above been supposed. Hence, the point *f* is higher than it ought to be. For a similar reason *h* is also somewhat higher than it ought to be. If the time from B to C is about the same as that from C to D, these two errors will nearly balance each other.

(iv.) *Adiabatic Methods.* — To eliminate entirely the necessity for correcting for the heat transfer between the calorimeter and its jacket, T. W. Richards[1] has devised various forms of calorimeters in which the bath surrounding the calorimeter is kept throughout the experiment at an equal or equivalent temperature. This device has been found to be particularly convenient in experiments on heat of dilution, heat of reaction, and recently it has been adapted for fuel calorimetry work. The precise method adopted for heating the jacket to keep it in step with the calorimeter varies. Richards has used the heat liberated by chemical reaction of the same character as that under test in the calorimeter. For most purposes, however, electrical heating is the more convenient. It is usually necessary to make a few blank experiments to settle the relative values of the current, so the method finds its greatest field of application when a large number of experiments have to be performed. Since the stirrer in the calorimeter generates an appreciable amount of heat, it is convenient to keep the temperature of the jacket at a temperature of a degree or so below that of the calorimeter, so that the residual heat loss just balances that generated by the stirring. Whilst the device cannot give greater absolute accuracy than that in which a stationary jacket temperature is employed, it has the advantage that the initial and final temperatures are stationary and hence more easily measurable with resistance thermometers than would be the case if the temperature were moving.

§ (8) Thermometer for measuring the Temperature Rise of the Water.—The most generally used instrument for the measurement of the temperature rise of the calorimeter is the mercury thermometer, but in work of precision the resistance thermometer is to be preferred.

Experience has shown that the inherent defects of the mercury thermometer limit the possible accuracy to 2 or 3 parts in 1000 for a 2° rise of temperature, while with a suitable resistance thermometer outfit ten times this accuracy may be obtained, but of course it necessitates an expensive equipment and more labour with the observations. For a discussion of calorimetric mercury thermometers reference should be made to the articles on "Thermometers" and "Resistance Thermometers" respectively.

§ (9) Appliances for heating or cooling the Charge. (i.) *Steam Heater.*—Regnault in his extended series of experiments used a steam-jacket heater to bring the charge to 100° before dropping it into the calorimeter. His form of heater consisted merely of a boiler with a tube containing the charge, and on inverting it the heated charge is dropped into the calorimeter. White has modified the Regnault heater to the form shown in *Fig.* 8 which is self-explanatory. He employs electrical heating, since then it is possible to move the apparatus about without danger of premature cooling. The apparatus is manipulated as follows: Just before discharging the temporary outlet is opened, the condenser and thermoelement removed, the opening stoppered, and lastly the heating chamber unstoppered and the charge dropped into the calorimeter. The object of the shallow cup below the chamber filled with condensed water is to shield the chamber against superheating. White points out that the usual practice of closing the upper end of steam heaters with corks is defective, since the ends are left comparatively cold, and consequently errors of the order of a few parts per 1000 may result.

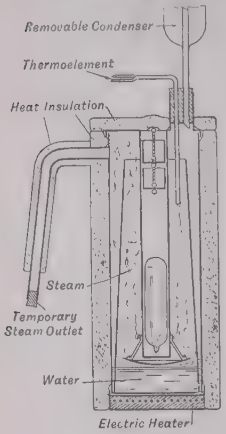

FIG. 8.

(ii.) *Electric Furnace.* — For heating the charge to high temperatures some form of electrical furnace is generally employed, as this permits of the attainment of temperatures up to 1500° C. It is, of course, necessary to ensure that the furnace should give a uniform temperature over the region occupied by the charge, and experience has shown that the simplest method of effecting this is to wind the tube uniformly, and over each end add additional coils capable of independent control; then, by adjusting the relative values of the current in the main circuit and the supplementary coils, a good degree of uniformity can be obtained. It might be remarked, however, that the ratio of the currents in the circuits which will give uniformity at one temperature may not necessarily apply to another, and consequently separate experiments are necessary to determine the best values for each point.

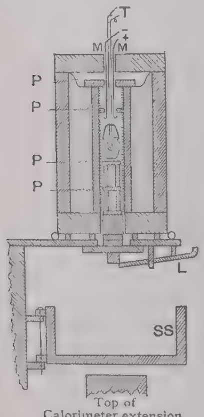

FIG. 9.—Arrangement of platinum-wound Furnace for Experiments between 500° and 1500° C.

P, partitions to shield against the cooling effect of the ends of the furnace; SS, swinging shield; L, latch for dropping out the furnace bottom; MM, heavy wires for the dropping current; T, thermoelement.

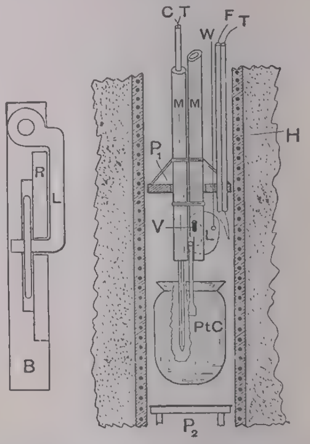

FIG. 10.—Apparatus of Marquardt Material and Platinum for automatically dropping the Platinum Container, PtC.

L, latch; V, its fulcrum; MM, tubes, about ·8 mm. in diameter; W, wire, whose pull unlatches the bail of the container; CT, charge thermoelement; FT, furnace thermoelement; P_1, P_2, shielding partitions; H, furnace winding. The platinum tube around CT in the container is supposed to be cut away. L is 2·3 mm. thick. MM were covered with sheet platinum, which was part of the equipotential shield.

In his work on the specific heat of silicates White employed a furnace with internal platinum winding. This has the advantage of permitting of the attainment of higher temperatures than is possible with a winding on the exterior of the tube, and also diminishes the lag between the coil and the chamber, so that equilibrium is obtained with greater rapidity. This furnace (*Fig.* 9) is mounted on a stout iron plate with an air space beneath. An opening of 5·5 cm. is cut through the furnace bottom and plate, which is closed by a plug of fireclay carried on a movable iron plate. This is held up against a large plate by the latch in such a way that a quick pull on the latch causes the plug to fall away without tipping. Upon the block and inside the furnace chamber is a pedestal made up of three fireclay partitions each faced on both sides, except on the side facing the crucible, with reflecting discs of platinum foil, and supported by a light frame made by grinding away as much as possible from the thin porcelain tube. This pedestal has two functions. It protects the crucible from the cooling effect of the furnace bottom and it also supports the crucible during the period necessary to reach the constant temperature. Platinum is very soft at high temperatures, and the fine wires which support the crucible for an interval of 1 second, which elapses between the fall of the crucible and the pedestal, would have to be very large if they were to hold for any length of time. At the higher temperatures the uppermost partition is apt to stick to the bottom of the crucible, hence it is tied by platinum wire to the plate below, the weight of which is enough to pull it away. Above the crucible another platinum partition is suspended. When the pedestal falls from the furnace it is caught in a light wooden box, which can be pushed out of the way, and at the same time switches off the furnace current.

The simplest method of supporting the charge in the furnace is to use a loop of platinum wire and fuse it by a strong current when it is desired to drop the charge into the calorimeter. This method was used successfully by Harker [1] in his experiments on the specific heat of iron.

White found some difficulty with the fused wire method of making a release at temperatures above 1000° C. owing to the arcing which occurred across the terminals after the wire was melted. This difficulty could no doubt have been overcome by making the current fuse a length of copper wire outside the furnace the same time as the supporting wire inside. He, however, devised a mechanical drop for releasing the charge. This was made of Marquart composition, which is obtainable in the form of tubes and plates. The complete arrangement is shown in *Fig.* 10. Stout platinum wire of 1·2 mm. in diameter was operated automatically to release the container as the wooden shield of the furnace was swung on one side. This was found to be generally satisfactory, but many troubles were encountered owing to insufficient rigidity of the supports, combined with a too rapid swing of the shield.

§ (10) THE SPECIFIC HEATS OF SILICATES AT HIGH TEMPERATURE. — With the above-described apparatus White [2] has made an extensive investigation of the heat capacity of various silicates at high temperatures. The data obtained are summarised in Table I., from which the "instantaneous" atomic heats have been calculated by the procedure described below:

TABLE I

[1] "The Specific Heat of Iron at High Temperatures," *Proc. Phys. Soc.* xix.; *Phil. Mag.*, Oct. 1905.

[2] "Silicate Specific Heats," second series, *Am. Journ. of Science*, Jan. 1919, xlvii.

For convenience the values are given as atomic heats, but can, of course, be readily converted back into specific heats by the use of the data given in Table III.

TABLE III

MEAN ATOMIC WEIGHTS, OR MOLECULAR WEIGHTS DIVIDED BY THE NUMBER OF ATOMS, USED AS MULTIPLIERS TO REDUCE SPECIFIC HEAT TO MEAN ATOMIC HEAT

Silica	20·1
Calcium metasilicate	23·27
Magnesium metasilicate	20·12
Diopside	21·70
Anorthite	21·45
Andesine	20·84
Natural albite	20 33
Natural microcline	21·23

The method of experiment gives the mean specific heat over a wide range of temperature and is not suitable for giving with accuracy the true specific heat, if this changes rapidly with temperature, as is the case at very low temperatures. At high temperature, however, the relation between specific and temperature is practically linear, hence it is possible to calculate the "instantaneous" or true specific heats with fair accuracy, as follows:

If the interval specific heat is sufficiently well expressed by polynomial equations with 5 constants, $A+B\theta+C\theta^2$, etc., where θ is centigrade temperature, the total heat from 0° C. up is $A\theta+B\theta^2+C\theta^3$, etc., and the true specific heat at any temperature, which is the differential of the total heat, is $A+2B\theta+3C\theta^2$, etc., so that the quantity which must be added to the mean specific heat to get the true heat is

$$B\theta+2C\theta^2+3D\theta^3+4E\theta^4.$$

But in a series of 4th-degree polynomials each first difference is

$$BP+2CP\theta+DP\left(3\theta^2+\frac{P^2}{4}\right)+EP(4\theta^3+\theta P^2);$$

each 3rd difference is $6DP^3+24EP^3\theta$, where P is the temperature interval between each two successive values in the series. It follows at once that by subtracting $\frac{1}{24}$ of the 3rd difference from the 1st, and then multiplying by θ/P, the difference of true and interval heats is obtained. The method is exactly equivalent to obtaining a series of 4th-degree equations and thus computing the true specific heat, but is much easier.

For quartz and silica glass the values of the *interval* specific heat to 100°, 300°, and 500° satisfy the expressions:

Quartz

$$0{\cdot}1685+0{\cdot}000194\theta-0{\cdot}00000011\theta^2.$$

Silica Glass

$$0{\cdot}1670+0{\cdot}0001890\theta-0{\cdot}000000125\theta^2.$$

§ (11) LOW TEMPERATURE APPLIANCES.—Nernst, Lindemann, and Koref[1] in their experiments at low temperatures cooled down the substance under test in a quartz vacuum vessel, through which passed a tube open at both ends, as shown in *Fig.* 11. This tube was surrounded by liquid air or a mixture of alcohol and solid CO_2. The device is operated as follows: As soon as the equilibrium of temperature has been obtained it is placed over the calorimeter. A slide is opened and the contents, suspended on a thread, are let down into the calorimeter.

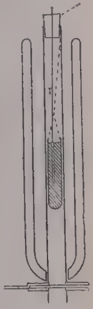

FIG. 11.

Instead of the expensive quartz vessel the following simple device may also be used (*Fig.* 12). In a large test tube A is placed a tube J, somewhat enlarged at the bottom and closed at both ends by means of rubber stoppers. Inside of it is a silver vessel, with the substance and the thermoelement suspended by a thread. The test tube is immersed in the constant temperature bath. The time required to obtain the equality of temperature may be shortened by passing through a slow current of dry hydrogen, which flows into the outer vessel through a small channel in the lower cork and then into the air through the cotton-wool. To bring the substance into the calorimeter the whole device is brought into the neighbourhood of the calorimeter, which is then opened. The inside tube J is rapidly removed from the test tube, the lower cork taken away, and the other one slightly lifted so as to allow the container to drop into the calorimeter. The whole manipulation takes about three seconds. In that time the substance is only slightly warmed up. With liquid air, for instance, it is claimed that the heat loss is hardly 1 per cent.

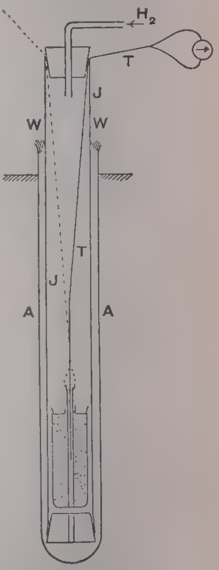

FIG. 12.

§ (12) THE THERMAL UNIT AND THE VARIATION OF THE SPECIFIC HEAT OF WATER WITH TEMPERATURE.—It is customary to express heat quantities in terms of the heat capacity of water for 1° change of temperature, and since this heat capacity is now known with accuracy in terms of the primary units—centimetre, gram, second—it is possible to express heat quantities in "ergs" by the use of an appropriate factor.

---

[1] Nernst, Lindemann, and Koref, *Königliche Preussische Akademie der Wissenschaften zu Berlin, Sitzungsberichte*, 1910; Koref, *Annalen der Physik*. 1911 (4), xxxvi. 49.

For a long time it was not fully realised that the specific heat of water varied with temperature, and consequently the practical heat unit varied with the range of temperature through which the water was heated when employed as calorimetric medium. Even when it became apparent that the specific heat could not be regarded as constant the data published as to the magnitude of the variation were so conflicting that the experimenters were compelled to neglect them in the reduction of their observations.

In later years the work of Rowlands (1879), Bartoli and Stracciati (1891), Griffiths (1893), Ludin (1896), Callendar and Barnes (1902), has proved conclusively that the form of the specific heat-temperature curve is that shown in *Fig.* 13, and that there is a minimum value at 35° to 40° C.

Hence the *calorie* is only fully defined when the particular degree (1° C.) of temperature is specified through which unit mass of water is heated. Professor E. H. Griffiths has pointed out that the calorie between 17° and 18° C. is equal to the mean calorie between 0° and 100°. So that the specific heat of water between 17° an 18° C. might be considered as a suitable unit for calorimetry.

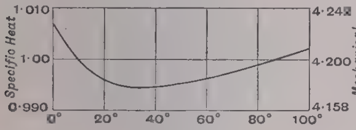

FIG. 13.

Callendar adopts 20° C., and suggests that the calorie be defined *not* as the heat required to raise one gram of water from 19·5° to 20·5°, but as the *mean* value between 15° and 25° of the quantity of heat required to raise one gram of water 1° C.

Whilst it would be a great convenience if experimenters would adopt a common unit, it is of greater importance that they should state the unit employed when the accuracy of their work is such as to justify taking into consideration the variation in the heat capacity of water.

§ (13) METALLIC BLOCK CALORIMETERS. (i.) *Nernst.*—A calorimeter in which the usual vessel of liquid is replaced by a heavy copper block has been employed by Nernst, Lindemann, and Koref for specific heat determinations. The block is hollowed out and the material dropped into its interior. Owing to the good thermal conductivity of copper it has practically the same temperature throughout, and the temperature changes of the block are determined by means of thermoelements. To obtain heat insulation the block is inserted into a Dewar vacuum vessel. The arrangement is shown in *Fig.* 14. The block K weighs about 400 grams. It is desirable to have good thermal contact between the copper block and the inner surface of the glass vessel which has to be made as thin as possible. To ensure this the block is fixed in the vacuum vessel by means of Wood's fusible alloy.

In the diagram T are the thermojunctions. The junctions of the thermoelements are inserted into thin-walled glass tubes which are fixed in holes in the block by means of fusible alloy. Good contacts between junctions and the tubes are also obtained by the use of alloy. The other junctions are in a ring-shaped copper block C by which the vacuum vessel is closed at the top. Through the middle of the block passes a glass tube R, through which the substance is dropped into the calorimeter. This tube can be closed by means of a slide as shown. The whole apparatus is submerged in a constant temperature bath, usually ice or solid CO_2, and the temperature thus maintained constant. To keep the apparatus water-tight a sheath of copper foil is soldered round as shown. To prevent the heated air from rising up in the calorimeter, which means a loss of heat after the substance has been dropped in, some cotton-wool is placed on the top of the silver vessel so as to just close the hole in a copper block after the material has been dropped in.

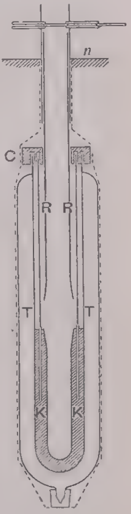

FIG. 14.

In their experiments the temperature changes of the calorimeter usually amounted to from 3° to 6°, giving a galvanometer deflection of 45 to 90 divisions. The apparatus must be calibrated by means of a substance whose specific heat is exactly known, and this was attained by using water for high, and lead for low, temperatures. The calibration had to be repeated from time to time in order to eliminate small errors.

(ii.) *Féry.*—Féry[1] has applied the metallic block method to the design of a bomb calorimeter and constructed a direct reading instrument. The bomb in which the combustion takes place is a nickel-lined, thick-walled vessel. It is supported by two discs of constantan, the disc being soldered to the bomb and also to the nickel-plated surrounding vessel B (*Fig.* 15). The constantan supporting disc forms with the iron of the bomb the hot junction of a thermocouple, the cold junction being made between the discs and the outer vessel B. The E.M.F. generated by the temperature of the bomb is measured by the millivolt calibrated to read direct in calories on the assumption that the same weight of fuel is always burnt.

---

[1] *Engineering*, Sept. 20, 1912; *Electrician*, Sept. 13, 1912.

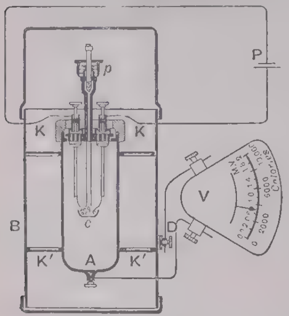

FIG. 15.

A, nickel-lined bomb of iron 3½ kilos. in weight; K, K′, two constantan discs soldered to bomb and to nickel-plated copper surrounding vessel B; C, quartz crucible.

The instrument has not yet been developed to a stage when it can be used for routine tests, several sources of error which influence the readings not having been eliminated. One important factor is the pressure of the oxygen in the bomb. Should the pressure be below that for which the instrument has been calibrated, combustion will become slower and heat loss due to radiation, etc., will be greater than that under normal conditions. A few typical curves illustrating this are shown in *Fig.* 16.

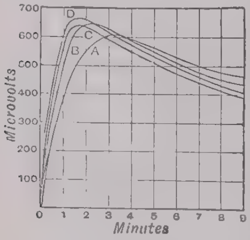

FIG. 16.

Curve A, pressure of gas = 100 lb. per sq. inch; curve B, pressure of gas = 150 lb. per sq. inch; curve C, pressure of gas = 200 lb. per sq. inch; curve D, pressure of gas = 250 lb. per sq. inch.

§ (14) SPECIFIC HEAT OF GASES BY THE "METHOD OF MIXTURES."—When defining the specific heat of a gas it is necessary to specify the conditions under which the heating takes place, since the change of volume with the rise of temperature is considerable under constant pressure, and the thermal equivalent of the external work done during expansion is a large fraction of the whole heat supplied during the change of temperature. Hence in the case of a gas it is customary to speak of two specific heats: (1) at constant volume, and (2) at constant pressure.

The earliest investigators to study the specific heat of gases were Lavoisier and La Place, who employed a calorimetric method based on the measurement of the quantity of ice melted. Later, Delaroche and Berard made some careful experiments in which a uniform current of gas, heated at 100° C., by passing through a tube surrounded by a vapour-jacket, was cooled by passing through a spiral contained in the calorimeter. The method was essentially that of mixtures, and most of the subsequent investigators adopted this method with various modifications to meet special requirements. Consequently, the published data are confined to the mean specific heat over a wide range of temperature. More recently Callendar and his associates have developed the method of electrical heating which permits of the determination of the *true* specific heat.

Amongst the workers employing the method of mixtures Regnault stands pre-eminent. He brought to bear upon the subject his unique skill and experience of calorimetric measurements, with the result that the data he obtained were accepted, almost without question, for the following half-century. There is, however, no doubt that the results given by Regnault were a little low, about 2·5 per cent, due to an inaccuracy in his method of determining the heat conducted into the calorimeter along the pipe through which the gas flowed. Without describing in detail Regnault's apparatus its essential features may be briefly reviewed.

The gas was contained in a large reservoir, heated up by passing through a long spiral immersed in an oil bath, and thence led to the calorimeter. Care was taken to ensure a uniformity of flow of gas through the calorimeter under constant pressure, and independent experiments were made to ensure that the gas leaving the calorimeter had cooled to this temperature. Since it was assumed that the temperature of the gas entering the calorimeter was the same as that of the heater bath, precautions have to be taken to avoid loss of heat by the gas in passing from the bath to the calorimeter, and at the same time prevent as far as possible conduction of heat from the bath to the calorimeter along the connecting tube.

The correction for the heat carried along this tube, which was made of low conductivity material, was deduced from observations of the change in temperature of the calorimeter without the gas flowing. This change of temperature is due to the combined effect of the conduction and the rate of heating or cooling of the calorimeter due to the difference in temperature between it and the surroundings.

If $\Delta\theta$ is the observed rate of change of temperature per unit time, then $\Delta\theta$ is equal to $A - B\theta$, where θ is the excess of the temperature of the calorimeter over that of the room.

The term A corresponds to the heat conducted through the connecting pipe from the heater to the calorimeter, and $B\theta$ to the heat loss by radiation, etc., from the calorimeter. Each of these terms corresponded to about 5 per cent of the total energy supplied by the gas per minute. Regnault measured the constant A and B by noting the rate of rise of temperature of the calorimeter before and after the gas had passed through it. Swann[1] has pointed out that an error arises in assuming that the heat conduction through the pipe is the same when gas is flowing as when no gas is flowing; in fact the hot gas keeps up the temperature of the pipe in the vicinity of the heater and reduces the temperature gradient. The result is that less heat is conducted from the heater into the pipe when the gas flows through than when no gas is flowing. Of course a great deal of heat is conducted by the pipe into the calorimeter when the gas is flowing, but the greater part of this comes from the gas itself. The fact that the average temperature of the pipe is higher when the gas is flowing also results in a greater radiation loss from the pipe. The error acts in the same direction as the other.

Swann made some experiments to verify the above suggestion, and by attaching thermo-junctions to a metallic tube he showed that the gradient was affected by the flow along it and the results were of the magnitude required to account for the difference between his results and those of Regnault.

In Regnault's time there was a lack of knowledge concerning the variation of the specific of water with temperature, which, together with uncertainty as to the absolute scale of temperature, might also cause an error of 1 per cent in his results.

§ (15) Variation of Specific Heat with Temperature and Pressure (over Moderate Ranges).—Regnault's observations cover the temperature interval from $-30°$ to $210°$ and pressures from 1 to 12 atmospheres. He found that the specific heat of the gases, air, oxygen, and hydrogen were independent both of the temperature and the pressure within the limits of the observations.

The specific heat of CO_2, on the other hand, showed a well-marked increase with rising temperature. Regnault's work was repeated by Wiedemann, who confirmed his results.

Witkowski investigated the specific heat of air at low temperatures from $+100°$ to $-170°$, and found that the specific heat was independent of the temperature but increased with pressure. He worked up to a maximum of 70 atmospheres. The variations with pressure increased as the temperature was lowered.

The method of mixtures is not suitable for the accurate determination of the pressure and temperature variation of the specific heat of a gas.

More recent work by observers employing the electrical method has supplied data which supersede those obtained in the above-described investigations.

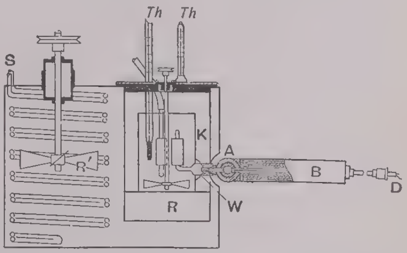

Fig. 17.

§ (16) Specific Heat of Gases at High Temperatures.[2]—Holborn and Austin,[3] and later Holborn and Henning,[4] have investigated the specific heat of gases up to 1200° C. Their method is identical in principle with that of Regnault's, but a special type of heater was necessary for bringing the gas to the high initial temperature. Their apparatus is shown diagrammatically in *Figs.* 17 and 18.

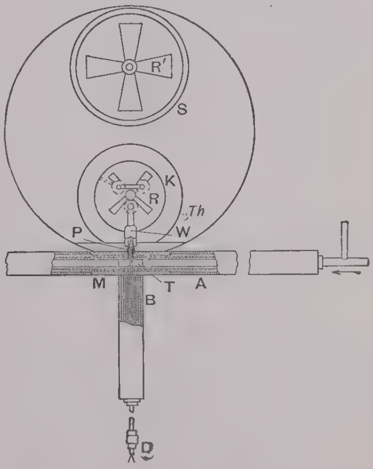

Fig. 18.

(i.) *Arrangement of Apparatus. The Heating Tube.*—The gas was heated electrically in a nickel tube A, about a metre long and of 1 mm. wall thickness, on which was wound a coil of nickel wire. The windings were insulated from the tube by asbestos. The gas was introduced at one end and was heated in the coarse nickel filings with which the tube was filled according to the plan of E. Wiedemann. At three-fourths of its length the tube was closed by a disc silver-soldered in place, and the gas was led out through a side tube into the calorimeter. In this way the influence of the cool end of the tube was eliminated. Otherwise it was found out that the gas in passing through the cool portion gave up so much of its heat that its temperature varied in a marked degree with the rate of flow.

[1] "Note on the Conduction of Heat along a Pipe through which Gas is flowing in its Relation to Measurements of the Specific Heat of Gases," *Phil. Mag.*, Jan. 1913.

[2] See also article "Gases, Specific Heat of, at High Temperatures."

[3] *Phys. Rev.* xxi. No. 4.

[4] *Ann. der Physik*, 1907, xxiii. 809.

Opposite the outlet tube W a second nickel tube B was joined to the heating tube and through this a platinum platinum-rhodium thermoelement T was introduced. This passed through the heating tube A, which at this point was kept free from nickel filings by the dividing wall M on one side and a disc of wire net on the other. The thermojunction lay in the outlet tube W, 1 cm. from its free end. In this space a thin silver band bent in the form of a screw was inserted to prevent radiation of the thermojunction to the cool calorimeter. The thermoelement consisted of wires 0·25 mm. in diameter, which were insulated through the greater part of the tube B with thin porcelain tubes. The hot junction of the thermoelement, which was hardly thicker than a single wire, was left bare.

Special care was taken that the end of the thermoelement should not come in contact with the tube wall. In one portion of the work this was attained by supporting the flexible end of the element on a bit of mica of the same width as the diameter of the tube.

The platinum band, which was intended for the protection of the thermoelement from radiation from the tube wall, also served to protect the quartz from the nickel oxide which was carried along with the gas current in minute quantities from the filings in the heating tube. Otherwise this after a time became opaque and disintegrated.

A secondary heating coil of nickel wire was placed on the tube B, to compensate for the loss of heat by conduction through the two side tubes and for the loss of one turn of wire on the main coil where the side tubes were attached.

(ii.) *The Calorimeter.*—The calorimeter K of about 0·5 litre capacity was made of pure silver 0·5 mm. thick (*Figs.* 17 and 18). In its centre were situated three silver tubes 1·5 cm. in diameter, filled with silver filings and connected by 0·5 cm. silver tubes. These absorbed the heat from the gas as it passed through. That the gas actually issued from the calorimeter at calorimetric temperature even when heated to the highest point (800°) was made certain by tests with a constantan copper thermoelement.

Later experiments by Holborn and Henning were made by a similar method with a platinum heating tube which extended the temperature range to 1400° C. The calorimeter necessarily gains some heat from the heating tube, and this gain, in the later experiments, was partly compensated by surrounding the calorimeter with a jacket maintained at a much lower temperature.

This compensation was found necessary at high temperature in order to prevent an excessively rapid rise of temperature of the calorimeter: but although it reduces the apparent magnitude of the correction required, it does not diminish the actual amount of heat transferred and does not reduce the uncertainty of the correction. The magnitude of the effect at high temperatures may be judged from the fact that it was found necessary, in the experiments at 1400° C., to maintain the jacket at as low a temperature as 40° C. by passing a stream of cooling water through it in order to prevent the calorimeter rising above 115° C. when no gas was passing. Under such conditions the calorimetric corrections become so uncertain that the probability of systematic errors must increase considerably with rise of temperature.

The rate of increase of the mean specific heat of nitrogen at atmospheric pressure between 840° and 1340° C., shown by the later experiments, was about double that found in the earlier series. Both series of experiments could be represented within the limits of probable error by the linear formula

$$S_{0t} = \cdot 2350(1 + \cdot 00008t).$$

It appears probable, however, that the value of the specific heat at 0° C. given by the formula is too low and that in the case of nitrogen the rate of increase is not uniform, but increases with rise of temperature to some extent.

(iii.) *Possible Sources of Error.*—Since the temperature of the hot gases was determined by a thermocouple near the entrance to the calorimeter, and the time of flow of the gas was only three minutes, there appears to be some doubt whether the couple gave the true mean temperature of the inflowing gas, and also whether the loss by radiation from the couple was properly corrected for. The value of the mean specific heat of air over the range 150° to 270° C. by Holborn and Henning was ·2315. This is about 5 per cent smaller than the probable value over this range. The rate of increase shown by the experiments was within the limits of probable accuracy of the work.

§ (17) Specific Heat of Steam.—Regnault's value, 0·475 for the specific heat of steam at atmospheric pressure over the range 125 to 225° C. was obtained by taking the difference between the total heats of steam, superheated to these temperatures, as observed by condensing the steam in a calorimeter. Since the difference, corresponding to 100° superheat, is only $\frac{1}{14}$th of the total heat measured in either case, it is evident that the method might give rise to large errors. For this reason many writers have preferred to deduce the specific heat of steam theoretically in various ways from Regnault's value of the rate of change of the total heat of saturated steam, namely, 0·305 cal. per 1° C., which, as Callendar[1] has pointed out, is subject to the same source of error in an aggravated form. Thus Zeuner gives $S=0{\cdot}568$; Perry, $S=0{\cdot}306$ at 0° C. to 0·464 at 210° C.: Grindley, 0·387 at 100° C. to 0·665 at 160° C.

A direct measurement of the specific heat of steam by Brinkworth,[2] employing the continuous electric method devised by Callendar, gave $S=0{\cdot}484$ at 108° C. Subsidiary experiments by Callendar in conjunction with Professor Nicolson, by the throttling calorimeter method, enabled the variation of the specific heat with pressure to be calculated. These gave the formula

$$S=0{\cdot}478+0{\cdot}0242p\left(\frac{373}{\theta}\right)^{3.3},$$

where p is the pressure in atmospheres. The approximate constancy of the limiting value 0·478 of the specific heat at zero pressure over the range 0 to 200° C. was verified by calculating the corresponding values of the saturation pressure, which were found to agree accurately with Regnault's observations over the whole range. The theory was also verified by a measurement of the ratio of the specific heats of steam by Makower,[3] which gave values 1·303 to 1·307, agreeing closely with that deduced by Callendar.

The experiments of Lorenz[4] and Knoblauch and Jacob and Linde[5] afforded a remarkable verification of the theory of the variation of the specific heat with pressure. They found the specific heat at 1 atmosphere to be practically constant over the range 100° to 300°, but their value, namely, 0·463, is decidedly lower than Regnault's.

Holborn and Henning[6] in their experiments on the specific heat of steam at atmospheric pressure, improved Regnault's method by employing an oil calorimeter at 110° C so as to avoid condensing the steam in the calorimeter. They determined the ratio of the specific heat of steam to that of air by passing currents of air and steam in succession through the apparatus under similar conditions, and obtained the following values of the ratio for different intervals of temperature:

Temperature Interval.	Ratio/Steam. Air.
110-270°	1·940
110-440	1·958
110-620	1·946
110-820	1·998

In their subsequent series with a platinum heating-tube at higher temperatures they obtained the following ratios:

Temperature Interval.	Ratio/Steam. Air.
115-826°	1·900
115-1180	1·973
115-1324	2·003

The second series appears to make the ratio about 5 per cent lower at 110-820° than the first, which suggests the possibility of constant errors depending on the type of apparatus employed or on the velocity of the gas current. The experiments of Callendar and Swann would make the ratio 2·05 at 100° C. This is higher than any of the values obtained by Holborn and Henning at 1400° C.

Holborn and Henning point out that their results at 1400° C. cannot be reconciled in the case of steam and CO_2 with any of the results of explosion methods. They are 6 per cent to 13 per cent lower than Langen's, which are among the lowest. But, having regard to the fact that the constant-pressure method which they employed appears to give results so much lower than Joly's or Callendar's methods at ordinary temperatures, and that the experimental difficulties increase so greatly at higher temperatures, it does not seem at all improbable that a considerable part of the discrepancy is to be attributed to systematic errors of the constant-pressure method.

§ (18) SPECIFIC HEAT OF CO_2.—The specific heat of CO_2 is of great theoretical interest in view of the considerable increase shown at ordinary temperatures. The table below gives the results obtained by various observers:

Temperature.	Regnault.	Wiedemann.	Swann.	Holborn.
0°	0·1870	0·1952	0·1973	0·2028
100	0·2145	0·2169	0·2213	0·2161
Increase	0·0275	0·0217	0·0240	0·0133

It may also be remarked that the variation of specific heat with density observed by Joly[7] agrees very closely with that calculated by Callendar[8] from the experiments of Joule and Thomson on the cooling effect on expansion.

CALORIMETRY, QUANTUM THEORY

THE VARIATION OF SPECIFIC HEAT WITH TEMPERATURE

§ (1) **THE VARIATION OF ATOMIC HEAT.**—The discovery by Dulong and Petit in 1819 of the empirical law, that the product of the atomic weight and the specific heat is approximately the same for all elements, proved to be of the greatest practical utility to chemists when assigning atomic weight values to newly discovered elements; and further, the simplicity of the law directed attention to the possibility of arriving at it from theoretical considerations of conceivable atomic structures constituting a solid. The mean value for the constant was determined by Regnault as 6·38 with extremes of 6·76 and 5·7. According to the kinetic theory of matter it is easy to see why a relationship of the form discovered by Dulong and Petit should exist. We suppose that the atoms are bound together by interatomic forces tending to bring them to positions of equilibrium about which they oscillate; then in this case the total energy of an atom is half-potential and half-kinetic; for the principle of equipartition of energy is assumed to be valid. Now in the case of a monatomic gas the energy is all kinetic, and proportional to the absolute temperature. Therefore the atomic heat should be half as great in the gaseous state as the solid state. The kinetic energy of a gramme molecule of a monatomic gas is $\frac{3}{2}$RT, where R is the gas constant which has the value 1·985. Hence, on the supposition that a monatomic solid body is built up of atoms each with 3 degrees of freedom, the energy content is 3RT, and from this the atomic heat at constant volume is obtained by differentiation with respect to T giving for the atomic specific heat the value 3R or 5·955.

It might be remarked in passing that the above equation, according to Boltzmann, is applicable to the case of crystals which have at the points of their space-lattice molecules of any degree of complexity, provided that the internal forces acting on each atom are proportional to the distance of the latter from its equilibrium position, or more generally are linear functions of the change of its co-ordinates.

Hence the Dulong and Petit generalisation is consistent with the atomic theory of matter and the equipartition theory of energy.

For nearly a century, however, the exceptions to the law—carbon, boron, and silicon—proved to be an enigma which defied solution. As far back as 1872 Dewar[1] and Weber,[2] working independently, showed that as the temperature increased the specific heat of carbon, whether as diamond or as graphite, continued to increase. Weber concluded that the specific heat of diamond is tripled when the temperature is raised from 0° to 200°.

Dewar's experiments showed the specific heat of carbon between 30° C. and the boiling-point of zinc (918° C.) was 0·32.

Some three years later Weber[3] published results of further experiments, and proved that from 600° C. upwards the specific heat of carbon ceased to vary with increase of temperature and became comparable with that of other elements. Further, the difference between the specific heat of different modifications disappeared. By plotting his results Weber showed that the specific heat temperature curve was of the form of an old English ʃ. He found a point of inflection for diamond at about 60° C., and that for graphite 0° C.

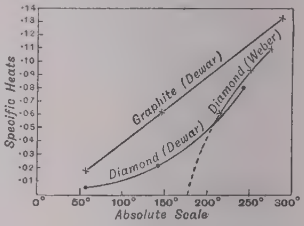

FIG. 1.

Recent researches have shown that the curve obtained by Weber is typical of all materials when the range of temperature investigated is sufficiently large.

By his development of the technique of low temperature research Dewar was able to pursue the subject to still lower temperatures, and the results for carbon obtained up to 1912 are shown graphically in *Fig.* 1. More recent research by various investigators employing the electrical method has shown that the general form of the atomic heat temperature curve closely resembles the curve of magnetisation of a ferromagnetic substance under a steadily increasing magnetic force, with its very gradual beginning, its subsequent rapid rise, and its final asymptotic approach to a limiting value. A few typical curves are shown in *Fig.* 2, the C_v curve being obtained by calculation from C_p and the value of $C_p - C_v$.

§ (2) THE QUANTUM THEORY EXPLANATION.—No satisfactory explanation of these facts was forthcoming until the development of the Quantum theory and its application to the problem of specific heat by Einstein,[1] Nernst and Lindemann,[2] Debye,[3] and others.

These physicists developed formulae connecting the specific heat of a solid at constant volume with the gas constant R, the quantum constant h, the frequency ν, and the absolute temperature T. Debye's formula involves a quantity ν_m, the maximum value of the frequency which can occur.

In the formulae quoted below β is written for the quantity h/R.

For further details reference should be made to the article "Quantum," Vol. IV.

The specific heat formulae found are

$$\mathrm{C}_v=3\mathrm{R}\left(\frac{\beta\nu}{\mathrm{T}}\right)^2\frac{\epsilon^{\beta\nu/\mathrm{T}}}{(\epsilon^{\beta\nu/\mathrm{T}}-1)^2}, \quad . \quad (\mathrm{E.})^4$$

$$\mathrm{C}_v=\frac{3\mathrm{R}}{2}\left[\frac{(\beta\nu/\mathrm{T})^2\epsilon^{\beta\nu/\mathrm{T}}}{(\epsilon^{\beta\nu/\mathrm{T}}-1)^2}+\frac{(\beta\nu/2\mathrm{T})^2\epsilon^{\beta\nu/2\mathrm{T}}}{(\epsilon^{\beta\nu/2\mathrm{T}}-1)^2}\right](\mathrm{N.\&L.}),$$

$$\mathrm{C}_v=3\mathrm{R}\left[\frac{4\pi^4}{5}\left(\frac{\mathrm{T}}{\beta\nu}\right)^3-\frac{3\beta\nu/\mathrm{T}}{\epsilon^{\beta\nu/\mathrm{T}}-1}\right.$$
$$-12\frac{\beta\nu}{\mathrm{T}}\sum_{n=1}^{n=\infty}\epsilon^{-n\beta\nu/\mathrm{T}}\left(\frac{1}{n\beta\nu/\mathrm{T}}+\frac{3}{n^2(\beta\nu/\mathrm{T})^2}\right.$$
$$\left.\left.+\frac{6}{n^3(\beta\nu/\mathrm{T})^3}+\frac{6}{n^4(\beta\nu/\mathrm{T})^4}\right)\right]. \quad (\mathrm{D.})$$

In the last expression ν is written for ν_m for simplicity.

Specific heat is measured at constant pressure. Thus to compare with the theory the experimental results need correcting by means of the formula

$$\mathrm{C}_p-\mathrm{C}_v=\frac{wa^2e\mathrm{T}}{\rho},$$

where a is the coefficient of cubical expansion, e the coefficient of volumetric elasticity, w the atomic weight, ρ being the density.[5]

§ (3) EXPERIMENTAL TEST OF FORMULAE.—E. H. Griffiths and Ezer Griffiths[6] tested the above formulae by means of their experimental data for the metals over the range 120° C. abs. to 400° C. abs.

They found that no one of the formulae was capable of representing exactly the experimental results over the entire range of temperature, even when the values of ν were chosen so as to bring the calculated values of the atomic heat into coincidence with the experimental values at one temperature (about 125° C. abs.).

The results are given in Table I.

TABLE I

COMPARISON OF THE EXPERIMENTAL RESULTS WITH THE FORMULAE OF EINSTEIN, NERNST AND LINDEMANN, AND DEBYE

Column I.—T, absolute temperature.

Column II.—C_p, from the smoothed curves through experimental points.

Column III.—C_p, calculated value from Einstein's formula (E.).

Column IV.—C_p, calculated value from Nernst and Lindemann's formula (N. and L.).

Column V.—C_p, calculated value from Debye's formula (D.).

The values of $\beta\nu$ are given at the top of the columns.

Note.—C_v was obtained by calculation from the formulae and the calculated value of C_p-C_v added.

It will be observed that, generally, near the boiling-point of liquid hydrogen, about 30° abs., Einstein's formula gives values which are too low; from Nernst and Lindemann's the values are too high; while Debye's formula gives values which are in fair agreement for Al, Ag, Zn, and Pb, and, in the case of other metals, it agrees with the experimental values better than either Einstein's or Nernst and Lindemann's. At liquid air temperatures all three formulae give values which are too high.

It is of but little use to calculate the appropriate values of ν from the elastic constants of the metals, since these constants are considerably influenced by the nature of the previous heat treatment and of the temperature. But it might be remarked that the values calculated from the elastic constants are in accordance with those required by the atomic heat results as shown by the data in Table II.

TABLE II

COMPARISON OF FREQUENCIES OBTAINED BY CALCULATION FROM THE PHYSICAL CONSTANTS WITH THE VALUES ASSUMED IN DEBYE'S FORMULA.

Frequencies $\times 10^{-12}$

Metal.	Al.	Fe.	Cu.	Ag.	Cd.	Pb.
ν_m (atomic heat) . .	8·2	8·0	6·7	4·5	3·5	1·9
$_m$ (elastic constants)	8·3	9·7	6·8	4·4	3·5	1·5

The above comparison of the frequencies shows that the values obtained from the specific heat equations are in fair agreement with those calculated from the elastic constants.

§ (4) APPLICATION OF DEBYE'S AND EINSTEIN'S FORMULAE TO THE NON-METALS.—Pure metals afford the most reliable data for testing heat theories, but comparisons with the available experimental data for complex substances such as crystalline salts (NaCl, KCl, KBr, AgCl) and diamond are of great theoretical interest.

One difficulty in making such comparisons is uncertainty in the value of C_p-C_v owing to the lack of data concerning the elastic constants. As data were not available for calculating C_p-C_v from the thermodynamical relationship,

$$C_p-C_v=\frac{wa^2eT}{\rho},$$

Nernst and Lindemann [1] obtained approximate values for C_p-C_v by a different procedure.

They based their method of calculation on Gruneisen's observation that the coefficient of expansion is proportional to the atomic heat, and obtained the approximate relationship

---

[1] *La Théorie du rayonnement et les quanta*, 1912, p. 265.

$$C_p - C_v = C_p^2TA,$$

where A is a constant characteristic of the substance which can be deduced from measurements of the compressibility and coefficient of expansion made at one temperature.

It is possible to test the validity of this formulae by comparing the data obtained from it with those given by the thermodynamical equation in the case of the metals Al, Ag, Pb, and Cu (see Table III.).

Nernst tested the formulae of Nernst and Lindemann and of Debye on the data for diamond, and Table IV. summarises the comparison.

It will be observed that Debye's formula gives an approximate representation of the experimental results. The Nernst and Lindemann formula gives values which are too low between 88° and 92° abs. In the case of Debye's the differences exceed the probable error of experiment, the general trend being for Debye's formula to give values which are too large at low temperatures and too small at high temperatures. In fact the decrease of atomic heat with decreasing temperature is more rapid than that given by Debye's formula. Ewald made experiments on the mean atomic heat of diamond between 83·8° and 194·0° abs. and found the value 0·2119, so that the total energy difference between these temperatures is 23·35 calories; the value calculated from Debye's formula is 25·34. Koref, employing the copper calorimeter described in "Calorimetry, Electrical Methods," § (13), found the mean atomic heat of diamond between 193·8° and 270·0° to be 0·864, corresponding to an energy difference of 65·8. Debye's formula gives 61·9 calories for this interval.

Polyatomic Substances.—The metals and diamond are regarded as monatomic structures, whilst the molecules of graphite and sulphur appear to be compounds of several atoms since the atomic heat curve is for these much less abruptly curved towards the temperature axis.

Nernst[1] has attempted to apply the formulae of Debye and Einstein to polyatomic substances such as KCl, NaCl, etc. He assumes the heat vibration to be of two types: first, the vibration of the molecules as a whole in exactly the same way as the atoms of a monatomic body; and, second, the vibration of each atom about its position of rest. The vibrations of the atoms are interpreted as giving rise to the "Reststrahlen" discovered by Rubens. Since at low temperatures the vibrations of the atoms become much more regular, and accordingly the absorption bands narrower and more pronounced, it is assumed that Einstein's function applies to the atomic vibrations.

Hence for the representation of the atomic heat of the salts the expression is

$$2C_v = F_1\left(\frac{\beta\nu_1}{T}\right) + F_2\left(\frac{\beta\nu_2}{T}\right),$$

in which F_1, F_2 are the functions of Debye and Einstein respectively, ν_1 the frequency calculated from the melting-point,[2] and ν_2 that found by Rubens by means of the optical method, since these salts show one very sharp infra-red absorption band.

For details of the comparison with experiment, reference should be made to the original papers already referred to. E. G.

CALORY OR CALORIE:

The 15°.—The quantity of heat required to raise one gramme of water through 1° C. at 15° C. See "Thermodynamics," § (2); "Heat, Mechanical Equivalent of," § (9).

The 17°·5.—For some purposes the range from 15° C. to 20° C. is taken and the calorie defined at 17°·5.

Gramme.—One-hundredth part of the heat required to warm one gramme of water from the melting-point to the boiling-point at a pressure of one atmosphere. See also "Thermodynamics," § (2); "Heat, Mechanical Equivalent of," § (9).

Pound.—A British unit of heat, being one-hundredth of the amount of heat required to raise one pound of water from the melting-point to the boiling-point at one atmosphere. See also "Thermodynamics," § (2).

CATHODE RAY MANOMETER

SIR J. J. THOMSON suggested the use of Piezo Electricity[1] as a means of measuring sudden pressures, and the method has recently been worked out by Dr. D. A. Keys.[2] Crystals of tourmaline are exposed to the action of the pressure and the electrical charge acquired, which is proportional to the pressure, is measured by a special form of cathode ray oscillograph.

The amount of the charge is measured by the deflexion of a beam of cathode rays which passes between two parallel condenser plates which receive the charge separated on the tourmaline crystals.

The beam is also deflected in a direction at right angles to this electrostatic deflexion by a magnetic field applied parallel to the electrostatic field by means of an alternating current of known frequency, giving a time displacement, perpendicular to the electrostatic displacement. The beam falls on a photographic plate, thus a charge time record is obtained, and since the charge is proportional to the pressure this is equivalent to a pressure time record. The advantage of the method lies in the fact that the inertia of the moving part of the recorder, the beam of cathode rays, is negligible.

The apparatus consists of two parts: (1) the pressure vessel, and (2) the cathode ray oscillograph.

The pressure vessel is shown in *Fig.* 1. It consisted in Dr. Keys' experiments of a brass vessel AB, about 6 in. in diameter and $1\frac{1}{2}$ in. deep closed by a $\frac{1}{2}$-in. steel plate HK, held down by 12 bolts. The walls of the vessel were $\frac{1}{4}$ in. thick. A sparking plug L and a tap N are fitted in the steel cover. DE is a thin lead plate electrically connected to a copper wire which passes through an insulating plug G in the side of the vessel.

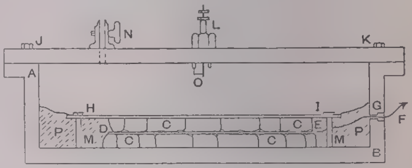

FIG. 1.

Half of the tourmaline crystals, about 1 cm. in thickness, are attached by a little wax to the bottom of the vessel, the other half are attached similarly to a steel plate HI. The lead plate DE separates these two sets of crystals, which are so arranged that all the positive faces are in contact with the lead plate. There are 5 or 6 crystals in each layer, the area of each crystal being about 12 sq. cm. HI is fixed by steel screws to the bottom of the vessel. The lower part of the vessel is filled with vaseline to delay the transfer to the crystals of the heat generated by the explosion.

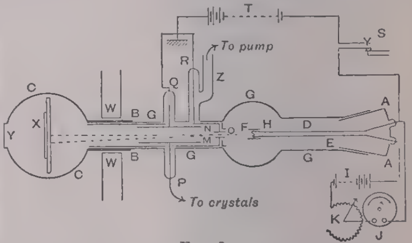

FIG. 2.

When pressure is applied above HI, DE becomes positively charged and the amount of the charge is proportional to the pressure.[3]

The insulated wire EGF conveys the charge to the condenser of the oscillograph. This is shown in *Fig.* 2. The cathode rays are generated by the fine tungsten filament F, which is heated to incandescence by an 8-volt accumulator. The cathode ray tube GG is cemented into a brass sleeve BB which is soldered into a brass cylinder CC—the axis of this cylinder is at right angles to the paper. The rays enter the sleeve BB through a small hole O, pass between the plates MN of a condenser and then between the poles WW of the electromagnet and fall on a photographic plate X in the cylinder CC. The plate slides in a rectangular box within the cylinder and can be moved from outside.[1] A window Y in the cylinder CC closed by a screen of willemite allows visual observations to be made when the plate is drawn aside and thus facilitates adjustment. The electromagnet is excited by an alternating current of known frequency, thus the time scale is fixed. LL is a brass guard tube $\frac{3}{4}$ in. in diameter. This guard tube and one of the condenser plates N are connected to earth and to one pole of a direct current generator supplying a constant potential difference of from 3000 to 5000 volts. The other pole of the generator is connected through a special double-action key S to the tungsten filament; the key also serves to fire the explosive mixture. The second plate M of the condenser is connected to the lead plate of the pressure apparatus. On depressing the key S the cathode potential supplied by the direct current generator is first communicated to the tube; a further motion of the key detonates the charge. The cathode rays are deviated in a direction at right angles to the paper by the magnetic field, and until the charge is fired trace a short vertical line on the photographic plate. The electrification of the condenser plate M due to the pressure produces a deflexion of the rays in the plane of the paper and thus the time-pressure curve is traced on the plate. The displacement of the spot depends on (1) the cathode potential and (2) the potential difference produced by the charge between the plates of the condenser MN; the apparatus requires calibrating for these. For the method of doing this reference should be made to Dr. Keys' paper.

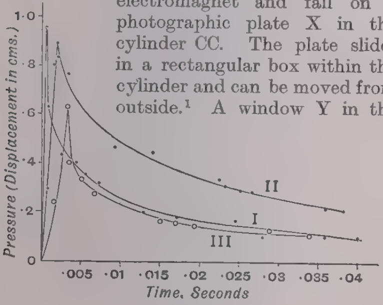

FIG. 3.

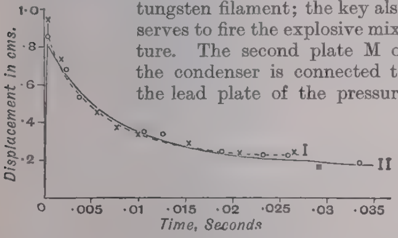

FIG. 4.

Figs. 3, 4, 5, 6, taken by permission from his paper, give the results of some of his experiments; the effect of the addition of air in slowing down the explosion of H_2 and O shown in *Fig.* 3 is very marked. With no air (curve I.) the maximum pressure of about 220 lbs. per sq. in. is reached in less than 0·0002 seconds. With some 60 per cent of air in the mixture (curve III.) the maximum pressure is reduced to less than 60 per cent of its former value and the rise continues for about 0·003 seconds, or some fifteen times as long as previously.

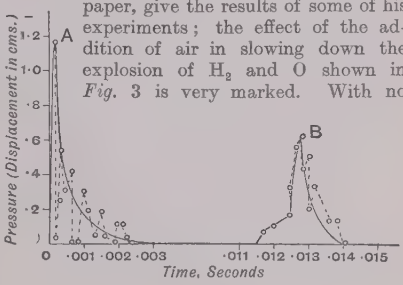

FIG. 5.

The curve A, *Fig.* 5, is a time-pressure curve for the explosion of gun-cotton under sea water; it gives the direct wave, while curve B is due to the wave reflected from the bottom. Again in *Fig.* 6, the effect of altering the distance of the charge from the pressure vessel is shown.

COAL CALORIMETER

Various forms of apparatus have been devised for determining the calorific value of coal. In practically all the selected sample of coal is burned in oxygen; the products of combustion are passed into a known quantity of water at a known temperature, and the rise of temperature is measured.

Fig. 1 is an illustration of the Rosenhain calorimeter as manufactured by the Cambridge and Paul Instrument Company. The instrument consists of two parts, the calorimeter proper containing the water and the combustion chamber in which the sample is burned.

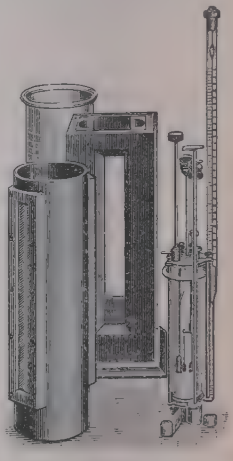

Fig. 1.

The combustion chamber is formed of a glass lamp chimney closed at the top and bottom by metal clamping plates, separated from the glass by rubber washers and held together by clamping screws on three uprights fixed to the lower plate; the wires connected to the electric ignition arrangement pass through the upper plate and also a tube for the supply of oxygen. The whole chamber is immersed in the water of the calorimeter. An aperture in the plate is closed by a ball valve through which the products of combustion can issue into the water, but which prevents the entry of water into the combustion chamber. On the completion of the experiment the valve is raised, allowing some water to enter; this is afterwards forced out by the oxygen and mixed with the rest of the water, thus ensuring that the calorimeter and its contents are brought to one temperature. To reduce the radiation losses the whole instrument is placed within a wooden case with a glass window in one side.

Oxygen from a supply at suitable pressure is passed through a coil of metal piping to bring it to the temperature of the room and then through a wash bottle fitted with a thermometer; from this it enters the ignition chamber; the temperature of the water is read and the coal ignited by connecting the ignition device to a four-volt accumulator; when the ignition is complete the chamber is washed out and the temperature again read. A knowledge of the water equivalent of the calorimeter is required, and this is most easily obtained by carrying out an experiment with a sample of known calorific value; if the temperature range during this experiment is approximately the same as that which occurs in the ordinary use of the instrument, the correction for radiation will be also covered. For accurate work the radiation correction can be found in the manner described in the article on "Fuel Calorimetry."

Coefficient of Performance of a Refrigerating Machine is the ratio of the heat taken in from the cold body to the work spent in the compressor (in heat units). See "Refrigeration," § (3).

Coefficients, Pressure- and Volume-, of Gases. The constant $(p_{100} - p_0)/100p_0 = 1/T_0$ is the "pressure-coefficient" of a gas at the initial pressure stated.

The constant $(v_{100} - v_0)/100v_0 = 1/T_0'$ is the "volume-coefficient" of a gas at the pressure stated. See "Temperature, Realisation of Absolute Scale of," § (18).

DYNAMICAL SIMILARITY, THE PRINCIPLES OF

I. General Principles

§ (1) **General.**—Scientific research concerns itself with the discovery and expressions of laws as exact relations between physical quantities of different kinds. Involved in the expression for the magnitude of any such quantity are two conceptions—the nature or kind of unit in terms of which it is represented, and the magnitude or number of times the unit occurs in the physical quantity considered. Thus, in the statement that the earth's diameter is 8000 miles, there is implied the nature of the fundamental unit (mile) in terms of which the diameter is measured, and the number (8000) of these units which are present in the physical quantity. If the whole function of scientific research consisted in a comparison of quantities of the same kind then the desiderata in the selection of a unit could be easily defined, and would merely involve such considerations as definiteness, non-susceptibility to secular change, and capability of accurate comparison with the quantities to be expressed in terms of it. Since, however, research in its wider sweep investigates and expresses relations between quantities of such different kinds as forces, temperatures, magnetic moments, etc., it follows that, for simplicity and clearness, not merely must these units be selected to satisfy the above requirements, but only such units must be accepted as express all the quantities concerned in the simplest manner possible in terms of the minimum number of independent units.

§ (2) Space Units.—For mere geometrical relations which are expressions of space truths involving lengths, areas, and volumes, it is clear that only one independent unit is required, which, apart from convenience and form, may arbitrarily be selected as the unit of length, of area, or of volume. If, for example, V, the unit of volume, be taken as the standard dimension, then since the product of three lengths provides a volume, the dimensions of length would be $V^{\frac{1}{3}}$, and that of area $V^{\frac{2}{3}}$. It is obvious that the clearest and, to us, the simplest expressions will be obtained by choosing as our standard unit a length L, giving as dimensions of area L^2 and volume L^3.

§ (3) Kinematic Units.—Passing to laws involving kinematic considerations it becomes at once clear that a new unit must be introduced to provide a measure of motion, a change in length with time; and once more the simplest mode of representation is arrived at by choosing, not a unit for speed or acceleration, and hence expressing the fundamental idea of time in a more or less complicated form, but by selecting a unit for time, say T. Speeds and accelerations are then at once seen to have the dimensions L/T and L/T^2 respectively.

§ (4) Dynamical Units.—But the two units of length and time are not in themselves sufficient to specify quantities which arise immediately we enter the domain of dynamics. At the basis of this section of analysis lies the fundamental idea of force and its representations in terms of mass and acceleration. Before a full expression for the dimensions of dynamical quantities can therefore be set out, either a new unit of force must be introduced in terms of which, by Newton's Second Law, the dimension of mass could be expressed, or a unit of mass must be presumed and the dimensions of dynamical quantities derived from it. Once more for reasons of simplicity we choose the latter. Accordingly, writing M as the dimension of the mass unit, the following table of quantities and their dimensional representation may be drawn up:

Quantity.	Dimension.	Quantity.	Dimension.
Length	L	Force	MLT^{-2}
Time	T	Kinetic energy	ML^2T^{-2}
Mass	M	Impulse	MLT^{-1}
Linear speed	LT^{-1}	Work	ML^2T^{-2}
Angular speed	T^{-1}	Moment of force	ML^2T^{-2}
Acceleration	LT^{-2}	Moment of Inertia	ML^2
Momentum	MLT^{-1}	Density	ML^{-3}

§ (5) Homogeneity of Dimensions in a Physical Equation.—Since the mathematical formulation of any physical law is a statement of equality or relationship between physical quantities necessarily of like nature, since indeed a force cannot be added to a mass but only to another force, nor a temperature equated to an electric charge but only to another temperature, it follows that all the terms in any equation having a physical significance must necessarily have identical dimensions. In the expression for the velocity acquired by a particle *in vacuo* dropped from rest under gravity, for example,

$$v^2 = 2gh,$$

the dimensions of the left-hand side are

$$(LT^{-1})^2 = L^2T^{-2},$$

while on the right-hand side they are

$$LT^{-2} \times L = L^2T^{-2},$$

the constant being of course non-dimensional. This fundamental principle serves not merely as a check on the intelligibility of any formula derived either on experimental or on theoretical grounds, but can be turned to much greater advantage by providing *a priori* information regarding the form which the result of any investigation ought to take. It will become apparent as the subject develops that there exists here a potent weapon for a preliminary analysis of any proposed problem. Particularly is this true in the realms of physics and engineering.

The method that may be adopted will become apparent from a few simple dynamical illustrations. Let us assume that the time of oscillation of a pendulum *in vacuo* is the problem for analysis, in order to determine how the period depends on the length of the suspension, the mass of the pendulum bob, and the value of gravity. Without a preliminary analysis along the present lines, and failing a complete mathematical investigation, it would appear at first sight that a complete experimental study of the problem would involve a threefold series of experiments corresponding to variations in length of suspension, mass of bob, and gravity. Consider the physical factors upon which the period might possibly be dependent. They are, mass of bob m, length of suspension l, value of gravity g, the form of attachment possibly, and the shape of the bob. The last two factors may or may not enter, but in any case it is not clear how they can be directly introduced by any single convenient symbol. Let us assume then that in all the experiments these are invariant, and therefore from our *a priori* knowledge we affirm

$$t = f(m, l, g),$$

where f represents the function which requires determination. Let us suppose this expanded in a power series in m, l, and g, so that $t = \Sigma A m^x l^y g^z$, where the terms A are constants independent of m, l, and g and functions only of the shape of the bob. This much, however, we can affirm, that each term in the expression must of necessity represent a quantity of the nature of time, and must therefore have the same dimensions as t.

Now the dimensions of

$$m^x l^y g^z \text{ are } \mathrm{M}^x\mathrm{L}^y(\mathrm{LT}^{-2})^z = \mathrm{M}^x\mathrm{L}^{y+z}\mathrm{T}^{-2z},$$

and equating these to the dimensions of t we find

$$x=0, \quad y+z=0, \quad -2z=1,$$
$$\therefore x=0, \qquad y=\tfrac{1}{2}, \qquad z=-\tfrac{1}{2}.$$

Hence

$$t=\Sigma \mathrm{A} m^0 l^{\frac{1}{2}} g^{-\frac{1}{2}} = c\sqrt{\left(\frac{l}{g}\right)},$$

where c is some unknown constant. A preliminary analysis of the problem has now reduced the necessity for a threefold set of experiments to one experiment, and one only, to determine the value of c. We have shown in fact that there are not in reality three variables m, l, and g in the problem, but one single variable $t\sqrt{(g/l)}$ which groups together a whole system of experiments as essentially of the same type. What then is the common principle that runs through the problems of the times of oscillations of pendula of different lengths under different values of g, that it should be possible to group them together? What is the physical or dynamical significance of this grouping?

§ (6) DYNAMICAL SIMILARITY.—In the foregoing analysis we might equally well have taken t to represent the time taken for the pendulum to swing out to a given angle α, then $t=c\sqrt{(l/g)}$, where c is now constant, when α is constant. It follows at once that if two pendula of lengths l_1 and l_2, at different points on the earth's surface such that gravity is g_1 and g_2 respectively, are allowed to swing, then at all times t_1 and t_2 such that $t_1\sqrt{(g_1/l_1)}=t_2\sqrt{(g_2/l_2)}$, the pendula will be displaced by equal angles. A series of photographs on plates of the same size taken of all such pendula at any such series of corresponding times will be identical. The geometrical configuration for all such corresponding times are similar. Systems in motion which can thus be grouped together quite generally as passing through geometrically identical phases for equal values of a non-dimensional grouping of corresponding quantities—in the above case for equal values evidently of $t\sqrt{(g/l)}$—are said to possess dynamical similarity.

§ (7) APPLICATION TO PARTICLE DYNAMICS.—Consider a further example from particle dynamics. A particle of unit mass is projected with velocity V in a field of force such that the acceleration at any point (x, y) is $\mathrm{A}(x, y)$, what information relative to the distance traversed after any time is supplied by the method of dimensions? For this purpose let us write $\mathrm{A}(x, y)=a\,.\,\alpha(x, y)$, where a is the actual acceleration at some special point, say the point of projection and $\alpha(x, y)$ is the function giving, as it were, the law of distribution of acceleration. Under these circumstances since both $\mathrm{A}(x, y)$ and a are accelerations, $\alpha(x, y)$ must be of zero dimensions. Restricting ourselves then to a series of problems for which this law of distribution remains unchanged although the magnitude of the acceleration at any point may vary—*i.e.* the function α remains unaffected, but a varies from problem to problem—we may say that S, the distance traversed after any time t, is a function of V, the velocity of projection, a the measure of the acceleration, and t the time, *i.e.*

$$\mathrm{S}=f(\mathrm{V}, a, t).$$

Writing as before

$$\mathrm{S}=\Sigma \mathrm{A}\mathrm{V}^x a^y t^z,$$

and equating dimensions, we find

$$(\mathrm{L}) \qquad 1=x+y; \qquad \therefore x=1-y,$$
$$(\mathrm{T}) \qquad 0=x+2y-z, \quad \therefore z=1+y,$$
$$\therefore \mathrm{S}=\Sigma \mathrm{A}\mathrm{V}^{1-y}a^y t^{1+y}=\mathrm{V}t\,.\,\Sigma \mathrm{A}\left(\frac{at}{\mathrm{V}}\right)^y.$$

Since y is quite arbitrary and may have any value whatsoever while still satisfying the dimensional conditions, this implies that

$$\mathrm{S}=\mathrm{V}t\,.\,\mathrm{F}\left(\frac{at}{\mathrm{V}}\right),$$

where F represents an arbitrary function. The particular case of constant acceleration along the direction of motion giving the well-known formula

$$\mathrm{S}=\mathrm{V}t+\tfrac{1}{2}at^2$$

is readily seen to be of this form, for it may be written

$$\mathrm{S}=\mathrm{V}t\left[1+\tfrac{1}{2}\,.\,\frac{at}{\mathrm{V}}\right].$$

§ (8) NON-DIMENSIONAL VARIABLES.—It should be particularly remarked that the problem has reduced itself to the determination of the relation between two non-dimensional groups of terms $\mathrm{S}/\mathrm{V}t$ and at/V, the functional relation between the two depending purely on the geometrical conditions of the problem and in nowise on the dynamical principles involved. In the same way the case of the oscillating pendulum was reduced to the determination of the value of the single non-dimensional group of terms, $t\sqrt{(g/l)}$ as a mere number.

In general, it will be seen that for dynamical problems, at most three equations can be obtained from the dimensions of mass, length, and time, although there may be less if any of these be absent. In general, therefore, if there are n quantities upon which the whole functional relation depends, the indices of three of these quantities can be expressed in terms of the others, and there will be left a relation between $n-3$ non-dimensional groups of terms.

§ (9) APPLICATION TO PLANETARY THEORY.—As a further example of a slightly different nature showing the insight here provided into a problem without actually analysing in detail the dynamical conditions, consider what may be deduced from Newton's Gravitational Law, regarding the periodic times of planets.

The attractive force between two planets of masses m_1 and m_2 at distance r apart is, according to Newton,

$$\mathrm{F}=\frac{km_1m_2}{r^2}.$$

Accordingly the dimensions[1] of k, a gravitational constant, are

$$[k]=[\mathrm{F}]\times\left[\frac{r^2}{m_1m_2}\right]=(\mathrm{MLT}^{-2})(\mathrm{L}^2\mathrm{M}^{-2})=\mathrm{L}^3\mathrm{M}^{-1}\mathrm{T}^{-2}.$$

If d be the major axis of the orbit of a planet of mass E moving round a central sun S, then τ, the periodic time of the motion, can depend only on d, E, S, and k,

$$\therefore\ \tau=f(d,\ \mathrm{E},\ \mathrm{S},\ k)=\Sigma \mathrm{A}d^x\mathrm{E}^y\mathrm{S}^z k^u,$$

$$\therefore\ \mathrm{T}=[\tau]=[d^x\mathrm{E}^y\mathrm{S}^z k^u]$$

$$=\mathrm{L}^{x+3u}\mathrm{M}^{y+z-u}\mathrm{T}^{-2u}.$$

Hence equating like dimensions

$$x+3u=0,\quad y+z-u=0,\quad -2u=1,$$

$$\therefore\ x=\tfrac{3}{2},\quad y=-z-\tfrac{1}{2},\quad u=-\tfrac{1}{2},$$

$$\therefore\ \mathrm{T}=\Sigma \mathrm{A}d^{\frac{3}{2}}(k\mathrm{E})^{-\frac{1}{2}}\left(\frac{\mathrm{S}}{\mathrm{E}}\right)^z$$

$$=\frac{d^{\frac{3}{2}}}{\sqrt{k\mathrm{E}}}\cdot\phi\left(\frac{\mathrm{S}}{\mathrm{E}}\right).$$

From which Kepler's Third Planetary Law follows immediately, that the square of the periodic time is proportional to the cube of the major axis of the orbit.

But it is not in the field of pure dynamics that the method here developed receives its most fruitful applications. In almost all branches of physics a preliminary analysis of any problem that requires investigation, provides an insight into the main factors which are at work, and thus generally indicates the direction in which the research should be developed.

In aerodynamics and aero-engineering, for example, we are concerned with the laws of air resistance to bodies of various shapes, and with the rates at which heated bodies such as radiators, etc., will cool in a current of air. Especially during recent years have innumerable problems of this nature arisen which, because of the complex and intricate mathematical expressions for the physical laws involved, have not yet yielded to theoretical analysis. On the experimental side, however, a considerable amount of work has been carried out, frequently without according the results the full interpretation that might have been given them from the present standpoint. It will become evident that only by an analysis along the lines developed here can the full and most reasonable interpretation for any such work be obtained.

§ (10) APPLICATION TO THE MOTION OF FLUIDS.—In dealing with the motion of fluids it is necessary, in the first instance, to set out in detail the defining properties of that medium, quite apart from any theories regarding the molecular constitution of the fluid—liquid or gas. In the selection of such definitive properties, then, we are only concerned with those that are called into action under the circumstances contemplated in the problem. It suffices accordingly to define any fluid as dense, viscous, and elastic in the first instance, omitting for the moment those properties that become evident on the application of heat. Other properties may make themselves apparent in special circumstances, whilst even some of those enumerated above may in other circumstances become of little consequence. If we are concerned, for example, with the dripping of liquid from a tube, the elastic properties of the fluid may be omitted, its viscosity may even play only a minor part, while surface tension enters as an important factor since the problem is clearly affected by the nature of the conditions at the surface between the liquid and the air.

As far as all these properties are concerned it is possible to express their measure, as in the case of purely dynamical quantities, in terms of the three fundamental units of mass, length, and time, from the mere definition of the physical properties they are intended to represent.

Viscosity, for example, is introduced through the coefficient of viscosity μ defined by: μ = viscous force per unit area per unit velocity gradient; from which it follows that the dimensions of μ are

$$[\mu]=[\text{Force}]/[\text{Area}]\times[\text{Velocity gradient}]$$

$$=(\mathrm{MLT}^{-2})/(\mathrm{L}^2)\times(\mathrm{T}^{-1})=\mathrm{ML}^{-1}\mathrm{T}^{-1}.$$

As already indicated, density (ρ) has dimensions ML^{-3}. Surface tension (S), defined as a force per unit length of a curve, has therefore dimensions

$$[\mathrm{S}]=[\text{Force}]/[\text{Length}]=\mathrm{MT}^{-2}$$

§ (11) SURFACE TENSION.—As an illustration of the use of these expressions, consider the question of determining the size of the drops of liquid which fall from a tube of given diameter when the liquid is allowed to flow slowly down the tube under the influence of gravity and capillary force. On general physical grounds — on the basis of our experience in fact—we assume initially that the mass of the drops will depend on the value of the surface tension between the liquid and the air, on the density of the liquid, and possibly on its viscosity; and as far as an initial scrutiny of the question is concerned, these would appear to be the only properties of the fluid that ought to enter. On general grounds, moreover, we are aware that for slow motions viscosity plays a very minor part, and since in the present instance the motion is essentially slow since the fluid is only dripping, viscosity might legitimately be omitted from the discussion, but whether or not this is justifiable is of course definitely a question of experiment. The only other factor that would enter then is the size and shape of the tube. Let the diameter be d, but the shape cannot be introduced by any definite symbol.

---

[1] It will be convenient to write symbolically in future—Dimensions of $x=[x]$.

Let the mass of each drop M be presumed a function of S the surface tension, ρ the density, g gravity, and d.

$$\therefore\ M=f(S,\ \rho,\ g,\ d).$$

Taking as a typical term in the expansion of this function $AS^x\rho^y g^z d^u$, and writing it dimensionally, we find

$$M=[M]=[S^x\rho^y g^z d^u]=(MT^{-2})^x(ML^{-3})^y(LT^{-2})^z L^u.$$

Hence equating powers of like dimensions

$$x+y=1,\quad -2x-2z=0,\quad -3y+z+u=0.$$

$$\therefore\ x=1-y,\quad z=-1+y,\quad u=1+2y.$$

The typical term is thus:

$$AS^{1-y}\rho^y g^{-1+y}d^{1+2y}=A\frac{Sd}{g}\left(\frac{S}{g\rho d^2}\right)^{-y},$$

$$\therefore\ M=\frac{Sd}{g}\,\phi\left(\frac{S}{g\rho d^2}\right).$$

From this simple analysis it can consequently be deduced that the problem under discussion must be regarded as the determination of the law of variation of the non-dimensional group Mg/Sd with the non-dimensional group $S/g\rho d^2$, and that since the form of the apparently arbitrary function ϕ can depend on nothing but the shape of the tube, the curve obtained by plotting Mg/Sd against $S/g\rho d^2$ will be characteristic of that shape of tube and quite independent of the actual values of S, d, ρ, etc. Actually, it has been found by experiment that M the mass of the drops is proportional to d the diameter of the tube (Tate's Law). If we now therefore examine the function $(Sd/g)\phi(S/g\rho d^2)$, it is clear that unless the function ϕ be a mere constant M cannot possibly be proportional to d, and consequently on the basis of one set of investigations during which d *alone* is varied, while S, ρ, etc. are maintained constant, it can be deduced that when *all* the quantities are varied

$$M=\frac{ASd}{g},$$

where the constant A may be determined from one experiment.

In the same way, if the drop of liquid be set in vibration, the frequency n will depend on g, ρ, d, and S as before, from which, noting that $[n]$ is T^{-1}, it can easily be shown that

$$n=\sqrt{\left(\frac{S}{\rho d^3}\right)}\cdot F\left(\frac{S}{g\rho d^2}\right).$$

§ (12) VIBRATIONS OF A GRAVITATING LIQUID GLOBE.—A globe of liquid, such as a planet in a fluid state, is held together by its own gravity, and is set into a state of vibration by some external disturbance. What information regarding the frequency of vibration in any of its modes can be derived by the Dimensional Method?

The frequency will clearly depend on ρ the density, d the diameter of the sphere, and k the gravitational constant, assuming that surface tension and viscosity are without influence on the question. Accordingly

$$n=f(\rho,\ d,\ k)=\Sigma A\rho^x d^y k^z.$$

The dimensional expressions for each of the quantities d and k are known and have already been used. Inserting these it follows at once that, $x=z=\frac{1}{2}$; $y=0$.

Hence $$n\propto\sqrt{(\rho k)},$$

and it appears that the frequency is independent of the diameter of the sphere and proportional to the square root of the density.

§ (13) VELOCITY OF WAVES.—By a similar process of reasoning it is easy to establish the formulae for the wave velocity in the case of heavy gravity waves in deep sea, $v^2\propto g\lambda$ where λ is the wave-length, and $v^2\propto S/\lambda\rho$ for small surface-tension waves.

A clear insight into the principles of Similitude that lie at the basis of this method is best afforded by a general treatment of the motion of a viscous fluid, correlating many apparently diverse phenomena, and laying them clear as natural consequences of the operation of the general principle of Dynamical Similarity.

§ (14) MOTION OF A BODY IN A VISCOUS FLUID.—Let it be supposed that a body or system of bodies of given geometrical shape, and size specified by the length l of some portion of the system, is moving with velocity V in a fluid of density ρ and kinematic viscosity $\nu(=\mu/\rho)$, and for the moment it will be presumed that the fluid is inelastic. As a matter of actual experiment it is found that not until the velocity approaches that of sound waves in the medium do its elastic properties make themselves apparent. Then the velocity v at some point of the fluid geometrically fixed with reference to the body may quite generally be written as

$$v=\phi_1(V,\ \rho,\ \nu,\ l),$$

while the slope θ of the stream line at that point is

$$\theta=\phi_2(V,\ \rho,\ \nu,\ l).$$

Applying the principle of Homogeneity of Dimensions and remembering that θ, the slope, is of zero dimensions being a mere number, it is found that

$$v = \mathrm{V}f\left(\frac{\mathrm{V}l}{\nu}\right)$$

$$\theta = \mathrm{F}\left(\frac{\mathrm{V}l}{\nu}\right).$$

The second equation indicates that the shape of the stream lines and the direction of motion at any time depend only on the value of the non-dimensional group $\mathrm{V}l/\nu$, and not on the separate constituents of that group. The magnitude of the velocity likewise depends on $\mathrm{V}l/\nu$ and on V alone. We see in fact that provided a system of bodies are all geometrically similar, their sizes being different, the systems of stream lines generated are likewise similar, provided $\mathrm{V}l/\nu$ is maintained constant throughout the system.

§ (15) REYNOLDS' NUMBER.—As a matter of actual experiment Reynolds,[1] by a brilliant series of investigations, demonstrated that the whole process which takes place during the motion of a fluid does not depend alone on any of the single quantities V, l, ν, but on the group; moreover that for any given problem—in his case the flow of fluid through circular pipes—$\mathrm{V}l/\nu$ is a critical variable, which when it attains a certain value corresponds to a more or less rapid change from one state of flow to another, from the steady so-called stream-line flow to the sinuous and turbulent state of eddy formation. Let us suppose then that eddying has originated, that is to say that the fluid on its passage past the obstacle forms in the neighbourhood of the sides of the latter a system of eddies which are shed periodically.

§ (16) FREQUENCY OF EDDY FORMATION.—Let n be the frequency of these eddies, then clearly it can only be a function of V, l, ν, and ρ apart from the geometrical shape of the obstacles.

$$\therefore n = f(\mathrm{V}, l, \nu, \rho).$$

Remembering that the dimension of n is T^{-1} and applying the method of this article, we easily find

$$n = \frac{\mathrm{V}}{l}f\left(\frac{\mathrm{V}l}{\nu}\right),$$

indicating once more that if $\mathrm{V}l/\nu$ is maintained constant for a series of similarly shaped bodies, for such a system

$$n \propto \frac{\mathrm{V}}{l} \propto \frac{\mathrm{V}^2}{\nu} \propto \frac{\nu}{l^2}.$$

Hence for a given value of $\mathrm{V}l/\nu$, and a given fluid so that ν is also constant, the frequency is proportional to the square of the velocity or inversely as the square of the size.

§ (17) DYNAMICAL SIMILARITY IN THE MOTION OF A VISCOUS FLUID.—What this implies may be summarised by saying that if a series of bodies all of the same geometrical shape be moving in a system of fluids, viscosities ν_1, ν_2, . . . with velocities V_1, V_2, . . . then provided $\mathrm{V}l/\nu$ is maintained constant, photographs of the flow pattern taken on cinematograph films of the same size will all be identical as far as the consecutive geometrical configurations of the stream lines and eddying systems are concerned.

The rates at which the processes unfold themselves will, however, be different, being in fact determined by the expressions for the frequency n, but clearly if the photographs be compared at corresponding times as indicated above, the pictures will be identical. We see in fact that the condition, $\mathrm{V}l/\nu = \text{constant}$, involves for geometrical similarity of boundaries, physical similarity in the motions.

This idea has been seized upon and used to great advantage in aerodynamical and naval architectural analysis, for, as will be immediately seen, it provides the basis for the analysis of full-scale problems in aeroplane, airship, and naval construction, by means of tests on models.

§ (18) RELATION BETWEEN EXPERIMENTS ON MODEL AND ON FULL SCALE.—Such analysis, in general, centres itself round the question of how, from measurements of the forces originated during the motion of the model, to predict the corresponding forces that will be called into play during the motion of a full-scale machine or part.

The details of this will be given in another section ("Aeronautics Scale-effect"),[1] but for the purposes of the present article we may note the main principles at work. If R = resistance of a body of dimension l in its motion through fluid of density ρ and viscosity ν with velocity V, we may say that $\mathrm{R} = f(\rho, \mathrm{V}, l, \nu)$, and applying again the method of the present article we easily determine R in the form

$$\mathrm{R} = \rho \mathrm{V}^2 l^2 f\left(\frac{\mathrm{V}l}{\nu}\right).$$

§ (19) NON-DIMENSIONAL RESISTANCE COEFFICIENT.—Stating the law of resistance in the manner that has been followed in previous analysis as a relation between two non-dimensional groups of terms,

$$\frac{\mathrm{R}}{\rho \mathrm{V}^2 l^2} = f\left(\frac{\mathrm{V}l}{\nu}\right),$$

indicating that the question of the forces resisting a body in its motion through a viscous fluid is most properly represented as a curve showing the variation of the "resistance coefficient" (non-dimensional) $\mathrm{R}/\rho \mathrm{V}^2 l^2$ as ordinate, against Reynolds' non-dimensional number $\mathrm{V}l/\nu$, as a base.

§ (20) CHARACTERISTIC CURVE.—Such a curve will be characteristic of that shape of body, but will be absolutely independent of the "scale" of the problem and of the consistent set of units in terms of which the various factors are expressed. If therefore by experiment on a model of an airship, aeroplane, or any portion of it, values of the resistance coefficient can be obtained for a sufficiently wide range of the single variable Vl/ν the same resistance derivative will be valid for the full scale at the same value of Vl/ν. In actual practice it is extremely difficult, except in rare cases, to attain a sufficiently wide range of this quantity, and methods of extrapolation supported by full-scale experiments have to be resorted to.[1]

---

[1] *Phil. Trans.* clxxiv. 935; *Collected Works*, ii. 51.

[1] See Vol. IV.

Fortunately, extrapolation is greatly simplified in practice by the fact that for increasing values of Vl/ν, the resistance tends to increase steadily as the square of the speed, so that $R/\rho V^2 l^2$, and consequently $f(Vl/\nu)$, tends to become constant.

§ (21) Forces during Accelerated Motion.—In the above discussion we have merely considered the question of the forces called into play when the body is in steady motion. Can we derive from first principles any information regarding the nature of the resistance when the body, moving under an acceleration a, say, passes through the velocity v, without our having recourse to the complicated mathematics of fluid motion? Employing the same symbols as previously, but writing v as the velocity not of steady motion but of the body at the instant under consideration, and a its acceleration at that moment, then following the process already adopted we obtain as the expression for the resistance

$$R=\rho v^2 l^2 f\left(\frac{vl}{\nu},\ \frac{al}{v^2}\right),$$

where in addition to the non-dimensional group Vl/ν already obtained, there is now introduced the expression al/v^2 on which the additional resistance depends, not, be it noted, on the acceleration alone, but on the variation of this group.

§ (22) Virtual Mass.—To determine more closely the effect this produces on the resistance, let R = resistance for steady motion at velocity v, and $R+\delta R$ the resistance for an acceleration term al/v^2 small compared to unity, then

$$R=\rho v^2 l^2 f\left(\frac{vl}{\nu},\ 0\right),$$

and

$$\begin{aligned}R+\delta R&=\rho v^2 l^2 f\left(\frac{vl}{\nu},\ \frac{al}{v^2}\right)\\&=\rho v^2 l^2\left[f\left(\frac{vl}{\nu},\ 0\right)+\frac{al}{v^2}f_1\left(\frac{vl}{\nu},\ 0\right)+\ .\ .\ .\right],\\ \therefore\ \delta R&=\rho a l^3 f_1\left(\frac{vl}{\nu},\ 0\right),\end{aligned}$$

indicating that the additional force originated by the accelerated motion is equal to that required to give a mass of fluid $\rho l^3 f_1(vl/\nu_1 0)$ the acceleration a of the body. But ρl^3 is proportional to the mass of the displaced fluid, and consequently it follows that for a given value of vl/ν, the effect of accelerating the motion is to give rise to an apparent increase in mass proportional to the mass of the fluid displaced.

Measurements of this so-called "virtual mass" are of importance in the stability of airships where the mass of fluid displaced is the same as the total weight of the ship, and where consequently the "virtual mass" may acquire a considerable magnitude. It may be remarked that for investigations of this nature the results would naturally be plotted showing the variation of the non-dimensional resistance coefficient $R/\rho v^2 l^2$ either with vl/ν for various values of al/v^2 or conversely, and for a complete investigation the full range, zero to infinity, of al/v^2 must be covered.

§ (23) Experimental Determination of Virtual Mass.—For longitudinal accelerations such experiments have been successfully conducted.[2] A body dropped from rest and allowed to fall in a fluid till it reaches its limiting velocity, gives at the commencement of the fall $v=0$ and a and l finite so that theoretically $al/v^2 \rightarrow \infty$ while, when the limiting velocity is reached $a=0$, and l and v are finite so that a photographic study of the change in motion then provides sufficient data to determine the virtual mass.

Numerous and careful experiments have been conducted to test the accuracy of the deduction that for non-accelerated motion of a viscous fluid the state of affairs depends merely on the value of vl/ν. Reynolds,[3] as already indicated, showed beyond doubt that for the flow of a liquid in a tube the passage from steady to sinuous eddying motion occurs more or less sharply at a definite value of this number. Stanton and Pannell,[4] following up these experiments, verified that for air a similar result held. Since then numerous predictions from model results in aeronautical and marine investigations to full scale have completely justified the deductions. On the other hand, it is clear that the circumstances of the problem must be such as will not involve the origination of properties of the medium presumed non-existent.

§ (24) Effect of Compressibility. — In ballistics, for example, we are concerned with the motion of a body at speeds approaching the velocity of sound, so that one might expect that not merely would energy be lost during the motion in overcoming viscous forces, but also in the production of waves: that is to say, we must now regard the medium as being both viscous and compressive. Now the velocity of sound in a medium of elasticity E, density ρ, and viscosity ν, is given generally by

---

[1] For a full explanation of this, see "Aeronautics," Vol. IV.

[2] Cowley and Levy, *Advisory Committee for Aeronautics, R. and M.*, 612.

[3] *Trans. R.S.*, *loc. cit.*

[4] *Ibid.* A., ccxiv. 199-224.

$$V = f(E, \rho, \nu) = \Sigma A E^x \rho^y \nu^z,$$

and equating like dimensions we easily find

$$x = \tfrac{1}{2}, \quad y = -\tfrac{1}{2}, \quad z = 0,$$

$$\therefore V = A\sqrt{\left(\frac{E}{\rho}\right)}.$$

To find the modified expression for the resistance in this case we write

$$R = f(\rho, v, l, \nu, E),$$

and following the normal procedure we derive

$$R = \rho v^2 l^2 f\left(\frac{vl}{\nu}, \frac{v}{\sqrt{E/\rho}}\right),$$

i.e.

$$\frac{R}{\rho v^2 l^2} = f\left(\frac{vl}{\nu}, \frac{v}{V}\right),$$

where V is the velocity of sound in the medium, indicating that for a given value of vl/ν, the resistance coefficient depends solely on the ratio of the velocity of the projectile to the velocity of sound.

§ (25) EFFECT OF ROTATION: PROPELLER: SHELL.—If in addition the body possesses a spin Ω due to rifling, there would be present a term $\Omega l/v$,

$$\therefore \frac{R}{\rho v^2 l^2} = f\left(\frac{vl}{\nu}, \frac{v}{V}, \frac{\Omega l}{v}\right).$$

Two points of importance may be noted. In the first place for such high speeds as would cause the elasticity of the medium to play an important part, the value of vl/ν would in general be so large as already to be well above the range for so-called scale variation for the viscous forces; that is to say, further increase in value of the term vl/ν would have no marked influence on the value of the resistance coefficient. In the second place, problems of practical importance involving the rotation of moving bodies divide themselves under two heads; those in which the term $\Omega l/v$ is of prime importance as in the case of the propeller; and those in which the spin has no appreciable effect on the resistance as in the case of bodies symmetrical about the axis of rotation—shells, bullets, etc. In the latter case the rotation exists only for purposes of stability and directivity, and plays no measurable part in affecting the resistance.[1] Restricting ourselves to the second part, experiments on ballistics conducted prior to and during the war (1914–18) have succeeded in providing a more or less complete representation of the forces on a projectile (shell) for speeds varying up to and well over 2000 feet per second. It is found that plotting $R/\rho v^2 l^2$ the resistance coefficient, against v/V, the curve remains practically straight and horizontal until a speed approaching that of sound is attained, when it rises steeply and turning at the critical speed diminishes slowly. It appears then that in the region of this critical speed properties of the medium enter which up to that point play no part. The most natural non-dimensional base for representation then changes from vl/ν at low speeds to v/V at high speeds.

It may be mentioned in passing that in the case of the screw motion of a body not symmetrical about the axis of rotation, such as a propeller for example, our discussion so far implies that at speeds at which the viscous scale effect due to the presence of the vl/ν term is no longer of importance as a variant, the term $\Omega l/v$ will become the principal non-dimensional base of variation until the speeds developed approach the velocity of sound, when the new factor v/V will begin to exercise an increasing influence. The anticipation that at such high speeds a critical state will set in is fully borne out by experiment.

By the method of this chapter it is evident that the expression for the pitch of the note produced by the rotation of a propeller at normal speeds will be given by

$$n = \Omega f\left(\frac{vl}{\nu}\right),$$

while for excessive speeds

$$n = \Omega f\left(\frac{vl}{\nu}, \frac{v}{V}\right).$$

For such an instrument as an Aeolian harp if d = diameter of wires, the pitch of the note is

$$n = \frac{v}{d} f\left(\frac{vd}{\nu}\right).$$

Actually Strouhal has found experimentally $n \propto (v/d)$ indicating that the function is a mere constant. It should be remarked that a similar expression was found for the period of the eddies produced by the passage of the wind past the wires, thus suggesting the connection between the two phenomena.

§ (26) DEDUCTION OF SAVART'S LAW.—An interesting illustration of the power possessed by the dimensional method of reducing experimental investigation to the necessary minimum is afforded by the investigations of Savart[2] on the notes sounded by similar vessels containing air. The law proposed by him after an elaborate series of experiments over extreme limits, many notes, and numerous shapes of resonating boxes, was that the number of vibrations per second, or pitch of the resonating note, is inversely proportional to the linear dimensions of the vessel. His experiments included tests on boxes in the shape of cubes, prismatic tubes, conical pipes, etc., all of which were set resonating in different ways. This result, to establish which required such an elaborate series of experiments, can be seen to follow at once from dimensional considerations, for, if n be the number of vibrations per second, E and ρ be the elasticity and density of the medium and l a linear dimension of the box, then $n=f(l, \mathrm{E}, \rho)$ and remembering that $[n]=\mathrm{T}^{-1}$, $[\mathrm{E}]=\mathrm{ML}^{-1}\mathrm{T}^{-2}$ and $[\rho]=\mathrm{ML}^{-3}$, it is easily seen that $n \propto 1/l\sqrt{(\mathrm{E}/\rho)}$ where the constant of proportionality depends purely on the shape of the vessel: Savart's Law follows at once.

---

[1] A discussion of the performance of propellers as a function of the non-dimensional group $\Omega l/v$ will be found under "Propellers."

[2] *Annales de Chimie*, Paris, 1825, xxix.

§ (27) TEMPERATURE.—In the foregoing discussion it has been presumed that the temperature of the medium remains constant, or at any rate it does not bring into prominence any new property of the medium. It is now proposed to remove this restriction. The conception of temperature is of an essentially different nature from any of those we have already discussed. The scale of temperature is selected to provide some basis for the measurement of "hotness" of a body. Having at our disposal standards of mass, length, and time only, it is manifestly impossible by means of them to determine or reproduce a temperature; for this purpose some other property of matter as affected by heat must be selected to serve as a standard of measurement. Accordingly, it becomes necessary at this stage to introduce a new unit Θ of temperature, and in terms of this and the units already adopted it should be possible to write down with comparative ease the dimensional expressions for the quantities that now arise.

In dealing with the conduction and convection of heat there are two coefficients, characteristic of any particular substance, whose dimensions will be required; they are, a quantity measuring the amount of heat that must be given to raise unit volume of the medium through unit degree of temperature, and a quantity measuring the heat transferred across a section of unit depth and unit area in unit time for unit difference in temperature. These quantities are of course respectively the specific heat (c) and the thermal conductivity (k) of the medium.

Expressing heat entirely in terms of energy units where it occurs, it then follows that

$$[c]=[\text{Heat}]/[\text{Vol.}]\times[\text{Temp.}]=\mathrm{ML}^{-1}\mathrm{T}^{-2}\Theta^{-1},$$

$$[k]=[\text{Heat}]/[\text{Length}]\times[\text{Time}]\times[\text{Temp.}] =\mathrm{MLT}^{-3}\Theta^{-1}.$$

In connection with many problems of convection, the effect of the expansion of the air under the influence of the heated surfaces may attain some considerable importance in the transmission of the heat, and as a consequence the quantity δ is introduced, representing the change in density per unit change in temperature, or

$$\delta=\frac{\partial\rho}{\partial\Theta},$$

$$\therefore [\delta]=\mathrm{ML}^{-3}\Theta^{-1}.$$

§ (28) RATE OF COOLING OF BODY IN QUIESCENT GAS.—As an illustration of the utility of the method of dimensions in the discussion of problems of cooling, consider the rate of loss of heat h of a body of given shape, of size l of one part, in a quiescent atmosphere of density ρ and kinematic viscosity ν. If k and c have the meanings previously attached to them and Θ be the temperature difference maintained between the body and the gas at a great distance, at which the latter is undisturbed by the presence of the body, it will be justifiable to write

$$h=f(l, k, c, \rho, \nu, \Theta),$$

assuming that in this case the changes in density with temperature are not sufficient to affect the question. The modifications introduced if this condition is violated will be apparent, and adjustment easily made.

Imagining the function f expanded as in previous illustrations in the form

$$\Sigma \mathrm{A} l^x k^y c^z \rho^u \nu^v \Theta^w,$$

then $$[h]=[l^x k^y c^z \rho^u \nu^v \Theta^w].$$

The dimensions of h, the rate of heat loss, are those of $(\text{Heat})/(\text{Time})=\mathrm{ML}^2\mathrm{T}^{-3}$.

$$\therefore \mathrm{ML}^2\mathrm{T}^{-3}=\mathrm{L}^{x+y-z-3u+2v}\,\mathrm{M}^{y+z+u}\,\mathrm{T}^{-3y-2z-v}\,\Theta^{-y-z+w};$$

$$\therefore [\mathrm{M}]\ldots y+z+u=1 \quad [\mathrm{L}]\ldots x+y-z-3u+2v=2;$$

$$\therefore [\mathrm{T}]\ldots 3y+2z+v=3 \quad [\Theta]\ldots y+z-w=o;$$

$$\therefore x=1-2u, \quad y=1+2u-v,$$

$$z=-3u+v, \quad w=1-u.$$

This provides a typical term in the expansion in the form

$$lk\Theta\left(\frac{\rho k^2}{l^2c^3\Theta}\right)^u\left(\frac{c\nu}{k}\right)^v,$$

and consequently since u, v, and the numerical coefficient of each term may as far as can here be determined have any value whatsoever, it is to be concluded that

$$h=lk\Theta f\left(\frac{\rho k^2}{l^2c^3\Theta}, \frac{c\nu}{k}\right).$$

Whether or not all the quantities which have been assumed of importance in the determination of h actually do enter is a question to be decided only by experiment, to which we shall return shortly.

§ (29) NON-DIMENSIONAL VARIANTS.—For the moment it can be concluded that the problem of rate of cooling in this instance reduces itself to a consideration of the variation not of h alone, but of the non-dimensional group $h/lk\Theta$ with the non-dimensional variants $\rho k^2/l^2c^3\Theta$ and $c\nu/k$. If we are dealing with the rate of cooling in gases then practically $c\nu/k$, the ratio of the emissivities for momentum and for heat, is a constant for all gases, and consequently this term may be omitted from the function f.

A considerable number of experimental investigations have been conducted on this problem and in all cases it has been found that the rate of heat loss varies directly as the temperature difference Θ. In effect this implies that h/Θ is independent of Θ and that consequently $f(k^2\rho/l^2c^3\Theta)$ above is a constant. Hence

$$h = alk\Theta,$$

indicating that the rate of cooling is proportional to the size of the body and to the conductivity. The coefficient a depends of course on the shape of the cooling body.

If, however, it is illegitimate to assume that the expansion of the gas due to heating is negligible as a factor in heat transmission, but that the expanded portions becoming thereby relatively lighter will tend to stream upwards, and as a consequence the heavier portions downwards, a new term introducing the change in weight of unit volume per unit change in temperature must be considered. Such a factor is of course $g(\partial\rho/\partial\Theta)$ or $g\delta$.
Hence generally

$$h = f(l,\ k,\ c,\ \rho,\ \nu,\ \Theta,\ g\delta),$$

and following the lines of the previous argument

$$h = lk\Theta\phi\left(\frac{\rho k^2}{l^2c^3\Theta},\ \frac{c\nu}{k},\ \frac{lg\delta}{c}\right).$$

For the reasons adduced in the former case, the final form sufficiently approximate for all practical purposes is

$$\frac{h}{lk\Theta} = \chi\left(\frac{lg\delta}{c}\right),$$

provided the problem is restricted to heat transmission in gases. The form of the function χ, depending as it does on the shape of the body under consideration, will now be completely determined graphically from a single set of experiments for which the non-dimensional group $lg\delta/c$ is allowed to vary over a range, for each point of which the non-dimensional term $h/lk\Theta$ is measured. The resulting curve obtained, invariable for all systems of units, will then be characteristic of those special boundaries.

§ (30) Rate of Cooling of a Moving Body in a Gas.—Problems of great practical importance arise in connection with the rate of heat transmission from bodies in motion in the air, as in the case of radiators and air-cooled engines. In these problems the rate of heat transmission will actually depend on the translational velocity V in addition to the quantities already enumerated above. The introduction of this extra symbol, as can easily be verified by an application of the dimensional method, gives rise to the "fluid motion" term Vl/ν in the functional expression. If under these circumstances it can legitimately be presumed that the term brought in by the rate of change of density would not materially affect the rate of heat transmission, an assumption that will be examined shortly, then, for reasons already set forth,

$$h = lk\theta f\left(\frac{c\nu}{k},\ \frac{Vl}{\nu}\right),$$

or, since $c\nu/k$ is constant for a gas,

$$\frac{h}{lk\theta} = \phi\left(\frac{Vl}{\nu}\right).$$

§ (31) Experimental Determination of Unknown Function.—In the case of heat loss from long circular wires past which air is streaming with velocity V, it has been found [1] that h varies approximately as $V^{\frac{1}{2}}$. If for the moment this be accepted as correct, it is possible immediately to determine the form of the function, for the only expression for ϕ such as will make $h \propto V^{\frac{1}{2}}$ is $A\sqrt{(Vl/\nu)}$. If the wire, moreover, is of diameter a, it is quite legitimate to substitute a for l in this term in order that when the wire is of infinite length there may result a finite heat loss per unit length. It follows, therefore, on the foregoing assumption that

$$h \propto lk\theta\sqrt{\left(\frac{Va}{\nu}\right)} \propto lk\theta\sqrt{\left(\frac{aVc}{k}\right)},$$

since $c\nu/k$ is constant.

The most rational method of representing graphically the experimental results referred to above would be by plotting the non-dimensional term $h/lk\theta$ on the non-dimensional base $\sqrt{(Va/\nu)}$ or $\sqrt{(aVc/k)}$, from which, if the above law is exact, a straight line would be obtained characteristic of that particular shape of wire.

§ (32) Dynamical Similarity.—It should be remarked that if Vl/ν and $\theta c/\rho V^2$ are maintained constant from problem to problem, the system of stream lines and state of flow generally will remain geometrically similar, for the velocity v at any point geometrically fixed with respect to the body will be of the form

$$\frac{v}{V} = f\left(\frac{c\nu}{k},\ \frac{Vl}{\nu},\ \frac{\theta c}{\rho V^2}\right),$$

and the argument follows closely that adopted in the case of the motion of viscous fluids, already outlined.

More recent investigations of the rate of cooling of wires in a current of air, by L. V.

---

[1] Russell, *Phil. Mag.*, 1910, xx. 591.

King,[1] have shown the presence of another term besides that involving $V^{\frac{1}{2}}$, viz. a term proportional to the square of the linear dimensions of the hot body. King in fact found that a close approximation to the results he obtained for the rate of heat transmission was given by the empirical formula

$$h=(\theta-\theta_0)l\{A\sqrt{Va}+B+Ca\},$$

where A, B, and C are constants for the particular gas and shape of wire—circular in his case. L. F. Richardson[2] has suggested that the presence of the term $c(\theta-\theta_0)la$ indicates that the velocity near the hot body is partly produced by the rising of fluid due to thermal expansion. It follows, therefore, if this is sound, that the additional term ought to be expressible in terms of the appropriate group already referred to, viz. $gl/c\,.\,d\rho/d\theta$.

§ (33) More accurate Determination of Unknown Function.—Writing therefore

$$h=lk(\theta-0_0)f\left(\frac{aVc}{k},\ \frac{ga}{c}\cdot\frac{d\rho}{d\theta}\right),$$

as derived on dimensional reasoning, and equating this to the empirical formula found by King,

$$A\sqrt{Va}+B+Ca=kf\left(\frac{aVc}{k},\ \frac{ga}{c}\cdot\frac{d\rho}{d\theta}\right),$$

it is indicated that the form of the function f must be

$$P\sqrt{\left(\frac{aVc}{k}\right)}+Q+R\frac{ga}{c}\cdot\frac{d\rho}{d\theta},$$

where P, Q, and R are now mere numbers determined solely by the geometrical conditions and universally applicable for any gas once the values of these three numbers have been derived from King's experimental results. The complete formula is consequently

$$h=lk(\theta-\theta_0)\left[P\sqrt{\left(\frac{aVc}{k}\right)}+Q+R\frac{ga}{c}\cdot\frac{d\rho}{d0}\right],$$

giving the relation between the rate of heat loss and the remaining quantities k, etc., which were not presumed variable in the actual experiment.

§ (34) Non-dimensional Groups are the Real Variables.—The real variables in fact in the problem are the dependent non-dimensional quantity $h/lk(\theta-\theta_0)$ and the independent non-dimensional groups aVc/k and $ga/c\,.\,d\rho/d\theta$, while the most rational graphical representation of the experimental results would be obtained by showing the law connecting the variation of this dependent variable with each of these independent variables, the system of curves obtained being then characteristic of this class of problem, and dependent only on the geometrical conditions.

II. Dimensions of Electric and Magnetic Quantities

§ (35) Electrostatics.—The treatment of electrical and magnetic phenomena from the standpoint of the present article presents some points of interest. Considering in the first place electrostatic quantities, we possess at present no means of expressing electric or magnetic charge directly in terms of any of the fundamental units already introduced. Accordingly a consideration of electrostatic quantities must introduce a new unit directly related to the charge. The simplest method of representation is through the quantity K, the specific inductive capacity, and the experimentally known law of force between charged bodies. Accordingly we write

$$\frac{1}{K}\cdot\frac{ee'}{r^2}=\text{force},$$

giving as the dimensions of a charge $K^{\frac{1}{2}}M^{\frac{1}{2}}L^{\frac{3}{2}}T^{-1}$. At once, from the definition of the quantities concerned, it is possible to draw up the following table :

Quantity.	Symbol.	Dimension.
Charge	e	$K^{\frac{1}{2}}M^{\frac{1}{2}}L^{\frac{3}{2}}T^{-1}$
Electric intensity .	F	$K^{-\frac{1}{2}}M^{\frac{1}{2}}L^{-\frac{1}{2}}T^{-1}$
Potential difference .	V	$K^{-\frac{1}{2}}M^{\frac{1}{2}}L^{\frac{1}{2}}T^{-1}$
Current	i	$K^{\frac{1}{2}}M^{\frac{1}{2}}L^{\frac{3}{2}}T^{-2}$
Resistance . . .	R	$K^{-1}L^{-1}T$
Capacity	C	KL
Specific independent capacity	K	K

In the same manner, commencing with the definition of magnetic permeability μ as

$$\frac{1}{\mu}\cdot\frac{mm'}{r^2}=\text{force},$$

m and m' being the strength of two magnetic poles, we can draw up a parallel list of quantities involved in magnetic phenomena, *e.g.* strength of magnetic pole has dimensions $\mu^{\frac{1}{2}}M^{\frac{1}{2}}L^{\frac{3}{2}}T^{-1}$. It would appear at first sight as if these two lists were quite independent and that two separate units, K and μ, for the discussion of electric and magnetic phenomena would require to be introduced, but it is known that magnetic and electric phenomena are closely interwoven, that currents flowing through wires originate magnetic fields in their neighbourhood.

§ (36) Relation between Electrical and Magnetic Units.—We have in fact this connecting link, that if a magnetic pole of strength m is made to thread a circuit *once* in which is flowing a current of strength i, the total work done is measured by

---

[1] *Phil. Trans.* A, 1914, ccxiv. 373-432.

[2] *Proc. Phys. Soc.* xxxii. Pt. V. 406. A discussion of the experimental results of numerous workers is given from the standpoint of the present article by A. H. Davis, *Phil. Mag.*, Dec. 1920, xl.

$$\text{work done} = 4\pi mi.$$

Hence the dimension of the product of magnetic strength and electric current are those of work.

$$\therefore (\mu^{\frac{1}{2}}M^{\frac{1}{2}}L^{\frac{3}{2}}T^{-1})(K^{\frac{1}{2}}M^{\frac{1}{2}}L^{\frac{3}{2}}T^{-2}) = ML^2T^{-2},$$

$$\therefore [\mu^{\frac{1}{2}}K^{\frac{1}{2}}] = L^{-1}T = [1/\text{Velocity}].$$

The most natural standard velocity to adopt in such circumstances would be the velocity of electromagnetic waves in the particular medium, and accordingly we have the relation

$$\mu K = A/V^2,$$

where A is some constant which accurate experimental investigations have, in fact, shown to be equal to unity. This simple yet fundamental relation between μ and K enables us at once to reduce the two systems of units to one, either by expressing all the electrical quantities in terms of magnetic units or *vice versa*. We express them here in terms of electromagnetic units as follows:

Quantity.	Symbol.	Dimension.
Charge	e	$\mu^{-\frac{1}{2}}M^{\frac{1}{2}}L^{\frac{1}{2}}$
Electric intensity .	F	$\mu^{\frac{1}{2}}M^{\frac{1}{2}}L^{\frac{1}{2}}T^{-2}$
Potential difference .	V	$\mu^{\frac{1}{2}}M^{\frac{1}{2}}L^{\frac{3}{2}}T^{-2}$
Current	i	$\mu^{-\frac{1}{2}}M^{\frac{1}{2}}L^{\frac{1}{2}}T^{-1}$
Resistance . . .	R	μLT^{-1}
Capacity	C	$\mu^{-1}L^{-1}T^2$
Specific independent capacity	K	$\mu^{-1}L^{-2}T^2$
Strength of magnetic pole	m	$\mu^{\frac{1}{2}}M^{\frac{1}{2}}L^{\frac{3}{2}}T^{-1}$
Magnetic force . .	H	$\mu^{-\frac{1}{2}}M^{\frac{1}{2}}L^{-\frac{1}{2}}T^{-1}$
Magnetic induction .	B	$\mu^{\frac{1}{2}}M^{\frac{1}{2}}L^{-\frac{1}{2}}T^{-1}$
Magnetic permeability	μ	μ
Coefficient of inductance	L	μL

By means of these dimensional relations it is possible once more to group together whole classes of investigations as dependent on the variation of certain non-dimensional groups, thus indicating a rational method of plotting the results obtained.

§ (37) APPLICATIONS.—The following selection of simple results can be derived directly by the method of the present article.

Time taken for a current in a circuit of resistance R and inductance L to fall to a given fraction of its intensity when switched off is proportional to L/R.

A periodic E.M.F. of any form whose amplitude is specified by E and period $2\pi/p$ acting on any system, of resistance R and inductance L, produces a maximum current given by

$$i_{\text{max.}} = \frac{E}{R} f\left(\frac{Lp}{R}\right).$$

For a simple E.M.F. given by E cos pt, it is known that

$$i_{\text{max.}} = \frac{E}{R}\left[1 + \left(\frac{Lp}{R}\right)^2\right]^{-\frac{1}{2}}.$$

Expression for the energy per unit volume of an electromagnetic field of electric and magnetic intensities F and H respectively is

$$\mu H^2 f\left(\frac{KF^2}{\mu H^2}\right).$$

The total energy of a charge e of dimension d moving with velocity v in a medium of constants μ and k is

$$\frac{\mu v^2e^2}{d} f\left(\frac{v}{V}\right),$$

where V = velocity of electromagnetic waves in the medium; consequently the electrical mass m is

$$m = \frac{2\mu e^2}{d} f\left(\frac{v}{V}\right).$$

The radiation R from an accelerated electron is

$$R = \frac{\mu e^2 a^2}{v} \phi\left(\frac{v}{V}\right),$$

where a = acceleration, and the radiation is assumed independent of the diameter of the electron.

III. THE APPLICATION OF THE PRINCIPLES OF SIMILITUDE TO MODELS

§ (38) MODEL EXPERIMENTS AND THEIR FULL-SCALE EQUIVALENTS.—The principles developed in the foregoing paragraphs, serving as they do to group together processes occurring in geometrically similar systems, provide the most natural method of approach to the problem of the relations of models to their full-scale counterparts. The lines of development in the case of the use of models for the determination of the wind forces on aircraft have already been discussed. Two further aspects of the general question will be here treated. What, in the first place, must a model fulfil as regards working conditions in order that its motions and working may be directly comparable with those of the full-sized machine? That is to say, what are the relations between weights, external forces, speeds, etc., that two systems initially geometrically similar may continue during their motion to remain geometrically similar, that the relative positions of the parts of one system after a time t may always be similarly situated to the relative positions of the corresponding parts at time t', where t and t' bear a constant ratio to each other. It is clear that if these conditions can be determined and a model produced to operate satisfactorily while working under them, then the full-scale machine will also operate satisfactorily. The second aspect, dealing with the strength of construction of the model and of the full-scale, will be treated shortly.

§ (39) Condition for continued Similarity in Working of Model and Full-scale.—Corresponding to each part of the system there will be a scheme of equations between the moving forces and acceleration produced, of the form $m(d^2x/dt^2)=X$ for the model, and for the full-sized machine $m'(d^2x'/dt'^2)=X'$, where m and m' are the masses of corresponding parts, occupying corresponding positions x and x' at corresponding times t and t'. X and X′ are the corresponding moving forces. For continued geometrical similitude at time t and t' connected by $t=Tt'$, where T is some constant, there must be $x=lx'$, $m=Mm'$, and $X=FX'$ where l, M, and F are constants determining the scale of the one with reference to the other. Hence, inserting these in the first equation,

$$\frac{Mm'l}{T^2}\frac{d^2x'}{dt'^2}=FX',$$

or

$$\left(\frac{Ml}{T^2F}\right)m'\frac{d^2x'}{dt'^2}=X',$$

and the motions will therefore remain identical if $Ml/T^2F=1$, the same equation then applying both to model and full-scale. Hence the moving forces of model and full-scale must be in the ratio F, where

$$F=\frac{Ml}{T^2}.$$

In the same way, had the corresponding times been eliminated by comparing the systems at corresponding speeds we would have found that for similarity the moving forces must be proportional to MV^2/l.

The following conclusions may accordingly be drawn for a comparison of the working of a model with that of the full-sized machine: Since the weights of the parts, regarded as external forces, are proportional to their masses, $V^2 \propto l$, and the velocity of working must be proportional to the square root of the linear dimensions; external moving forces must bear a constant ratio to the weight and must therefore increase as the cube of the linear dimensions, if model and machine are made of the same material.

IV. Similitude of Structures

§ (40) Structural Strength.—Turning to the question of the relation between the structural strengths of models and full-scale constructions, it is proposed to show that the theoretical basis of model strength tests on structures may be developed in a rigorous yet simple form by an application of the method of Dimensions.

When a homogeneous prismatic strut of length l and flexural rigidity EI, simply supported at the ends, is subjected to axial end thrust F up to a load given by

$$F=\frac{\pi^2 EI}{l^2},$$

the undeflected position is one of stable equilibrium provided the ultimate stress is not exceeded. Beyond this so-called Euler's Critical Load, the straight position is one of unstable equilibrium. If the strut be deflected, as long as the load is maintained the axis will continually undergo change in shape until it ultimately takes up a form of elastica. During this process the yield point of the material may be exceeded and the material may rupture. The strut may thus be supposed to fail for two possible reasons, on the one hand because its shape has been permanently changed from the straight normal position owing to the instability of that position, and on the other hand because the actual material has failed to withstand the stresses originated. This conception is of course not limited to such a simple structure as a strut, for it may be seen that in general a framework of any kind may fail for either of these two reasons. It is proposed to investigate what information may be furnished regarding these two types of failure, rupture and instability, for a structure in general, by an application of the dimensional theory.

Consider the case of a structure of the type of an aeroplane framework for definiteness, although the argument is quite general, where it is supposed that the assumptions made in the ordinary beam theory apply to every part. Let the length of one part, say a bay, be given by l, the area of a particular section by A, moment of inertia I, and the elasticity and density of the material of which it is composed E and ρ respectively. Given these quantities for this one portion, it will be assumed that the shape and geometry of the structure involve an exact specification of how to derive the corresponding quantities for the remaining portions. Let the external load be F, applied in some given manner specified geometrically, and suppose this is sufficient to produce a stress just greater than the yield stress f in the material of the weakest member. F can only depend apart from the geometry and manner of application upon the quantities enumerated above, defining the properties of the material. These are as follows:

Quantity.	Symbol.	Dimensions.
Young's modulus .	E	M/LT^2
Area	A	L^2
Moment of inertia .	I	L^4
Length	l	L
Density	ρ	M/L^3
Yielding stress . .	f	M/LT^2
Gravity	g	L/T^2
Load	F	ML/T^2

Since F, the load which will cause collapse by rupture of the material, must involve these quantities grouped together in such a manner as to make the dimensions of the product identical with those of F, we may write

$$F=\psi(E,\ A,\ I,\ l,\ \rho,\ f,\ g).$$

Applying the method already used frequently in this discussion, we easily find

$$F=\frac{EI}{l^2}\psi\left(\frac{f}{E},\ \frac{A}{l^2},\ \frac{W}{fA},\ \frac{I}{l^4}\right),$$

where ψ for the moment is an arbitrary function. Writing

$$\phi^2=\frac{Fl^2}{EI}$$

so that this quantity may be considered as a *non-dimensional* critical loading coefficient, it follows finally that

$$\phi^2=\psi\left(\frac{f}{E},\ \frac{A}{l^2},\ \frac{W}{fA},\ \frac{I}{l^4}\right).$$

§ (41) Non-dimensional Critical Loading Coefficient.—It is clear from the definition of ϕ that for a given structure where l, E, and I are known ϕ is uniquely determined when F, the breaking load, is found, so that the discussion of collapse by rupture may equally well be centred round ϕ. Let it be clearly understood that the exact form of the function ψ above depends only on the geometry of the structure, including the manner of loading and the law of distribution of material.

Out of the general class of framework embraced in this discussion so far, let there be selected a series of which all members are identical with respect to external shape, differing only in scale. This implies that A, the area of cross-section of any selected part, is proportional to l^2, and I to l^4. For this series, therefore, A/l^2 and I/l^4 are constants depending only on the geometry, and accordingly the expression for ϕ now takes the simplified form

$$\phi^2=\psi_1\left(\frac{f}{E},\ \frac{W}{fA}\right).$$

It is not difficult to give an interpretation to the two non-dimensional quantities f/E and W/fA. The former, being the ratio of the yielding stress to Young's modulus, may be taken as the strain at the yield point, on the assumption that Hooke's Law applies rigorously over the whole range. In the same way W/fA is the ratio of the weight of a particular member, say the weakest, to the maximum tensile or compressive force, as the case may be, which that member is capable of withstanding without yielding, assuming that the section A is taken at the position of collapse.

§ (42) Non-dimensional Variables.—As far as a discussion of the breaking load coefficient ϕ^2 is concerned, it is evident that if a series of geometrically similar structures be selected, two distinct non-dimensional variables, and two only, functions of the material, affect the question. These are the strain at the yield point for the weakest member, and the ratio of the weight of that member to the maximum tensile or compressive force it can withstand at the point of yield. It is equally clear, however, that the so-called geometrical restrictions determining the distribution of the constants of the materials in a composite structure are not absolutely vital to the above discussion, so that violations of the laws determining the selection of the material from member to member would not necessarily vitiate the conclusions arrived at here. For example, one would not be rigorously entitled to vary I, A, and E in certain members, since such a change would clearly upset the geometrical similarity of shape and the distribution of force, with the possible result that the previously weakest member might now not remain such. No such trouble, however, could arise if the selection of the materials was made without changing these factors, but allowing a variation in f, the yielding stress, so long as the previously weakest member always remains so in the series. This is equivalent to an increased latitude in the scope of selection of material.

Generally in experimenting with a model of this nature it is convenient, of course, to have corresponding parts in the model and the full-scale structure composed of identical materials. If, for example, the frame of an aeroplane was under discussion, wires in the model would be composed of the same metal as those in the original; corresponding struts, spars, ribs, etc., of the same wood.

Since the quantities f, E, l, ρ, etc., in the expressions for ϕ^2 all refer ultimately to the same part of the model, to ensure geometrical similarity in the widest sense it follows that the assumption that f/E is a constant is one which is obvious experimentally. Under these circumstances also W/fA, as can easily be verified, becomes proportional to the linear dimension l. The breaking load coefficient ϕ^2, therefore, when the weight of the structure contributes towards rupture, is purely a function of l,

$$\therefore\ \phi^2=\phi_1(l),$$

and the form of the function is determined only by the shape of the various parts, the geometry of the loading and the so-called geometry of the material.

§ (43) Limiting Size of a Heavy Structure.—This expression for ϕ^2 may likewise be supposed solved for l in terms of ϕ^2. For every external load coefficient this equation then determines the size of the structure corresponding to failure. When there is no external load and failure is due to weight alone, $\phi_1(l)=0$, an equation determining the smallest size of a structure that will collapse under its own weight.

When the material is not sufficiently heavy to involve the weight of the structure appreciably as a factor in causing collapse, the term

W/fA may be omitted in the general equation and the expression for ϕ^2 takes the relatively simple form

$$\phi^2=\phi_2\left(\frac{f}{E}\right).$$

§ (44) NON-DIMENSIONAL BASES, AND "CHARACTERISTIC CURVE."—Let us imagine that the weakest member is replaced by another of the same geometrical shape and size but with a different value of f/E, though not so different as to prevent its remaining the weakest member; then a test on each one of these models will give a particular value of ϕ^2, breaking load coefficient, and these when plotted against f/E will give a "characteristic curve" for the structure of the given geometry. For geometrically similar structures of which the corresponding parts are made of the same material, so that f/E is constant, the breaking load coefficient becomes an absolute constant for the series depending for its value purely on the shape. *It follows that a simple test to destruction on a model will suffice under these conditions to determine the breaking load coefficient* ϕ^2, and therefore the breaking load F for any other member of the series of geometrically similar structures.

§ (45) FAILURE DUE TO INSTABILITY.—It is assumed in this section that the failure is not necessarily accompanied by collapse or rupture in the material, but is due merely to permanent deformation of the configuration of the structure. It follows that, in the expression for the critical load, the yield stress does not enter although all the other terms A, l, E, I, ρ, g may do so. Using ϕ^2 as a critical load coefficient defined by $Fl^2/EI=\phi^2$, then

$$\phi^2=\psi_1\left(\frac{A}{l^2}, \frac{W}{EA}, \frac{I}{l^4}\right),$$

obtained by the same method as in the previous section.

On the understanding that the structures in the series are all geometrically similar as regards external shape without reference to material composing them, then A/l^2 and I/l^4 are constants for the series, and

$$\phi^2=\psi_2\left(\frac{W}{EA}\right),$$

where W/EA is the ratio of the weight of a member to the tensile or compressive force required to produce unit strain at some particular section of that member.

If corresponding members of the series are made of the same material, then W/EA is easily seen to be proportional to l, from structure to structure, and as before the critical loading coefficient

$$\phi^2=\psi_3(l)$$

depends on the size only.

§ (46) CRITICAL LOADING COEFFICIENT A CONSTANT FOR COLLAPSE DUE TO INSTABILITY.—When the weight of the structure is negligible as far as its effect in contributing to failure is concerned, the whole instability arising from the external loading, then ϕ^2 is a constant for a series of structures of identical form irrespective of the material of which it is composed, and *a test to destruction on one model suffices for the series.*

It has been found that the critical loading for a uniform prismatic strut of negligible weight under end thrusts and simply supported at the ends is given by

$$F=\frac{\pi^2 EI}{l^2}$$

so that ϕ for this structure is π. For a strut under the same conditions, but with clamped ends, $\phi=2\pi$.

In certain cases of simple shapes of structures, it is obvious that the function ϕ may be derived by calculation, as for example in the above two cases, but for more complicated problems where the calculation is too abstruse a number of points on the characteristic curve may be derived by a series of tests to destruction on models.

In the special cases where ϕ is a constant for the series a single test on one model is clearly sufficient. This, as has been shown, applies with equal force where the collapse is due either to instability or to failure of the material.

The basis of the experimental method thus having been made secure, no scale effect difficulty of the type normally arising in, say, aerodynamic work being present, it should now be possible to proceed to a direct accurate test of failure and its causes under various circumstances.

§ (47) WHIRLING OF SHAFTS.—While the foregoing analysis applies to structures under forces of the static type, a parallel argument can be applied where fluctuating stresses are introduced, or where parts of the structure are in motion. In illustration consider the problem of whirling of a rotating shaft of given outline and section. As before, suppose the geometrical shape longitudinally and cross-sectionally to be given, length l, mass per unit length m, and flexural rigidity of a particular section EI_o: then if q be the speed of rotation, the deflection d at the centre, say, will be a function of l, m, E, I_o, and q, *i.e.*

$$d=f(l, m, E, I_o, q).$$

Hence $$\frac{d}{l}=F\left(\frac{mq^2l^4}{EI_o}, \frac{I_o}{l^4}\right)$$

on equating the dimensions of the typical group. For a shaft of given geometrical outline I/l^4 is a constant dependent on the geometry, hence in varying the size of geometrically similar shafts the ratio of the deflection at the centre to the total length will depend only on the quantity mq^2l^4/EI_o.

§ (48) Non-dimensional Variable.—If a whirling speed exists, then, for some value of q, the ratio d/l will theoretically become infinite, or at least indeterminate, and this can only occur for some value of the variable mq^2l^4/EI_o, say a. Hence we find that the real variable in whirling shaft problems as the size and material of the shaft are varied, but maintaining the geometrical shape constant, is mq^2l^4/EI_o. In actual fact the whirling speed of a straight shaft is known to be

$$q=\frac{\pi^2}{l^2}\sqrt{\frac{EI}{m}},$$

i.e.

$$a=\frac{mq^2l^4}{EI}=\pi^4,$$

and for a homogeneous circular stepped shaft made up of three portions, the two end pieces of length $l/4$ and diameter $d/4$, and the central portion of length $l/2$ and diameter d,

$$\frac{mq^2l^4}{EI_o}=3,$$

I_o being taken for the central portion.[1]

From the foregoing analysis, moreover, it is apparent that shafts of identical geometry but differing in size and material will maintain their identity in geometry under rotation provided they be compared at corresponding speeds q_1 and q_2 given by

$$q_1l_1^2\sqrt{\frac{m_1}{E_1I_1}}=q_2l_2^2\sqrt{\frac{m_2}{E_2I_2}}$$

§ (49) Expansion in Terms of the Class Variables.—It has become apparent in the application of the method of the present article to various branches of physics and engineering that in all cases the investigation has centred itself round the behaviour of some expression represented as a function of a certain non-dimensional group of terms. This quantity, connecting together as it were a whole class of problems possessing certain geometrical and dynamical similarities, may be termed the *class variable.* Many problems in mathematical physics expressible in terms of differential equations would appear then to demand a solution as a function of the class variable, and accordingly an expansion of the solution of the differential equation is sought for as a power series in the class variable. This method has been applied with considerable success to the problem of the crippling of struts, the whirling of shafts of variable flexural rigidity, and to the motion of a viscous fluid.[2] In effect this is simply an analytical method of representing the "characteristic curves" on non-dimensional bases obtained so frequently in the foregoing discussion.

DYNAMOMETERS

§ (1) Fundamental Principles.—The work done by a prime mover or other agent when transmitted by a rotating shaft may be expressed by $PR\phi$, and when by a moving chain, rope, or similar agent, by Pd, where P is the force acting, R the torque arm, ϕ the angular displacement, and d the linear displacement.

A dynamometer is an instrument which is used for the measurement of the force P, or the torque PR; the values of the quantities ϕ and d are usually determined independently.

The work done by the prime mover may either be absorbed by the dynamometer or transmitted to a machine in which it is employed usefully after having been measured.

It is necessary that the instrument adopted should perform its function with accuracy. The whole of the energy developed by the prime mover should be included in the measurement made without neglecting that absorbed by shaft bearings in the dynamometer itself or by gearing or bearings which may be interposed between the prime mover and the dynamometer.

The load should be capable of fine adjustment under running conditions, and this adjustment should preferably be over a considerable range of power in order that the prime mover may be tested from its minimum to its maximum power capacity without the necessity for frequently stopping down.

The construction of a dynamometer should be such that it imposes no force on the prime mover other than that for which it was designed. For example, a dynamometer suitable for testing a petrol motor should exert a pure torque, otherwise the motor bearings will be called upon to take loads, and the shaft to resist bending and shear stresses, additional to those for which they were intended.

It is desirable, in the type of dynamometer in which the power is absorbed, that the inertia of the rotating parts should be small in order that a stoppage may readily be effected if failure of the prime mover should occur, as the energy stored in a heavy rotor revolving at a high speed may be sufficient to cause very serious damage.

---

[1] Cowley and Levy, *Phil. Mag.*, 1921, xli. 592.

[2] *Ibid.*

In order that accurate measurements may be made, it is essential that the dynamometer should apply the load extremely steadily, otherwise violent oscillations will be set up rendering the employment of heavy dash pots necessary, which is undesirable.

The variation of load with speed for the same setting of the apparatus should be such that "hunting" of the load is eliminated.

(i.) *Absorption Dynamometers.*—In these the energy generated is converted either into heat by the intermediary of solid or fluid friction, or into electrical energy by means of a generator.

The apparatus in most common use is the fluid friction brake, this being simple in construction, easy to regulate over a wide range, and extremely steady in action.

The solid friction brake for large powers requires considerable experience in manipulation in order to avoid unsteadiness due to violent snatching of the load. In its simplest form for small powers, that of the rope brake, it is a very efficient and accurate brake and runs very steadily if proper precautions are taken.

(ii.) *Transmission Dynamometers*, for the measurement of power transmitted by a shaft, exist in three fairly common forms, viz.:

(1) Torsionmeters, in which the angle of twist of a length of the shaft due to torsional stress is measured either optically or by mechanical means.

(2) Torque-meters, in which the torque load is transmitted by springs, or by hydraulic plungers, the extensions of the former and the fluid pressure set up by the latter being indicated or recorded.

(3) Instruments for measuring the power transmitted by means of a belt on the shaft of the prime mover.

The last vary considerably in form but the object achieved is the same in each case, viz. the measurement of the difference in tension of the belt on either side of the driven pulley.

Another important form of the transmission dynamometer is the traction meter for the measurement of the tractive effort of self-propelled vehicles. Dynamometers have been designed for measuring and recording the tractive effort of locomotives, motor cars, and traction engines and the tractive resistance of railway carriages, wagons, wheels, and ploughs.

§ (2) ABSORPTION DYNAMOMETERS. (i.) *The Prony Brake.*—In its original form this brake consisted of two stout beams of wood clamped upon the shaft or on a pulley fixed thereto. The beams were suitably bored in order to grip a large proportion of the circumference of the shaft, and the nuts on the clamping bolts served as a means of adjusting the frictional resistance between the shaft and the brake. A horizontal arm, usually an extension of the upper beam, supported a load pan on which the weights were hung, a fine adjustment being provided by a jockey weight, the position of which could be adjusted along the beam. The movement of the end of the arm was confined within small limits by rigid stops, one above and one below the arm. *Fig.* 1 shows diagrammatically the arrangement.

Very liberal lubrication of the frictional surfaces was necessary to ensure smooth running, but at best considerable vibration of the arm took place due to the variation in frictional resistance between the brake and the shaft, the end of the arm oscillating violently between the stops and rendering a good balance difficult to obtain.

The torque T exerted by the shaft when the brake is balanced is represented by FR where F is the frictional resistance between the brake surfaces, and R the radius of the surfaces; it is measured by the algebraic sum of the moments of the load, jockey weight, and the brake beams about the centre of the shaft.

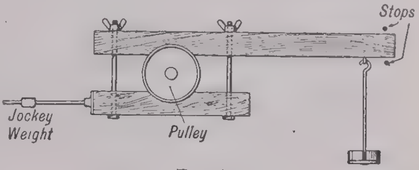

FIG. 1.

In calculating the horse-power developed the factor ϕ is required and is obtained by means of a tachometer or by revolution counter and stop watch.

The rate at which work is absorbed is expressed by

$$\text{Horse-power} = \frac{2\pi TN}{550},$$

where N is the speed in revolutions per second, and T the torque as measured by the brake in pound feet units.

(ii.) *Modifications of the Prony Brake.*—Several improvements and modifications have been made on the original brake as first used by Prony. They consist chiefly in arranging that the grip of the brake blocks shall automatically alter with the value of the coefficient of friction, thus maintaining the total frictional force and therefore the value of T more or less constant.

The Appold brake is shown in *Fig.* 2 and is an example of one of many compensating brakes. The wooden blocks forming the brake are connected together by a steel band provided with a hand adjusting screw at A, the ends of the steel band being connected to the compensating lever at B and C as shown. The end of the lever D is pivoted to the engine frame. The load is supported, as shown, from a hook attached to the steel band, a pointer being provided to indicate when the hook is level with the centre of the shaft.

In the normal position the hook is opposite the pointer and the lever BD is vertical. When the load is lifted, the lever moving about D as centre rotates with the steel band and virtually increases its length, thus slackening the band and partly relieving the load.

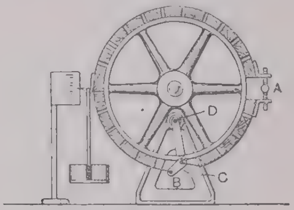

FIG. 2.

If the load falls, due to the coefficient of friction decreasing, the compensating lever shifts round in the opposite direction, tightens the band, and thus increases the grip and lifts the load.

In practice it is found that nearly as much adjustment of the load is required as without the compensating device, but the chief objection to the brake is that when a heavy torque is being measured the lever reacts on the frame with sufficient force to cause an appreciable error in the result obtained if the ordinary method of calculation is adopted.

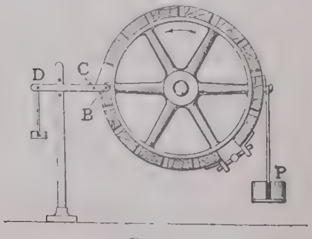

FIG. 3.

A better form of compensating brake, but one perhaps not so well known, is that designed by Mr. Balk and originally used by Messrs. Ransomes Sims and Jeffries. It is shown diagrammatically in *Fig.* 3.

The compensating lever is here outside the disc of the brake wheel, and is connected at B and C to the ends of the strap and the load pan is hung from the point D. Suitable stops are provided for the lever. The weight of the brake adjustment load must be taken into consideration in determining the torque: it must be considered as acting at a radius equal to its horizontal distance from the centre of the shaft, and its moment must be deducted from that of the load P.

Solid friction brakes may be used to absorb greater powers if the wheel is water cooled. The major portion of the energy which is converted into heat is thus quickly disposed of, and one of the chief sources of trouble, namely overheating, is then removed. After a preliminary period of running with water cooling the brake blocks assume a more constant frictional resistance, rendering the brake much steadier to run.

Water cooling of the wheel is very simply effected by making the rim of the brake wheel of trough section, thus enabling it to hold water when revolving by virtue of the centrifugal forces called into action. Water is supplied by a pipe dipping into the trough at the bottom of the wheel, the end of the pipe being turned in the direction of rotation. The outlet pipe is usually flattened at the end which is directed against the stream of water which passes round with the wheel and out through the discharge pipe.

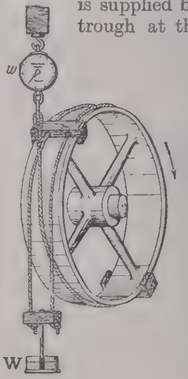

FIG. 4.

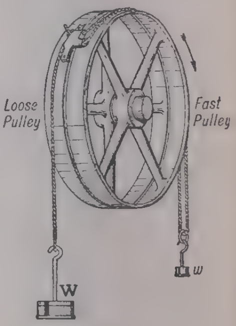

FIG. 5.

The flow is adjusted until a reasonable steady temperature is attained.

(iii.) *Rope Brakes.*—For small powers the rope brakes introduced by the late Lord Kelvin and Professor James Thomson are very successful. The former is illustrated in *Fig.* 4 and the latter in *Fig.* 5.

Lord Kelvin's brake consists of a loop of rope wrapped round the fly wheel of the prime mover, one end of the loop supporting a weight W, the other being held vertically by a spring balance. Wood blocks are secured to the ropes in order to keep them properly spaced to prevent the ropes from rubbing together where they leave the wheel tangentially. The wood blocks are not used as brake blocks.

If the wheel turns in the direction of the arrow the torque is represented by $(W - w)R$, where w is the force indicated by the spring balance and R the radius from the centre of the wheel to the centre of the rope.

When the value of the frictional force changes, the load rises or falls against the action of the spring balance, the brake thus adjusting itself to the new condition.

In using the brake it is advisable to have the ropes and wheel rim either perfectly free from grease, by using new rope and cleaning the wheel rim with petrol, or else thoroughly greased.

If the lubricant is scanty or in patches the weight will hunt, rising and falling regularly, rendering it difficult to obtain a reading of the spring balance with any degree of accuracy.

The brake of *Fig.* 5 consists of fast and loose pulleys mounted side by side on the driving shaft. It is arranged that a rope dipped on the loose pulley hangs down over the fast pulley on one side and over the pulley to which it is fixed on the other.

The frictional resistance between the fast pulley and the rope causes the loose pulley to rotate through a small angle in the direction of rotation of the shaft, and in doing so it lifts a weight suspended by the rope hanging over it. At the same time the rope over the fast pulley, which also supports a weight, is, by the rotation of the loose pulley, slightly unwound from the running pulley, thus reducing its arc of contact, and, therefore, its braking effect. The resistance is thus automatically adjusted.

It should be noted that solid friction brakes, in consequence of the frictional resistance being practically constant over a wide range of speed, cannot be successfully employed for the measurement of power generated by a prime mover such as a petrol motor in which the torque also remains constant over the same range of speed.

In such a case it is extremely difficult to maintain the speed of the prime mover at even an approximately constant value, and the brake needs continuous attention if steady values of the power are to be obtained.

(iv.) *The Froude Water Brake*[1] (*Fig.* 6).—This brake is of the fluid friction type and is very extensively used both commercially and in the laboratory. It consists of a wheel or rotor attached to a driven shaft revolving inside a casing through which water is circulated. The casing is mounted on trunnions which enshroud the shaft at either end but are free from it, and it is free to rotate through a small angle in either direction in bearings offering very little frictional resistance. On both sides of the brake wheel are formed semi-elliptical annular channels divided into 24 pockets by narrow oblique partitions or vanes which are approximately semicircular discs inclined at an angle of 45° to the axis. The vanes on one side of the rotor are inclined at right angles to those on the opposite side, but are also at 45° to the axis. The faces on the inside of the brake casing are formed in the same manner as those of the rotor, the vanes being in the same planes as those on the adjacent rotor face completing the formation of the circular disc inclined at 45°. The number of pockets in the rotor and stator differ by one on each side. The pockets between the rotor and casing thus form complete annular channels of elliptical cross section divided into sections by the vanes. There is only a very small clearance between the faces of the rotor and the casing.

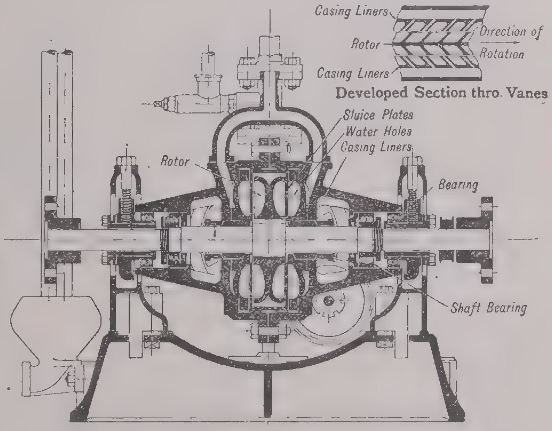

FIG. 6.

The formation of the channels and vanes is shown in detail in the developed section of rotor and casing in *Fig.* 6, the section being made by a cylinder passing through the water holes shown in the principal section.

It will be seen that the vanes are inclined at an angle of 45° to the direction of motion, and that those on opposite sides of the centre line are at right angles to each other.

The difference in pitch of the vanes which may be observed is due to the difference in the number of vanes in the rotor and casing respectively.

If, in the view shown, the rotor be moved until one of its vanes comes into line with one of the vanes of the casing, then the line thus formed is a section across a diameter of an approximately circular disc, one half of which is formed by the rotor and the other half by the casing. The circular disc viewed along the direction of motion has the elliptical appearance shown in the principal sectional view.

---

[1] See also "Hydraulics," § (61).

When the shaft is rotated, centrifugal action sets up vortices in the pockets in a plane at 45° to the axis, and the wheel and case are thus urged in opposite directions also at an angle of 45°.

The components of the forces produced are balanced in the direction parallel to the shaft due to the arrangement of the vanes on opposite sides of the centre line, but tangentially they react on the casing. The moment required, therefore, to prevent rotation of the case is equal to the torque on the shaft. The water which is supplied continuously to the brake, when running, passes from pocket to pocket, at the same time rotating at a high rate of speed, finally emerging at a temperature which can be regulated by the supply valve.

The brake is regulated by means of thin sluice gates or plates, inserted between the channels in the rotor and casing. The resistance offered by the brake for a particular setting of the plates varies approximately as the square of the speed, so that the brake is well suited for testing under conditions of constant torque.

The stator case is provided with bearings and packing glands where the shaft passes through it, but the friction of these reacts on the casing and is measured. The case is also provided with a torque arm supported by a spring balance, which in turn is suspended from a hook which can be adjusted in a vertical direction in order that the torque arm shall remain horizontal. The load is hung at the end of the torque arm directly under the spring balance, and the effective torque load is obtained by taking the difference of the load and the spring balance reading.

The effect of the sluice gates is to reduce the effective surface, thus increasing the range of service. The capacity of a dynamometer absorbing 800 horse-power at 800 revolutions a minute can be adjusted to absorb 40 horse-power at 200 revolutions per minute.

(v.) *Electrical Brakes. The National Physical Laboratory Dynamometer.*—In this brake the power developed is absorbed electrically but measured mechanically. The electrical measurement of the power depends in some measure on the accuracy of the instruments employed and on the temperature of the field magnet and armature windings of the generator.

The prime mover under test is coupled direct to the shaft of a generator, the outer frame of which is mounted on bearings offering small frictional resistance, and the torque on this frame is measured. The power generated is carried by very flexible cables to resistance mats by which it is dissipated as heat.

Fig. 7 shows the method of supporting the field magnet frame. The latter is provided with hard steel rings A at either end, these rings being ground truly concentric with the axis of the shaft and securely fixed to the frame.

The rings rest on the sectors B, B, which are also of hard steel ground truly cylindrical on the curved surface with the knife edge as centre. The sectors support the whole weight of the generator, which being thus mounted can oscillate through a small arc with extremely little resistance to motion.

Ball bearings mounted on vertical posts are provided at each end of the generator frame, bearing against the sides of the steel rings to limit the end motion and to take the thrust should the frame inadvertently be moved too far in a longitudinal direction.

The frame is provided with torque arms, one on either side, so that the torque can be measured when the brake is running in either direction.

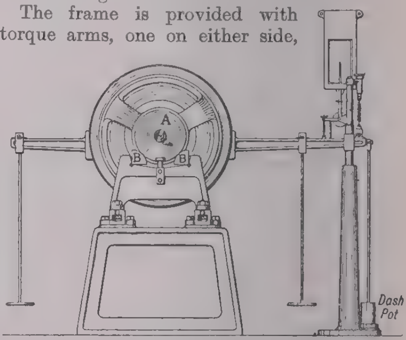

FIG. 7.

The torque arms are balanced, and one is provided in the usual manner with stops to limit the angle of oscillation.

The load is hung from a knife edge on one of the arms, a fine adjustment being obtained by means of a spring which partly relieves the load. It is arranged that extensions of the spring are magnified and indicated on a moving sheet of paper so that the variations in torque of the prime mover under test are recorded. The paper movement is effected by a clock mechanism, and indications of speed are also recorded electrically.

The arrangement of the recording instrument is clearly shown in the figure.

As in the case of the Froude water brake, the bearing friction, and incidentally the brush friction, is measured at the torque arm, so that the method affords an accurate means of measuring power. It has the disadvantages of having a small range of power and speed, and a heavy rotor, but these are somewhat compensated for by the fact that the generator can be used as a motor either for starting an internal combustion engine or for supplying power to a machine whose torque resistance is required to be measured.

It is estimated that, under steady conditions of running, determinations of torque can be made on this dynamometer to an accuracy of 0·1 per cent.

(vi.) *Eddy-current Brake* (*Fig.* 8).—A very successful form of eddy-current brake has been developed by Dr. D. K. Morris and G. A. Lister, and is described fully in a paper to the Birmingham Local Section of the Institution of Electrical Engineers, 1905.

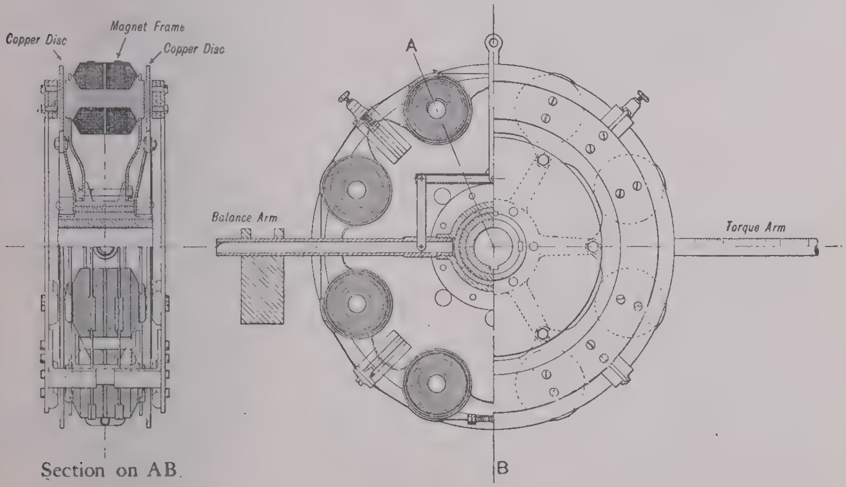

Fig. 8.

The brake was designed to absorb 5 horsepower at 1000 revolutions per minute, and made for use in the Electrical Laboratory of the University of Birmingham.

The apparatus is made for attachment to the shaft of the prime mover in place of the ordinary pulley, and consists of two elements, one in the form of copper discs fixed to and concentric with the shaft, and the other a circular frame also concentric with the shaft and carrying magnetising coils at regular intervals round its periphery.

The magnet frame, or stator, is centred by a revolving bush securely keyed to the shaft and is provided with a torque arm, jockey weight, and stops, in the usual manner.

Two copper discs are provided on the rotor, and are fixed to the revolving bush one on either side of the magnet coils, the axes of which are parallel to the shaft axis, and by this arrangement both electrical symmetry and mechanical balance are assured and the brake is rendered astatic.

The shaft is partly relieved of the weight of the frame by a link suspension attached to an overhead spring balance, and this method of suspension enables the frame to be supported without producing a twisting moment about the shaft centre.

The overhung load on the shaft can be varied as desired by adjusting the tension of the support.

The air gap between the copper discs and the field magnet poles is fixed, and the rigidity of the construction enables it to be made small. External yoke rings are provided and are supported by brackets from the magnet frame, the brackets being clamped in such a manner that the external gaps between the yoke rings and the copper discs can be adjusted.

The limit of the capacity of the brake is determined by the temperature of the magnet coils.

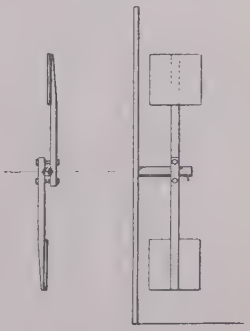

Fig. 9.

(vii.) *Fan Brakes. The Centrifugal Fan* (*Fig.* 9).—The Centrifugal Fan Brake usually consists of two square or rectangular plates held by radial arms in such a manner that they are presented normally to the direction of motion. The brake is more frequently used as a ready means of applying a load to a shaft rotating at a high speed than as a means of measuring torque. It is necessary that it should be calibrated by means of an accurate dynamometer, but the calibration is affected by variations in temperature and pressure of the surrounding atmosphere, cross-currents of air, and the proximity of supports, adjacent walls and floor, and of the prime mover under test.

The load is adjusted either by moving the plates along the radial arms or by fitting plates of a different size, these methods of adjustment having the great disadvantage of necessitating the stoppage of the prime mover under test.

Attempts to render the blades adjustable during rotation have met with little success, owing chiefly to the difficulty of designing the adjusting mechanism to operate against the centrifugal forces acting on the blades.

The torque due to the blades alone, for ordinary speeds and sizes, varies as the square of the speed, the cube of the radius of the blades, the area of the blades, the density of the fluid in which the fan is working, and on a factor depending on the environment.

The fan brake is cheap to manufacture and is usually easy to fit to the shaft of the prime mover. For these reasons it is frequently used commercially as a brake for "running in" and "endurance" tests where the power absorbed is not required to be known with accuracy. It may be used for comparative tests provided the atmospheric conditions and the environment remain constant throughout the tests, but neglect of these factors may effect an error of 10 to 20 per cent in the measured torque.

(viii.) *The "Escargot" Fan Brake for testing Aeronautical Engines.*—In order to reproduce as far as possible the cooling effect produced on an aeronautical engine under flying conditions, it is essential that the engine under test shall work in a current of air projected on it at a speed comparable with the flying speed.

The cooling is effected in the escargot arrangement by a fan brake driven by the engine under test and mounted in a chamber resembling that of an ordinary fan casing.

The intake of the air is in the side of the casing opposite the fan centre.

Rotary or radial engines are usually mounted inside the escargot, *Fig.* 10, being then in the direct path of the incoming current of air.

Vee or vertical engines are fixed on a bed outside the fan chamber, and the air from the discharge orifice is directed on to the engine either from above or from the front.

In the latter arrangement the fan is driven through an intermediate shaft and universal couplings.

For "running in" and "endurance" tests the brake may be calibrated by means of an electric motor, but is open to the objections which have already been summarised under the heading of the "Fan Brake." For tests of greater accuracy it is usual to mount the engine on a floating torque-balance gear by which the reactive torque on the engine may be measured.

When the engine is so mounted it is essential, if accurate results are to be obtained, that the axis of the rocking frame shall coincide with the fan axis, otherwise the moment measured will differ considerably from the true torque according to the position of the fan in the escargot.

§ (3) Transmission Dynamometers. *Torsionmeters.*—In cases where it is desired to keep a check on the power developed by a prime mover, or where the absorption of the power cannot conveniently be effected, a transmission dynamometer is employed. This instrument exists in several forms of torsionmeters, the function of which is to measure the angle of twist in a length of the shaft driven by the prime mover, and from this measurement, by previous calibration or by calculation, the torque is deduced.

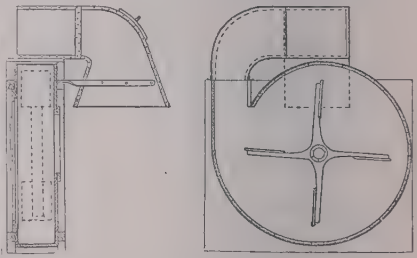

Fig. 10.

(i.) *Hopkinson-Thring Torsionmeter* (*Fig.* 11). —This instrument was designed by Professor Bertram Hopkinson and Mr. Thring for the determination of the power transmitted by turbine shafts, and is used to a very large extent on steamships. The principle of the apparatus is the measurement of the relative angle of twist between adjacent sections of the shaft and the indication of this movement on a fixed scale. The length of the shaft taken up by the instrument is very small, being, for sizes over 8 inches diameter, about three diameters long, and for smaller shafts about four diameters.

The instrument consists essentially of two flanges clipped to the shaft at a measured distance apart. A sleeve enclosing the shaft connects the two flanges, being formed solid with the one but free to rotate through a small angle on the other, by which it is retained concentric with the shaft. The twist of the latter causes relative angular motion between the free end of the sleeve and the flange adjacent to it, and this motion is indicated on a fixed scale by means of a mirror.

The mirror is mounted on trunnions working in bearings fixed to the flange, the axis of the trunnions being radial. The mirror is provided with a short radius arm which is connected to an adjustable block on the sleeve by a thin phosphor-bronze link. The tangential movement of the sleeve block is governed by a micrometer screw in order that the relation between the movement at the radius of the mirror from the centre of the shaft and the spot of light on the scale may be ascertained.

A fixed mirror is attached to one of the flanges, which is adjusted so that the spot of light reflected from it is received at the same point on the scale as that from the movable mirror when there is no torque on the shaft.

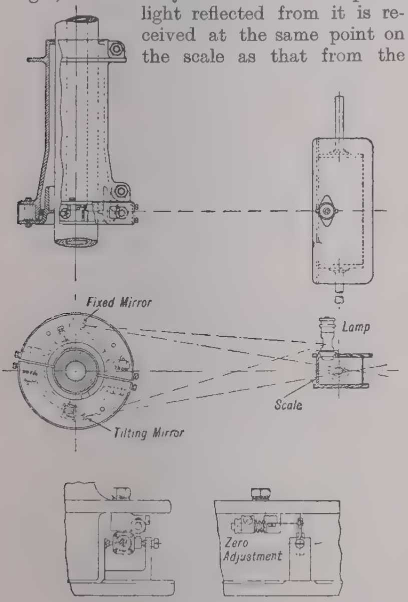

FIG. 11.

An electric lamp fixed just above the scale provides the beam of light which is reflected from the two mirrors on the scale successively as the shaft rotates.

A shift of the apparatus relative to the scale is indicated by an alteration of the position of the beam reflected by the fixed or "zero" mirror, and this can readily be adjusted by moving the scale.

The moving mirror is silvered both back and front so that two reflections, one on either side of the zero, are received from it during one revolution of the shaft. The mean of the two readings may thus be taken whatever the position of the zero.

The instrument may be calibrated directly by applying a known torsion to the shaft and noting the reading of the scale, or by calculation from a knowledge of the torsional rigidity of the shaft and the various leverages and distances involved in the conversion of the twist to the movement of the spot of light on the scale.

The apparatus gives an instantaneous reading of the torsion in the shaft at a particular angular position in the revolution, the angle being fixed by the positions of the mirrors and scale.

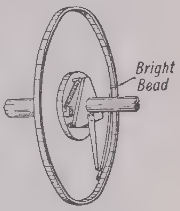

FIG. 12.

The torsion at any other part of the revolution may be obtained by mounting the scale on a circular frame concentric with the shaft and shifting the scale and lamp to the angular position required.

(ii.) *The Ayrton and Perry Torsionmeter* (*Fig.* 12).—This dynamometer is designed for use in the place of the ordinary shaft coupling, which purpose it also serves. The two halves, one on each shaft, are connected by means of helical springs, three or four in number, arranged in a position approximately tangential to the shaft. When power is transmitted, the drive is taken through the springs which extend under the load. The stretch of the springs allows relative angular movement between the shafts, and this is indicated by a lever arrangement which has the ultimate effect of reducing the distance of a bright bead from the shaft centre. The radial position of the bead is observed against a black disc on which a scale is marked.

The apparatus is calibrated directly or by calculation from the stiffness of the springs and the magnification of their extension which has been employed. Calibration against an absorption dynamometer is preferable if it is thought that the arrangement of the springs adopted is likely to give different calibrations statically and dynamically.

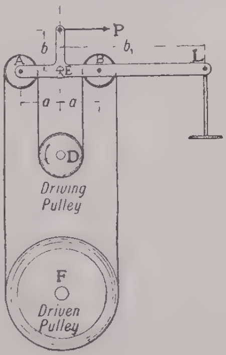

FIG. 13.

§ (4) THORNYCROFT OR FROUDE BELT DYNAMOMETER.—The arrangement of this transmission dynamometer is shown in *Fig.* 13. The pulley D, fixed to the shaft of the prime mover, drives the pulley F by means of a belt which passes in turn round the two pulleys A and B. The latter are supported by a frame ABL which is pivoted at E. It is obvious that the downward force on the pulley A will exceed that on the pulley B by twice the difference in tensions of the tight and slack sides of the belt on either the driving or driven pulley. The frame ABL will therefore tilt downwards at A, but its symmetrical position is restored either by a force at P, or by adding weights to a scale-pan hung on an extension of the arm AB at L. The motion of the end of the lever is confined within small limits by means of stops.

The belt tension difference is expressed by $T = Pb/2a$ and the horse-power developed by $H.P. = 2\pi TRN/550$, where R and N are the radius in feet and speed in revolutions per second respectively of the driven pulley.

The power is not transmitted entirely without loss because of the slip of the belt and the pulley bearing friction. These losses, however, can be determined by independent dynamometer tests.

§ (5) Dynamometer Cars and Traction Dynamometers.—Many instruments have been designed to measure the resistance of vehicles to traction and also the tractive effort of self-propelled vehicles. The pull is usually transmitted through either a small plunger or diaphragm, in which case the pressure set up in a liquid column is recorded by means of a pressure gauge, or through helical or laminated springs the deflection of which is indicated on a scale.

(i.) *The British Association Apparatus.*—Some of the earliest tests in this country were carried out with a special dynamometer, designed for the British Association, for the measurement of the resistance of road vehicles to traction.[1]

The apparatus comprised a castor frame in which could be mounted a single wheel on which the experiments were to be made, a system of levers for transmitting to a small plunger the pull exerted on the wheel, a recording pressure gauge for registering the pull, and a recording speedometer.

The castor frame was of wrought iron and rectangular in shape, and was adapted to take wheels of various widths. The axle of the experimental wheel was mounted on springs, one under each side of the frame. The springs used were of the ordinary laminated carriage type constructed in such a manner that their stiffness could be adjusted by varying the number of plates forming a spring. The frame was loaded by cast-iron weights fitting over the castor frame.

An attachment was made to the levers transmitting the pull by a swivel joint which allowed the frame to oscillate vertically and to follow freely round a curve without affecting the records, but so held it that the wheel always remained vertical. The fulcrum of the lever could be moved to either of four positions such that the pressure on the plunger was equal to, or two, four, or eight times the pull exerted on the frame. The range of the apparatus could thus be varied from 5 to 500 lbs.

The record of pressure and speed was made by pencils on a sheet of paper which was rotated by a roller the motion of which was obtained through gearing from the road wheel.

(ii.) *The Hyatt Instrument.*—This dynamometer has been specially designed for the determination of the draw-bar pull of farm tractors and the tractive resistance of ploughs working under various conditions.

The pull is transmitted from the tractor to the plough through a link or chain and a piston working in a cylinder. The latter contains a rubber bag containing liquid which is compressed by the piston. This pressure unit is hitched in one of three different ways giving different ratios between the pull and the pressure on the rubber bag. The three hitches correspond to maximum pulls of 300, 600, and 1200 lbs. respectively.

The recorder consists of a Bristol recording pressure gauge. It is connected to the pressure unit by a flexible metallic tube which conveys the liquid under pressure from the rubber bag to a Bourdon pressure tube which actuates the pen mechanism. A needle valve, inserted in the pressure tube, may be adjusted to control the flow of liquid and to damp out excessive vibrations of the pen.

The chart is a circular sheet of paper divided by a series of concentric circles across which the pen travels in an approximately radial direction from the centre outwards with increasing pull.

The chart is caused to rotate by a wheel which rolls over the ground and which is connected to the recording instrument by a flexible shaft and suitable gearing. The circumference of the chart is divided into equal parts each representing a distance travelled of 100 feet.

A second pen records the elapsed time on an annular space at the edge of the chart. A clock in the recorder case, fitted with a cam, trips the time pen at one-minute intervals, and fractions of a minute may be estimated by counting the number of smaller spaces over which the pen has travelled. The division is accomplished by dividing the annular space by a number of concentric circles and by causing the time pen to travel from the outer to the inner ring in the minute interval, after which it is again tripped back to the outer ring, its path being practically a radial line.

The recorder is lightly built and is provided with straps by which it is carried by an assistant during a test. It is arranged that the rolling wheel may either be clipped to the tractor or guided by hand.

---

[1] British Association Report, 1902.

From the chart obtained, the draw-bar pull, the distance travelled every six seconds, and the speed during the test may be deduced.

(iii.) *The National Physical Laboratory Tractor Dynamometer Car.*—This apparatus was constructed solely for measuring and recording the tractive effort of farm tractors, for which purpose it has been successfully used. The car employed was a heavy four-wheeled lorry trailer, the rear wheels of which were fitted with speeds and band brakes, the latter being operated by a hand wheel from the front of the vehicle. The apparatus was mounted on an extension of the bogie frame carrying the wheels of the trailer.

The pull of the tractor was converted to pressure on a leather diaphragm by means of a bell-crank lever suitably pivoted, the diaphragm being faced on the pressure side with a rubber disc to prevent leakage of the liquid in the diaphragm box through the leather. A flexible hydraulic pipe connected the diaphragm casing to a Bourdon pressure tube operating a pen mechanism, and a record of the pressure was thus obtained on a roll of paper. The latter was caused to move proportionally to the distance travelled by the car, the driving drum being rotated by means of gearing and a flexible shaft from the leading road wheels.

Two other pens were also provided, one operated by a clock in order to give time indications every two seconds, and the other operated through gearing and giving indications of the revolutions of the tractor engine.

The diaphragm box, to which was attached the fulcrum of the bell-crank lever, could be adjusted vertically so that the rope or chain connection to the tractor could be arranged horizontally.

In carrying out a test, the brakes of the car were adjusted, and the car loaded with dead weights, until either the engine of the tractor was pulled up or the driving wheels began to slip. Thus the maximum pull of the tractor on the particular surface chosen for the tests was obtained.

(iv.) *Railway Dynamometer Cars.*—Dynamometer cars have been constructed for traction tests on locomotive engines and tractive resistance tests on railway rolling stock. The car usually takes the form of a special coach, the draw-bar pull and buffer thrust being recorded, with the speed, on a paper-covered drum driven through gearing from one of the road wheels.

A most successful car of this type is that designed by Mr. George Hughes for the Lancashire and Yorkshire Railway Company. The various instruments with which this car is fitted enable complete records of the performance of the locomotive to be taken, including draw-bar pull (or push) speed, acceleration or retardation, and boiler pressure of the locomotive.

Other factors influencing the performance are also indicated on the chart by observers.

Considerable care and experience is required in the design of a car of this kind, and the more salient features of the Lancashire and Yorkshire Railway car are here described for the first time by the courtesy of the Chief Engineer of that Company.

(v.) *The Lancashire and Yorkshire Railway Company's Dynamometer Car.*—The draw-bar pull and the thrust on the buffers of the car are transmitted to two compound springs, one being provided for the pull and the other for the push. Each is made up of a number of independent plates bound together by a pair of buckles at the centre and connected by links at the ends. The link pins can be withdrawn separately as desired, and this enables the number of plates in operation to be adjusted to suit the load hauled, from a single coach to the heaviest train, utilising the full deflection of the springs.

The spring deflection is recorded directly on the record paper without the intervention of levers, showing draw-bar pull above, and buffer thrust below, a datum line.

The external carriage coupling arrangements are standard practice so that the car can be coupled up as readily as any other vehicle.

The draw-bar and buffers are connected to a rigid frame which moves each set of springs in one direction only so that the tightness of the screw shackle between the engine and the car does not affect their indications.

A compensating beam equalises the thrust on the buffers when negotiating a curve.

The draw-bar passes through a friction device which can be brought into operation to take the load off the springs when tests are not being made. The device is also used to absorb exceptional shocks during the last inch of deflection of the springs. A main cross-beam near the centre of the car under-frame forms a foundation for the springs and the instrument table.

The motion of the car is not recorded from the ordinary road wheels but from a special measuring wheel arranged between the leading and trailing wheels of the bogie, so that there is little lateral movement when rounding curves. The measuring wheel is pressed on the rail by a spring and can be raised or lowered as required. The motion is transmitted to the instrument table by worm gearing and flexible couplings forming a positive drive.

The instrument table carries the record paper drums, the speed gear which regulates the relative speeds of the paper and the train, a distance indicator, a work integrator, a recording and a visual speedometer, a standard electrical clock, and an inertia ergometer.

The record paper can be driven at speeds varying from six inches to twenty feet per mile travelled; a counter marks the paper every mile.

The work integrator consists of a disc rotated from the road wheel, and across the face of the disc a roller is moved by the extensions of the springs. The rotation of the roller is therefore proportional to the product of the draw-bar pull and the distance travelled, and this work is continuously recorded on the chart as a serrated diagram, each peak representing approximately 50 horse-power minutes per pair of springs in use. A counter gives the total positive, total negative, or algebraic sum of the horse-power minutes done by the draw-bar, as required.

The speed recorder works on a positive principle, namely, that the distance travelled in a definite time (4 secs.) gives a measure of the mean speed during the four seconds.

(vi.) *The Inertia Ergometer.*—This was introduced by Joseph Doyen, Chief Engineer of the Belgian State Railways, and is a combination of the Desdouits Inertia dynamometer (pendulum) and the Adbank-Abakanowicz integrating roller. The pendulum is mounted on knife edges and swings in the direction of motion of the car. The tangent of the angle of the pendulum with its neutral position is proportional to the algebraic sum of the force of gravity and the force producing change of velocity (acceleration or retardation). The integrating roller multiplies this force by distance and the result is indicated on the record paper as an inclined line. The change in the ordinate of this line represents the change in the algebraic sum of the potential and kinetic energy per unit mass of the train. When coasting free, the loss of energy recorded is due to train resistance, and is therefore a direct indication of it.

By means of a run made up of alternate haulings and coastings the ergometer provides data from which the work done by the prime mover can be calculated. By combining this information with that of the draw-bar integrator the locomotive resistance, train resistance, total resistance, and accelerative effect of the locomotive can be obtained for any speed.

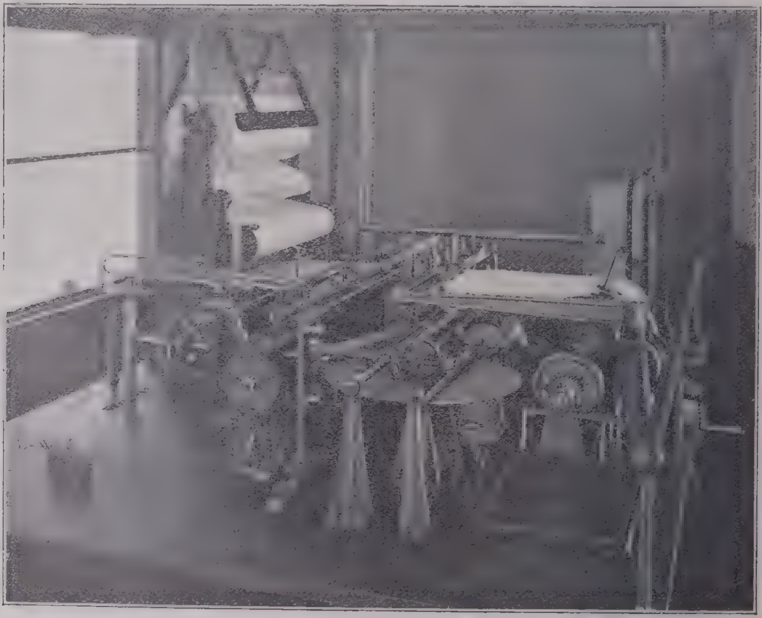

Fig. 14.

Curvature of the track is indicated and has been found to account for many peculiarities in the diagrams obtained. *Fig.* 14 is a general view of the instrument table. The work integrator is shown in the centre foreground; the lever from the draw-bar springs stands up through the central slot in the table and the pendulum lever through the slot on the left. The ergometer drum can be seen to the left of the top of the draw-bar lever. The clock is removed to expose the ergometer to view.

Fig. 15 is a specimen, reduced in size, of the chart obtained for a run of approximately six miles.

FIG. 15.

(vii.) *The Swiss State Railway Car.*—Much of the apparatus fitted in this dynamometer car is in many respects similar to that of the Lancashire and Yorkshire Railway Company's instrument. The principal difference between the two cars lies in the method of measuring the tractive effort, which in the present instance is by the use of hydraulic gear. Undoubtedly the hydraulic dynamometer has distinct advantages over the spring type, provided it is carefully designed and accurately made.

The pull of the draw-bar is transmitted to a steel plunger working in a steel cylinder, both elements being ground so accurately as to render the use of packing unnecessary. The cylinder is filled with oil by which the pressure is transmitted to the recording instrument, and it is arranged that there is a very slow leak of oil between the plunger and the cylinder wall in order to provide lubrication for the former and to minimise its frictional resistance.

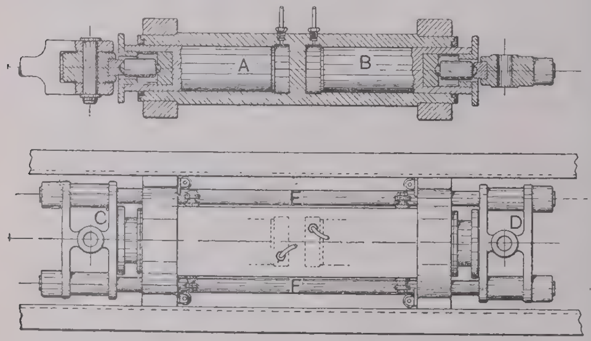

Fig. 16.

The arrangement of the pressure unit is shown in *Fig.* 16. There are two plungers, indicated at A and B, fitting into cylinders which are placed back to back and formed in a solid forging. The draw-bar pull is transmitted to one of the plungers, and the buffer thrust to the other, by means of the crossheads C and D and the rods E and F. The latter are guided by rollers suitably supported by a rigid frame. The clearance spaces in the cylinders, behind the plungers, are connected by pipes to a distributing valve, and from thence to the recording mechanism.

The recorder consists of two small measuring cylinders arranged in tandem and provided with differential plungers opposed to each other. This arrangement provides that by a suitable setting of the distributor valve the resultant area of the plungers exposed to the oil pressure from the main cylinders may be varied in the ratio of 1 : 2 : 3 : thus by rotation of the distributing valve it is possible to select either of three scales for recording the load.

A calibrated helical spring is fitted between the two differential plungers and is compressed by their motion. The compression of the spring is a measure of the resultant end force on the plungers and, therefore, of the difference between the draw-bar pull and buffer thrust, and this motion is transferred directly to the record paper by a rod carrying a style.

During prolonged runs the slow leakage past the main plungers may cause one of them to touch the base of its cylinder, but before such a condition can arise an equalising valve is brought into operation which has the effect of equalising the pressures in the two cylinders and restoring their central positions as shown in the figures. Fresh oil is drawn into the cylinders from a reservoir, through a non-return valve, when required.

§ (6) SPECIAL DYNAMOMETERS. (i.) *The Daimler Lanchester Worm-gear Testing Machine.*—This machine was designed by Mr. F. W. Lanchester for the accurate measurement of the efficiency of worm-gearing. A diagrammatic sketch of the apparatus is given in *Fig.* 17.

The efficiency of modern worm gears for power transmission is of the order of 95 per cent, and, under the best conditions of loading and lubrication, as high as 97 per cent. With such efficiencies, separate determinations of the torques in the worm and worm-wheel shafts by any of the methods already described would be liable to give misleading results unless the accuracy of the measurement in each case was within a small fraction of 1 per cent of the true value. For example, in the case of a gear of 97 per cent efficiency, if the torques could be measured separately to an accuracy of 0·2 per cent, the experimental determinations of the efficiency might range from 96·6 to 97·4 per cent. It is evident, therefore, that the ordinary methods of torque measurement in which the error may be as much as 2 per cent are quite useless for the purpose, and that a method of much greater accuracy is required. The Lanchester machine measures, in effect, the ratio of the two torques, and the over-all efficiency of a worm gear with its bearings can be obtained within an accuracy of 0·2 per cent. Indeed, differences of efficiency due to such causes as change in the temperature of the lubricant can be easily detected.

Referring to *Fig.* 17, the gear box is supported in a cradle A in such a manner that it has freedom of motion through a small angle about two axes at right angles. The worm is driven by a shaft B through the intermediate shaft C, the latter being provided with universal couplings at each end. In the same manner the wheel shaft is connected to the bevel box E through the shaft D and the universal couplings FF. The load is supported by a bracket K fixed to the arm G, the axis of the arm being parallel to, and in the same vertical plane as, the worm-shaft axis.

The load is not fixed directly to the bracket but is carried by a slider from which it is hung: by a screw and nut device the distance of the load from the axis of the arm can be varied.

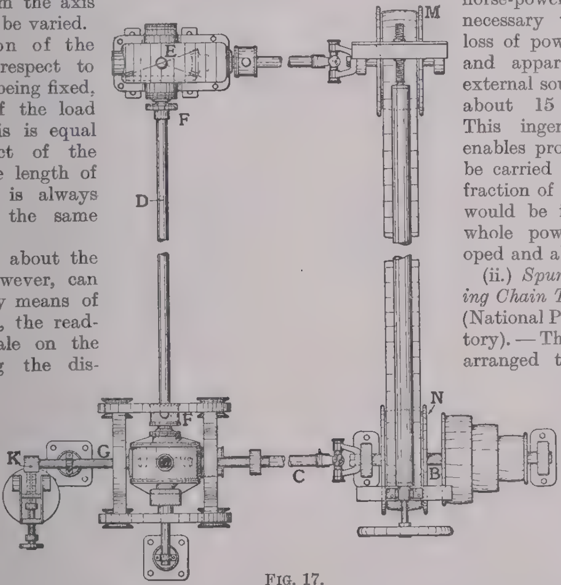

FIG. 17.

The position of the bracket with respect to the wheel axis being fixed, the moment of the load about that axis is equal to the product of the weight and the length of the arm, and is always the same for the same load.

The moment about the worm axis, however, can be adjusted by means of the screw gear, the reading of the scale on the bracket giving the distance of the weight from the axis.

It will be seen, therefore, that assuming the gear efficiency as 100 per cent, and the gear ratio as R, the speed of the worm being R times that of the wheel, the torque on the worm shaft will be 1/R times the torque on the wheel shaft. The load being the same for each torque, the distance of the weight from the worm axis will be 1/R times its distance from the wheel axis.

The efficiency of the gear being less than 100 per cent, the load must be moved farther from the axis of the worm in order to balance the gear box against the two torques when running under load.

The calculated distance of the weight from the worm axis, assuming 100 per cent efficiency, divided by the distance required to produce a balance, gives the efficiency of the gear.

The drive from the worm wheel is taken through the bevel box to the belt pulley M, the latter being of such a diameter that it tends to drive the pulley N on the driving shaft B at about 5 per cent higher speed than is established by the bevel and worm gears.

In other words, it is arranged that the peripheral speed of the pulley M is 5 per cent higher than that of the pulley N.

The belt connecting the two pulleys can be adjusted in tension, over a wide range, an increase in the tension producing an increase in the torque. By this means the pressure between the teeth of the worm and wheel can be made to correspond with the transmission through the box of as much as 150 horse-power, it being only necessary to supply the loss of power in the gear and apparatus from an external source developing about 15 horse-power. This ingenious principle enables prolonged tests to be carried out at a small fraction of the cost which would be involved if the whole power were developed and absorbed.

(ii.) *Spur Gear and Driving Chain Testing Machine* (National Physical Laboratory).—This machine is arranged to measure the difference of the torques of two shafts, together with the measurement of one of the torques separately.

It will be evident that the high degree of accuracy required in the Lanchester machine is not essential in the present machine.

Thus, supposing the true efficiency of a spur gear or chain drive is 97 per cent, and that the determinations of the torque and torque difference are each within 2·5 per cent of their true values, the estimated value of the efficiency of the transmission from the observations may range from 96·9 per cent to 97·1 per cent, which is of a higher degree of accuracy than that obtained by measuring the torque ratio to ± 0·2 per cent.

Fig. 18 shows the arrangement of the machine, The frame carrying the gears is entirely supported by horizontal knife edges, and both driving and driven shafts are considerably extended and provided with ball-bearing universal joints at each end. Being supported in this manner, the frame can execute small oscillations in a vertical plane about its neutral position.

The intermediate wheel is rendered necessary in order to secure that the reaction on the frame should be equal to the difference between the torques of the driving and driven shafts, and for this to be the case it is requisite that the shafts should rotate in the same direction.

The first and intermediate gears and the intermediate and the third gears form two pairs under test.

Fig. 18.

When a chain drive is under test no intermediate gear is necessary for the shafts to rotate in the same direction.

If no intermediate wheel were used in the gear test, the reaction on the frame would be equal to the sum of the torques of the two shafts, and the object which it has been attempted to achieve would be defeated.

The frame is provided with an oil dash-pot for damping its oscillations and a torque-arm scale-pan and spring for the torque difference measurement. Rigid stops are provided for the torque arm to limit its amplitude, readings being taken when the arm is level.

A Hopkinson-Thring torsionmeter is used to determine the torque on the driving shaft, and in carrying out a test an observer regulates the torque and maintains it at the desired value, whilst a second observer is employed with the torque measurement on the tilting frame.

The method of increasing the pressure between the gear teeth is on the same principle as that adopted in the Lanchester machine. This secures that only the loss of power needs to be supplied from an external source. The centre distance of the two shafts is made adjustable over a wide range to accommodate varying sizes of gears and lengths of chain drive.

During testing the tilting frame is totally enclosed in a light case and provision is made to spray the lubricant on the gears, the oil being supplied by means of a flexible pipe in such a manner that no control on the frame is exerted.

In testing spur gears the value of the torque T_2 on the last gear can readily be obtained from the observed data. The efficiency of a pair of gears is given, therefore, by $\eta = \sqrt{T_2/T_1}$, where T_1 is the measured torque on the driving shaft.

The efficiency of a chain is given by $\eta = T_2/T_1$.

(iii.) *Spur Gear-box Testing Machine* (National Physical Laboratory), *Fig.* 19.—In this machine the gear box is mounted in such a manner that it is free to oscillate about a mean position on the axis of the driving shaft, and the torque on the frame of the gear box is balanced and measured. The method can only be used in cases where the driving and driven shafts of the unit are coaxial and leave the box at opposite ends: this is usually the form of gear boxes for automobiles for which the apparatus was originally designed.

The unit under test is fixed in a rectangular frame provided with hollow trunnions coaxially with the main shafts. The trunnions are supported in ball-bearings so that the frame and gear box can tilt in either direction, the frame being fitted with a torque arm provided with the usual dash-pot, measuring spring, balance weight-pan, and stops to limit its motion.

The two shafts of the gear box are connected to a prime mover and an absorption dynamometer respectively, or the prime mover may be fitted as a dynamometer, in which case a steadily running brake only is required at the transmission end.

The method of test is very much more accurate than that of measuring the "input" and "output" torques, for in the latter arrangement, when the efficiency of the gear box is of the order of 97 per cent, no exact results can be obtained, because the errors in estimating the two torques directly affect the calculated efficiency.

Consideration of the two cases will show that in the latter, assuming the accuracy of both torque readings as ±1 per cent, the efficiency obtained will vary from 95 to 99 per cent if the actual efficiency is 97 per cent.

On the other hand, using the more accurate method, and assuming the accuracy of the dynamometer as ±1 per cent, as before, and that of the torque measurement on the gear-box frame as ± 2 per cent, the efficiency determination will vary between 96·9 and 97·1 per cent, *i.e.* a variation of only one-twentieth of the first method. In practice the accuracy of the measurement of the torque on the rectangular frame can be determined to about 3 per cent.

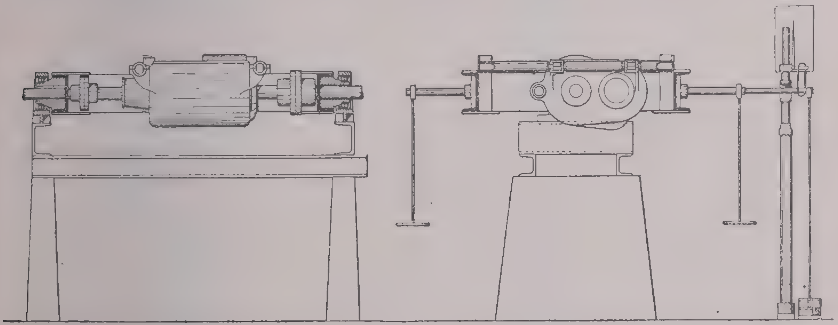

FIG. 19

The apparatus has been used to determine efficiencies under different conditions of lubrication, and differences due to temperature and quality of lubricant have been observed.

§ (7) AERIAL PROPELLER DYNAMOMETERS.—In order to accurately determine the performance and efficiency of airscrews, two dynamometers have been designed and made in the Aeronautics Department of the National Physical Laboratory.

The problem of the design of such an instrument involves the determination of the air speed relative to the propeller, the torque and the thrust, observations of each being made at the same instant of time.

In the two widely different forms described below experiments were made on scale model airscrews about one-sixth full size.

§ (8) WHIRLING ARM DYNAMOMETER.—A sectional drawing of the dynamometer is given in *Fig.* 20. The airscrew shaft is driven through flat coiled springs S, the extensions of the springs, proportional to the torque transmitted, being indicated by the relative displacement of a pointer over a drum which carries a slip of paper. The position of the pointer at any time during an experiment is recorded by passing a series of high-tension electric sparks through the paper so that the magnitude of the torque may be directly calculated from the known calibration of the springs. A pencil or pen could not be used for the indicator because of the difficulty of balancing the centrifugal forces called into play by the high speed of rotation and also the friction of the pen or pencil on the drum. Alternate torque springs are wound in opposite directions so that the forces produced by the tendency to unwind due to centrifugal action counterbalance each other; with this arrangement it was found that the static and dynamic torque calibrations agreed with each other. The airscrew shaft is allowed a small axial movement, and it is so supported that this movement takes place with extremely little friction. The end of the shaft bears against an oscillating lever, being directly controlled by the thrust spring *b*, the tension of which is adjusted by means of the micrometer screw *f* and two adjustable stops, both the latter being insulated electrically from the frame of the instrument.

When the thrust of the airscrew balances the pull of the spring the lever floats between the stops, but when the thrust is too great or too small contact is made with one or other of the stops and an indication is thus given by means of a galvanometer.

Oscillations in the torque springs due to small irregularities in the driving torque are damped by the oil dash-pot K. This consists of a series of concentric discs, alternate discs being attached to the sleeve carrying the inner ends of the springs and to the drum to which the outer ends are fixed. The oscillations are damped by the fluid friction between the discs.

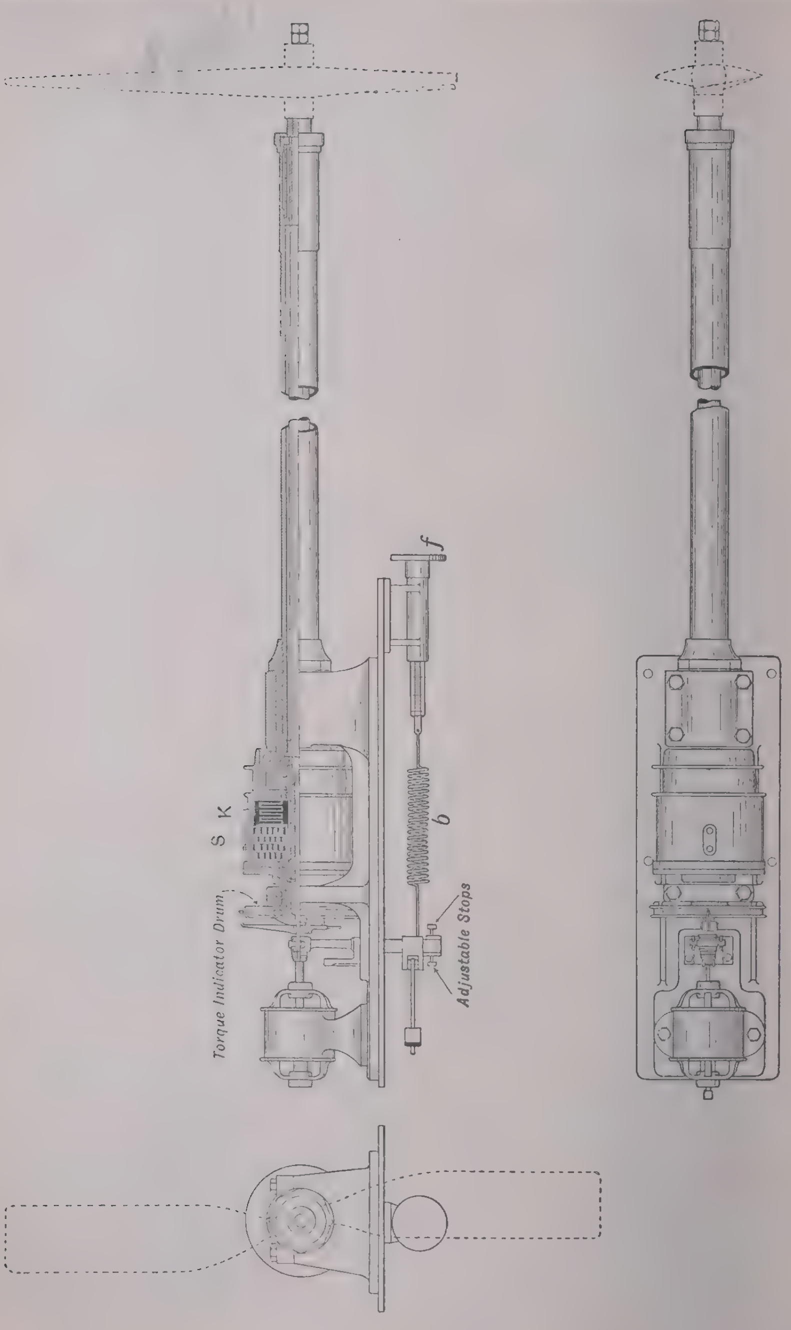

FIG. 20.

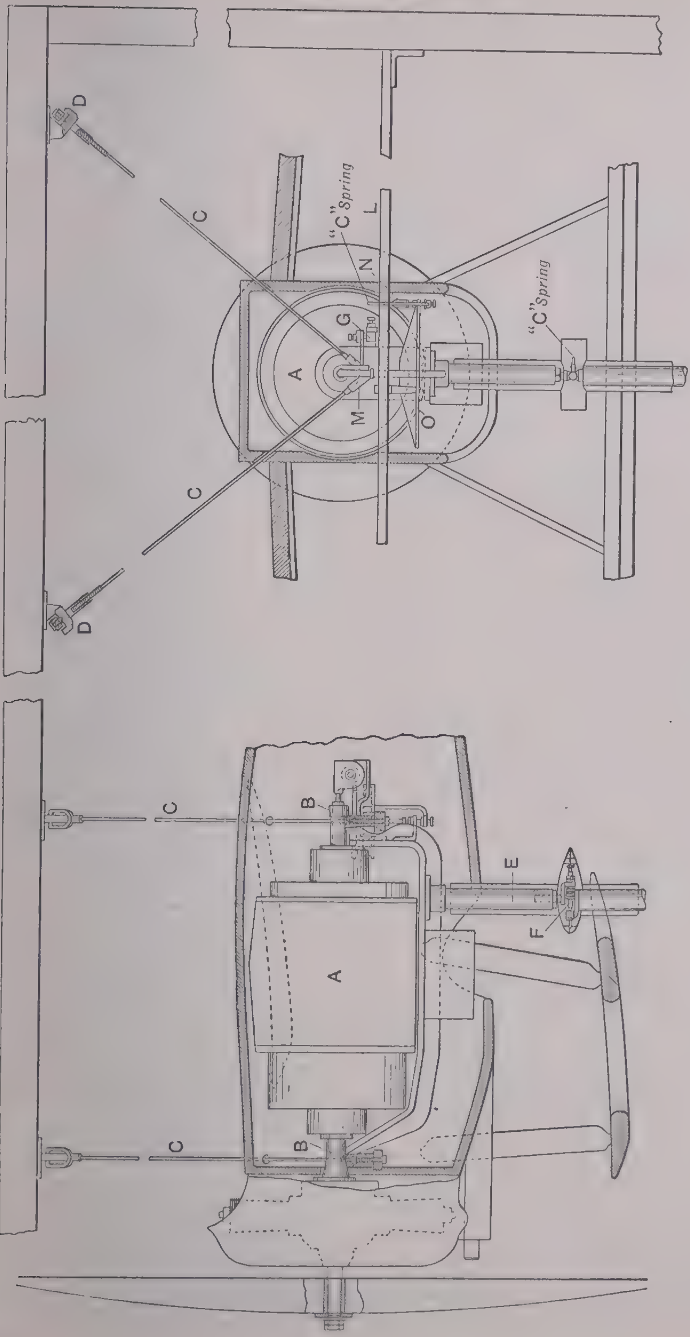

FIG. 21.

The apparatus is mounted on a whirling arm about 30 ft. in radius, and the centrifugal force on the airscrew has no component in the direction of the thrust. Certain forces due to centrifugal action are automatically balanced by suitably placed masses.

The airscrew speed is measured by means of the voltage obtained from a small electric generator driven by the propeller shaft, or alternatively by measuring the time elapsed for each hundred revolutions of the shaft. The speed of the apparatus relative to the air is obtained by means of a Dines tube. All electrical and air connections are taken to the central shaft of the whirling arm, from which they are again taken to an observing table where the speeds of the arm and propeller shaft are controlled.

§ (9) FIXED AERIAL PROPELLER DYNAMOMETER FOR USE IN A WIND CHANNEL.—A sketch of this apparatus is given in *Fig.* 21. It consists of a small electric motor A bolted to a cradle, the ends of which are attached to two hardened steel points bearing in the cups of the "Y" pieces M. These "Y" pieces are rigidly connected to the lower ends of the diagonally arranged wires C, the upper ends of which are supported from the roof of the tunnel by stirrups carrying hardened steel points bearing in the cups D. With this method of support the electric motor is capable, if there is no other constraint, of a swinging motion in the direction of the motor shaft and also of a rocking motion about the axis passing through the points B, B, this axis being parallel to, and slightly below the axis of, the shaft. A spindle arm E, projecting from the underside of the cradle, is connected by a strut and a "C" spring to the top of a spindle clamped to the head of an aerodynamical balance the vertical head of which projects up through the floor of the wind channel. The spindle arm E and the top of the balance arm are enclosed in a guard which is streamline shape surrounding the strut and "C" spring. A revolution counter driven by the motor shaft and in electrical communication with a bell enables the rotational speed of the airscrew to be measured. To avoid any unnecessary constraint of the moving parts of the apparatus the electrical connections to the motor are made through the mercury cups G. The scale of the model airscrew used with the apparatus needs to be such that the motor with its contiguous parts is completely enclosed in a shell of the model aeroplane body K, and such as to ensure sufficient clearance between the surrounding shell and the moving parts of the measuring apparatus. The body is suitably supported by bars from the sides of the channel.

When measuring torque, the rocking axis BB of the motor and airscrew, which is parallel to the airscrew shaft, is fixed parallel to the centre line of the channel by rigidly attaching the "Y" pieces to the bars L. The brackets at the lower end of the arm E and at the top of the balance spindle are adjusted so that the strut which transmits the load to the top of the balance arm is at right angles to the airscrew shaft. A direct calibration of the apparatus may be made by applying a known torque and weighing directly with the balance.

To measure thrust, the "Y" pieces are detached from the bars L so that the motor and airscrew have freedom to swing in a longitudinal direction about the points D at the upper ends of the wires, and the points B of the motor cradle. The brackets on the lower end of the arm E and the top of the channel spindle are adjusted so that the strut F which transmits the thrust to the top of the balance is parallel to the airscrew axis. A strut N, which is held in position with a "C" spring between the bracket O and the cradle and one of the bars L, prevents the motor rocking about the axis BB. The calibration of the thrust apparatus may be obtained by applying a known thrust along the airscrew axis and measuring directly the airscrew balance.

The air velocity in the channel is measured by a tilting manometer. J. H. H.

Efficiencies of Petrol Engines. See "Petrol Engine, The Water-cooled," §§ (2)-(4).

Efficiency of a Heat-engine. The efficiency is measured by the ratio $(Q_1 - Q_2)/Q_1$, Q_1 and Q_2 being the amounts of heat taken in and rejected respectively. If T_1 T_2 be the corresponding temperatures on the Absolute Thermodynamic Scale, we have for a reversible engine

$$\frac{Q_1 - Q_2}{Q_1} = \frac{T_1 - T_2}{T_1}.$$

Thus the efficiency of any reversible engine working between temperatures T_1 and T_2 is

$$\frac{T_1 - T_2}{T_1}.$$

ELASTIC CONSTANTS, DETERMINATION OF, AND THE TESTING OF MATERIALS OF CONSTRUCTION

§ (1) Introduction.—The reasons for the testing of materials of construction are various and depend upon the point of view in which the inquirer approaches the subject.

The designer, in order to proportion the parts of his machine or structure and apply his theoretical calculations, requires to know the physical constants of the materials with which he deals. The aim of the scientific experimenter is to supply this data in order that the theoretical researches in applied mechanics may be applied to the problems with which the engineer is confronted in his practice. Absolute results concerning definite properties of materials form the basis of *scientific testing.*

The material to be used in the construction of any structure can usually be obtained from several sources of supply and of several grades and prices. The engineer wishes first to indicate to the manufacturer the class of material he needs, and for this purpose he supplies him with a specification containing among other things particulars of the properties required. The design is based on certain values for the physical constants, and these values are the real criterion of the suitability of the material for the purpose for which it is intended. The determination of the constants is usually a slow laborious business requiring considerable skill and scientific ability. Approximate tests have been devised, which are only intended to give a comparative indication of the physical properties of the material. The results expected from these tests are inserted in the specification; in some cases they approximate closely to the scientific tests.

It is, obviously, important for the engineer to be assured that the material supplied fulfils the terms of the specification, and for this purpose he selects sample portions of the material and subjects them to the specified tests. *Commercial testing* is therefore carried out to determine whether materials conform to the terms of specifications.

There is a further section of the subject which has been given a great impetus in the last few years, viz. *investigatory testing,* undertaken to determine causes of failure of material in actual practice and to improve processes of manufacture and design of machines and structures.

The science of engineering is advanced by a systematic study of failures probably quite as much as by any other branch of research. In investigatory testing, methods are employed to exaggerate certain properties in order to compare them in various materials with ease and certainty. These same properties can probably be studied by a careful analysis of the absolute results obtained by scientific testing, but the process is difficult and cannot be attended with success without considerable practical experience.

I. Testing Machines

§ (2) General Methods.—There are certain methods of test which are applicable to all branches of test work. The complexity of the machines employed for these tests depends upon the number of purposes for which it is intended to use them. This complexity is contingent upon

(1) The variety of materials it is required to test.
(2) The kinds of straining action needed.
(3) The form and size of the specimens to be tested.
(4) The magnitude of the forces to be exerted and measured.
(5) The accuracy required in the results.

By limiting the requirements, the testing apparatus can be made of great simplicity. For instance, in a transverse testing machine such as is used for checking the quality of cast iron in a foundry, the test pieces can all be of one size, the straining action is always the same (the test piece being broken as a beam), and there is not a great deal of variation of the breaking load. A machine such as this is simple and effective.

Every increase in the requirements adds additional apparatus to the machine. An accessory for one purpose will often interfere with the running of the machine for another purpose, thus causing loss of time in making the necessary adjustments for the experiments in hand, involving great care in the setting of the machine and making it more difficult to handle. It is therefore in the interest of the user to consider carefully the functions which the machine will be called upon to perform, and to limit them to a minimum. In this way increased efficiency is obtained with minimum cost.

The simplest method of testing is by direct loading, and the earlier researches on strength of materials were carried out by this method. Galileo (1638) and Muschenbrock (1729) made many tests on a small scale by this means, and where it can still be applied it is the simplest and best method of testing available. Owing to the difficulty of handling heavy loads it is only suitable for use with weak materials.

When at the beginning of the nineteenth century the demand came for tests on a larger scale, it was necessary to consider other means of applying the force than by direct loading, and within a few years the three arrangements found in modern testing machines were employed, viz.:

(*a*) Load applied by hydraulic press—no weighing device, but load calculated from the pressure on the ram.
(*b*) Load applied by gearing at one end—weighing lever at the other end.
(*c*) Load applied by hydraulic press at one end—weighing lever at the other end.

In 1813 method (*a*) was employed by Brunton & Co. for a chain-cable testing machine. The arrangement for arriving at the load was not capable of giving very great accuracy. It was necessary to make an allowance to the load, which was deduced from the indication of a pressure gauge, for the friction of the packing of the ram or the cup leather, and the amount of this friction was extremely variable.

The Whitworth hydraulic testing machine [1] and the 600-ton testing machine of the Union Bridge Company at Athens, Pa., U.S.A., both use the same principle. The 5000-ton Olsen [2] compression machine of the Geological Survey and the Bureau of Standards, and the 600-ton Olsen compression tester of the Rensselaer [3] Institute at Troy both record the load by the pressure in the hydraulic press, but with these machines the pressure is transmitted to a diaphragm whose area is smaller than that of the main ram. The pressure on the diaphragm is measured by a system of levers. Method (*a*) has been applied to modern testing machines by eliminating the packing and having an accurately fitted ram and cylinder with small clearance. By using oil the slight leakage between the ram and cylinder reduces the friction to a practically negligible quantity.

The evolution of the other two testing machine arrangements, (*b*) and (*c*), from the direct loading method was due to the introduction of the lever. By placing a lever in between the test piece and the load, the amount of dead weight required was reduced by the ratio of the lever arms. This arrangement, although quite suitable for small pieces possessing little ductility, was found to be open to the objection that, as the material stretches, the position of the lever alters and cannot be adjusted.

In 1817 Captain Brown constructed a cable testing machine in which the deformation of the cable was neutralised, and the load applied, by means of gearing at one end, while the load was measured by a lever at the other.

The use of gearing was the method of straining used in America on machines of the lever type. The same arrangement, although common on small machines in this country worked by hand, had not, however, been used on power-driven machines until recently.

Another method of counteracting the deformation of the test piece was applied by Lagerjhelm, of the School of Mines at Stockholm, who conducted experiments in 1825 on a 7-ton machine in which a hydraulic ram neutralised the give of the test piece and applied the load, which was measured by weights acting on a knee lever. About the same time, that principle was also employed by Bramah [4] in the construction of a machine used at Woolwich Dockyard by the late Professor Barlow for some of his experiments on the strength of materials. This method of construction is, however, always associated with the name of David Kirkaldy, who in 1866 erected, in London, his well-known machine of 400 tons capacity. The combination of hydraulic ram and levers has since been in common use in machines of many designs, the chief differences in these designs being in the arrangement of the lever or levers and their position relatively to that of the test piece.

Thomasset,[5] in about the year 1872, measured the load on the lever by means of a diaphragm piston with an extremely limited motion, and balanced the load on the piston by a mercury gauge. Maillard and

---

[2] *Engineering Record*, Feb. 1909, lix.
[3] *Proc. Am. Soc. Test. Mat.*, 1909, ix.
[4] Barlow, *Strength of Materials*, London, 1851, p. 258.
[5] Lebasteur, *Les Métaux*, p. 52.

Emery a few years later dispensed with the lever and transmitted the whole load to the diaphragm. Emery[1] constructed a machine of 450 tons capacity in which the pressure on the diaphragm piston was measured by transmitting it to a smaller one in which the mercury gauge of Thomasset was replaced by a system of levers and weights.

The first essential requirement of a testing machine is accuracy—the load shown by the machine should be an accurate indication of the real load to which the test piece is subjected. In order to obtain complete accuracy it is necessary that:

(1) Simple means should be available for establishing the truth of the indications of the machine—it should be capable of being easily calibrated. This calibration may alter with use; if of the lever type the knife edges may wear or be displaced, and, on a three-inch fulcrum distance, 1 per cent error in the readings would be caused by a displacement of only 0·03 inches.

(2) The sensitiveness in working should be adequate, *i.e.* small differences in the load should be readily indicated.

Another desirable feature is simplicity—not simplicity resulting from a mere reduction of the attachments for the various tests, but that obtained by ensuring that the varied requirements are carried out without undue complications. This not only reduces the parts liable to alteration with use, but renders the machine capable of rapid and easy manipulation during test, a feature which is especially important in a machine to be used for commercial testing. Other requirements necessary in a machine or commercial testing are:

(*a*) The tests should be accessible from the front of the machine, and the scale and control levers within easy reach of the operator.

(*b*) The test piece should be easily inserted in the machine, *i.e.* the method of gripping should be simple and convenient. For laboratory work it is advisable that the machine should be conveniently arranged to take an autographic apparatus for registering the results, and should be generally adaptable to all sorts of conditions which may from time to time be necessary for varied experimental work.

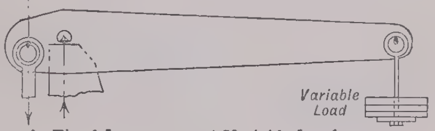
The liability of the testing machine to subject the specimen to momentary shocks should also be considered. The inertia in the lever and weights (in that type of machine) may increase the stress in the test piece beyond that indicated by the scale reading of the jockey weight. The construction of each machine should therefore be understood by the operator, and in skilful hands errors due to this cause can be reduced to a very small amount.

§ (3) Horizontal and Vertical Machines.—Testing machines may be arranged in either of two ways:

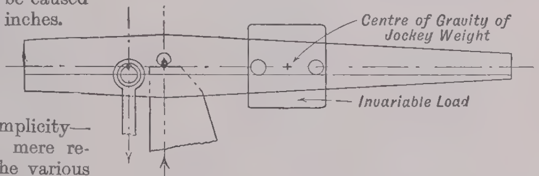
(i.) In which the load is applied horizontally—horizontal testing machines.

(ii.) In which the load is applied vertically—vertical testing machines.

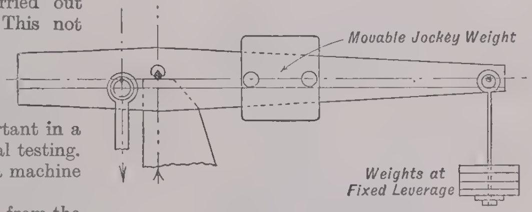
For testing long specimens it is usual to employ a machine of the horizontal type in which it is necessary to support the test piece and the grips which hold it, otherwise forces are applied to the test piece which are not measured by the load-measuring apparatus. The vertical testing machine, however, is more convenient to handle and, except in the circumstances mentioned above, is the arrangement generally adopted.



A. Fixed Leverage and Variable Load



B. Fixed Load and Variable Leverage



C. Movable Jockey Weight combined with a Load at a Fixed Leverage

Fig. 1.

§ (4) Modern Testing Machines.—Modern testing machines usually consist of four main parts:

(i.) An arrangement for applying the load.

(ii.) An adjustment to neutralise the effect of the deformation of test piece so as to provide that there is no movement of the point of attachment of the test piece to the weighing apparatus.

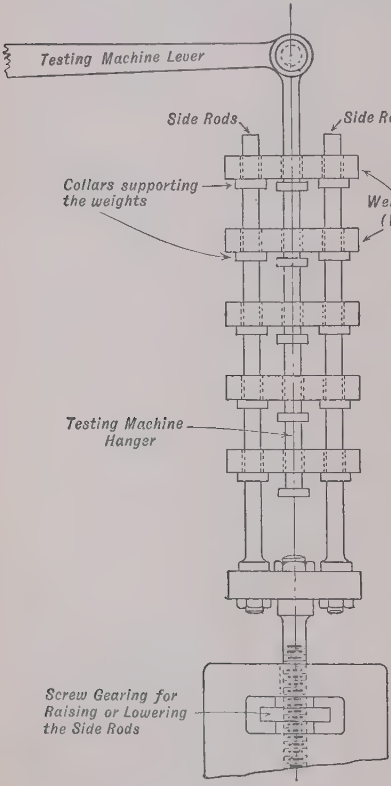
(iii.) A method of measuring the applied load.

(iv.) Holders for connecting the test piece to (i.) and (iii.).

---

[1] See Towne, *Inst. Mech. Eng. Proc.*, 1888, pp. 206 and 448.

The various types of testing machine differ in the way in which these requirements are carried out. The first and second parts are usually combined, and the load on the test piece is applied to one end either by (1) a straining cylinder actuated by a pump and accumulator, screw compressor, or oil pump (hydraulic rotary or direct driven); or (2) screw gearing driven by hand or by power (such as an electric motor). Screw power testing machines are divided into two general types—the rotary screw and the rotating nut.



Testing Machine Lever
Side Rods
Side Rods
Collars supporting the weights
Weights (W)
Testing Machine Hanger
Screw Gearing for Raising or Lowering the Side Rods

FIG. 2.

The load or force exerted on the test piece is measured (*a*), more commonly in Great Britain, by a lever or system of levers with weights or a movable counterpoise forming a weighing apparatus;

(*b*) by balancing it with fluid pressure acting on a diaphragm;

(*c*) by measuring the pressure of the oil or water in the straining cylinder;

(*d*) by calculating the load from the angle through which a weighted pendulum is lifted.

Testing machines using methods (*b*) and (*c*) have the advantage that they are cheaper to make than the weighing lever machine, are practically free from inertia forces, and the load is automatically adjusted to the stress. They, however, require very careful attention and calibration, and are considered by the Board of Trade to be undesirable for use when making acceptance tests.

§ (5) TYPES OF TESTING MACHINES. *Lever Testing Machines.*—By far the largest number of machines measure the load by the use of a lever. The loading of the lever is effected either by (*a*) adding separate weights to a scale pan placed at a fixed leverage (*i.e.* fixed leverage and variable load); (*b*) having a single jockey which travels along the beam (*i.e.* fixed load and variable leverage); (*c*) a combination of (*a*) and (*b*).

These arrangements are indicated diagrammatically in *Fig.* 1. With either of the methods the following points must be borne in mind:

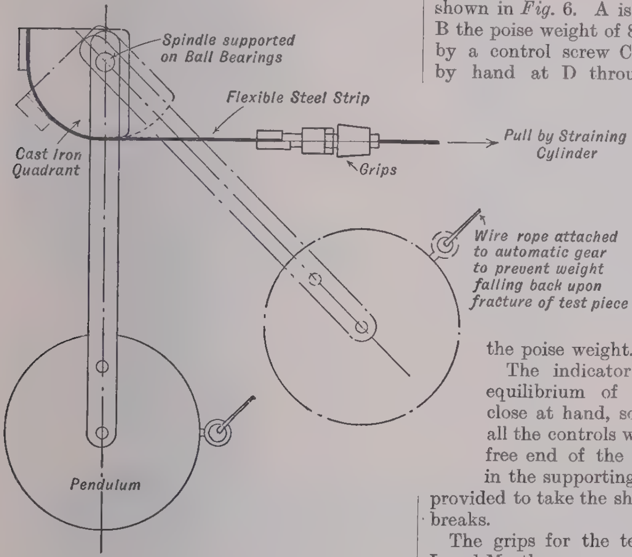
(1) The lever during the test will change its position, and in order to secure constant leverage the points of application of the loads must be in a straight line, *i.e.* the centre of gravity of the moving weight and any knife edges employed must all lie in a straight line or, if the moving weight is hung from a knife edge, the knife edge must travel along that line.

(2) Any addition of weights during a test must be carried out without producing shocks on the specimen. In those machines in which weights are added to the scale pan it is usual to carry this out by a mechanical arrangement such as is shown in *Fig.* 2.

In some machines the load is measured by the height to which a pendulum bob is raised. This can be considered as a modification of the lever method. *Fig.* 3 shows how it was employed in the tests described in the British Engineering Standards Association Report No. 55.

It is desirable that, on the same machine, the percentage accuracy of reading the load should be the same with small as with large specimens, and it is therefore usual to arrange modern testing machines so that the same length of scale is equivalent to at least two values of the load. This is carried out either by varying the leverage or varying the weight of the moving poise.

The leverage is varied by providing alternative fulcra. This method is introduced into the Wicksteed vertical machine (see *Fig.* 10A), and consists in providing a third knife edge which can be put in or out of gear. When it is in place, the knife-edge distance is large and the machine is arranged for use with weak specimens, otherwise the full capacity of the machine is available. Thus the same counterpoise may represent say 50 or 100 tons for the same travel of the counterpoise along the lever, according to which fulcrum is used. The method of operating the third knife edge is shown in *Fig.* 4. The three knife edges are in the same line, but the movable support Y for the third knife edge Z is raised so that when it is placed in position by the worm gear there is a slight clearance over the support X, as shown in *Fig.* 4 (B).



Spindle supported on Ball Bearings
Flexible Steel Strip
Cast Iron Quadrant
Pull by Straining Cylinder
Grips
Wire rope attached to automatic gear to prevent weight falling back upon fracture of test piece
Pendulum

FIG. 3.

The weight of the moving poise is varied in machines supplied by Messrs. W. & T. Avery, Ltd. The counterpoise is split, and for small loads a part of it is detached and used as a separate poise.

In order to obtain a high mechanical advantage, without making the short arm of the lever very small, some machines use a multiple system of levers, each with comparatively small mechanical advantage. It is therefore convenient to divide lever machines into two sections, (1) those using a single lever, (2) those in which the levers are compounded, and to subdivide those sections according as to whether the test pieces are vertical or horizontal and whether the load is applied by a straining cylinder or screw gearing.

§ (6) SINGLE-LEVER MACHINES. (i.) *Vertical.*—*Fig.* 5 shows diagrammatically the simplest arrangement of a single-lever machine, this being the principle adopted by Mr. Wicksteed.[1] It is a vertical machine with a single horizontal lever A on top, to which one end of the test piece B is connected. A movable poise C weighs the load, which is applied to the other end of the test piece by the ram of a hydraulic press (as shown) or by screw gearing. The following are modern examples of machines which use this principle.

(ii.) "*Avery*" *10-ton Electrically Driven Single-lever Testing Machine.*—This machine is shown in *Fig.* 6. A is the weighing lever and B the poise weight of 840 lbs., which is moved by a control screw C. The screw is driven by hand at D through gearing E and F and a hooked joint G which is placed on a line with the fulcrum. The straining of the test piece is produced through worm and spur gearing by means of an electric motor H, whose control is located at I on the standard near to the hand wheel propelling the poise weight.

The indicator J, which shows the equilibrium of the steelyard, is also close at hand, so that the operator has all the controls within easy reach. The free end of the lever plays in a space in the supporting pillar K. Springs are provided to take the shock when the test piece breaks.

The grips for the test piece are shown at L and M; these are provided with attachments for test pieces with either screwed or enlarged ends. The upper grip is attached to the lever, while the lower one, which slides in guides in the standard O, is connected to the straining screw P. The second knife edge Q rests on the standard O.

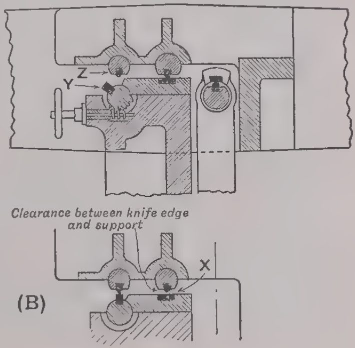


FIG. 4.

(iii.) "*Denisons*" *30-ton Testing Machine.*—In this machine, shown in *Figs.* 7 and 8, the load is applied by a straining cylinder, the pressure to which is supplied by a patent hydraulic rotary oil-pump. This pump has a variable delivery in either direction whilst being continuously driven in one direction. The drive can either be by direct coupling to an electric motor, as shown in *Fig.* 7, or by a belt from a countershaft. A similar pump is used for driving the standard jockey weight in either direction; the speed at which it travels can be varied by means of a lever placed in a convenient position.

---

[1] *Inst. Mech. Eng. Proc.*, 1882, p. 384.

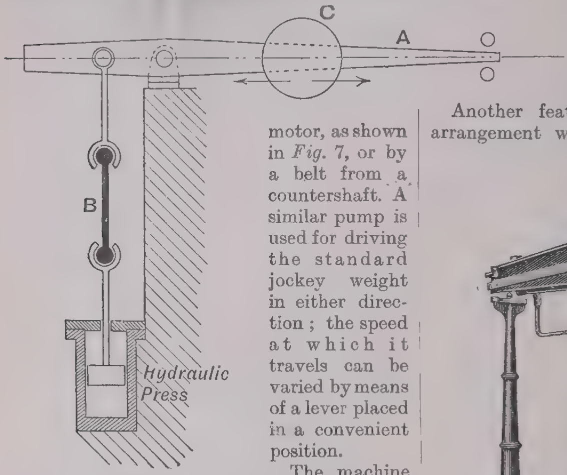

FIG. 5.

The machine is supplied with tell-tale devices, for indicating to the operator the functions of the various parts, as well as all the features which are indispensable for accurate work.

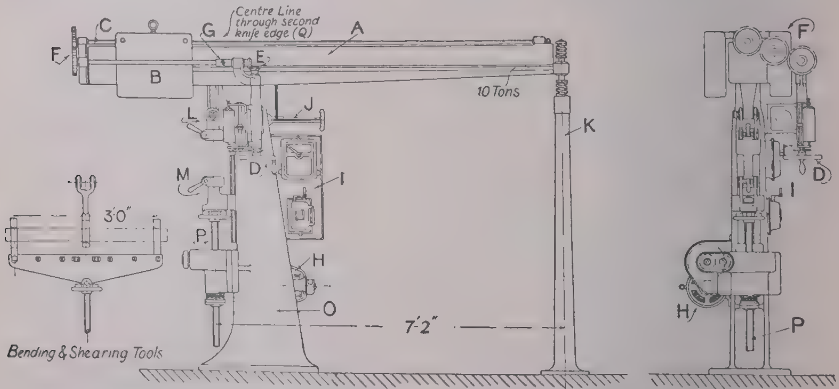

FIG. 6.

(iv.) *Buckton's 100-ton Machine.*—A photograph of the machine of this type which is installed at the N.P.L. is shown in *Fig.* 9. The load is applied by a hydraulic ram and cylinder which are placed in a pit below the floor level. A pressure of 1 ton per sq. in. is supplied to the cylinder by a hydraulic pump and accumulator driven by an electric motor. The counterpoise is driven by hand or mechanically by fast and loose pulleys operated from a suitable line of shafting. The machine seen in the photograph is fitted with alternative fulcra (see § (5)) giving a short knife-edge distance of either 3 or 6 inches, so that the jockey weight of 1 ton in travelling the full length of the scale can be arranged to give either a load of 100 or 50 tons.

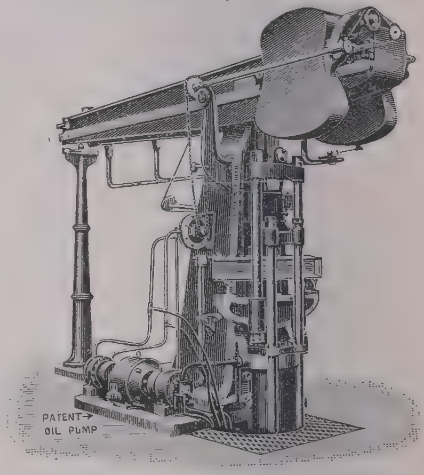

FIG. 7.

Another feature of the machine is the arrangement which has been added at the N.P.L. to prevent the jockey weight accidentally running past the end of the scale in either direction. When a considerable number of tests have to be carried out, it is usual for the operator to measure the extension, contraction of area, etc., and enter up his results, while the counterpoise is running back for the next test. It detracts from his attention if he has to be continually on the alert to stop the counterpoise at the right time. The gear is shown in detail in *Fig.* 10, and operates on the belt-throw-over gear. The shaft A operates the gearing for driving the weight along, placed at the end of the beam, and is worked from the small countershaft (not shown) through bevel wheels B. The striking gear of the countershaft is operated by a shaft C, which has a handle (not shown) on its lower end. A spur gear on shaft A operates a screw D through gearing. This screw is so arranged that it does not rotate but traverses horizontally as the weight is run along the beam. The screw carries a projection E working in a bracket F attached to the striking gear shaft C. Adjustable lugs G and H are fitted on to this projection and are arranged so that when the counterpoise reaches the extreme end of its travel, in either direction, one or other of the lugs G and H will rotate the striking gear shaft and throw the driving belt on to the loose pulley of the countershaft. The lugs can be adjusted so that, for any series of tests, the counterpoise will be stopped at any predetermined position along the beam. A photograph of the gear is given in *Fig.* 10A.

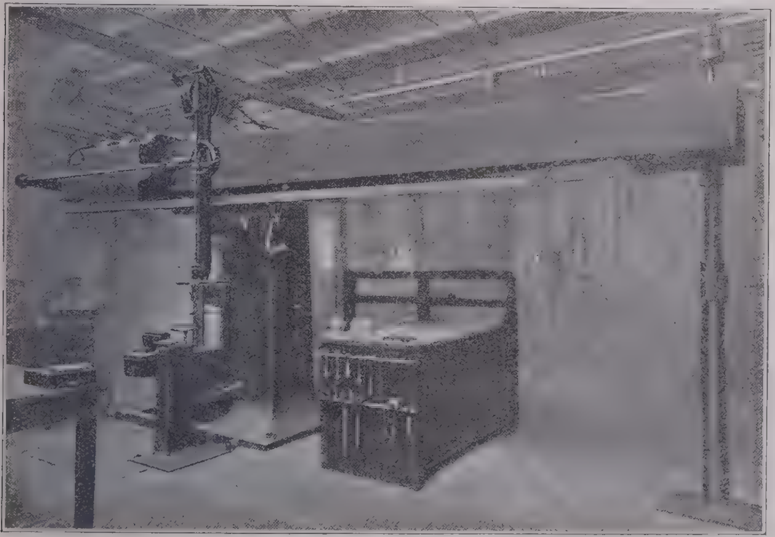

FIG. 9.

(v.) (*Horizontal*). *The Werder Testing Machine.* — The Werder machine, extensively adopted in Germany, is a horizontal single-lever testing machine, in which the load is applied by hydraulic pressure, but is measured by dead weights on a single lever. The type was originally designed by Ludwig Werder in 1852 and exhibited at the Munich exhibition in 1854, since when a considerable number of similar machines have been constructed. The arrangement of the machine is illustrated diagrammatically in *Fig.* 11, from which it will be seen that, (1) only one lever is required for a 500 to 1 leverage, and (2) by an ingenious arrangement, the ram, lever, and weights are all at one end of the machine. It is thus a simple matter to adapt the machine to take test pieces of any length.

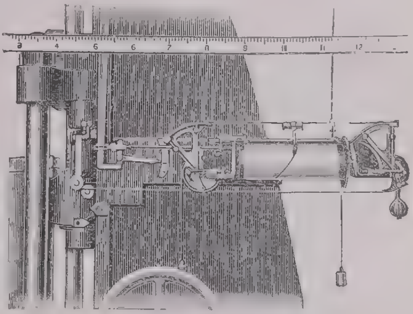

FIG. 8.

The test piece T is held at one end in the framework of the machine A, and at the other pulled by the short arm L_1 of the lever, to which it is connected by a crosshead and long bolts, shown in the diagram by a connecting rod EF. At the end of the long arm of the lever hangs a scale pan W. The central fulcrum of the lever G rests on the end of the ram C, so that, as the test piece extends, the ram moves out, carrying the whole measuring apparatus with it. The arm L is kept horizontal by the help of a level which is fixed to it. *Fig.* 12 shows a sectional elevation illustrating the principal knife edges, and *Fig.* 13 gives a plan of the machine.

FIG. 10.

FIG. 10A.

The test piece is pulled from the main crosshead V by four rods (two shown in plan as T_1 and T_2); these rods are connected vertically in pairs by crossheads U_1 and U_2, and pull through knife edges C_1 and C_2 on to a large U-shaped block Q, to which the lever Q_1 is rigidly attached. Block Q has two openings in it, through which the crossheads U_1 and U_2 pass. The horizontal line through C_1 and C_2 passes through the axis of the test piece.

The whole system of rods and crossheads hangs from the ram crosshead at N_1 and N_2 on the traverse bar OO. The block Q hangs from this bar by the knife-edge links P_1, P_2 (the knife edges being in the same line as C_1, C_2), its balance being adjusted by the sliding weight S.

In the middle of the block Q the knife edge *b* is fitted; this bears against a steel face *a* forming part of the ram crosshead. This knife edge is 3 mm. lower than the line of the others. Thus the ram coming out applies a load to the test piece through the block Q, knife edges C_1 and C_2, crossheads U_1 and U_2, and the rods T_1 and T_4. As the knife edge is 3 mm. out of line with C_1 and C_2 a bell-crank lever is formed, the small arm of which is 3 mm. and the long arm 1500 mm., *i.e.* the distance the scale pan is away from the knife edge.

It is clear that the length of the short arm of the lever (3 mm.) cannot be directly checked with sufficient accuracy, a controlling arrangement is therefore provided consisting of a knee lever f_2 having a fulcrum on the frame K and a ratio of 10 to 1. The knife edges on this lever can be accurately measured by ordinary means, and, to test the accuracy of the 500 to 1 ratio, a direct calibration can be made.

The ram C is 11·8 inches in diameter, the knife edge *b* is $14\frac{1}{2}$ inches long, and the two knife edges C_1 and C_2 are together 15 inches long, so that the pressure upon them is about 7 tons per linear inch at full load (100 tons).

The pressure is obtained from two pumps worked by hand or power and placed at the side of the machine—a small one of 0·4 inch diameter, used for the full load, and a larger one, 1·2 inches diameter, for use up to a load of 20 tons.

The arrangement shown is for tension tests; for compression tests the pull is transmitted through links from V to a back plate, or for short specimens the space between V and the back of the cylinder is utilised.

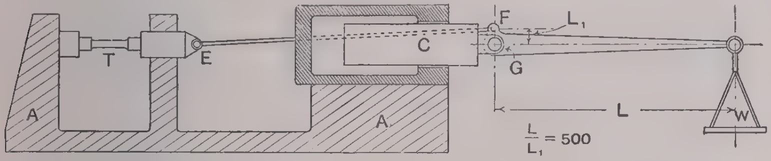

Fig. 11.

§ (7) Compound-lever Machines. (i.) *Vertical Machines with Screw Power.*—This is the arrangement of machine which is largely used in America and is shown diagrammatically in *Fig.* 14. The straining mechanism is of two types — the rotating screw and the rotating nut.

With the rotating screw machines, the pulling screws pass through nuts which are fastened to the pulling head A. The screws are keyed to and rotate with the main gears through bearings in the cover plate, thus moving the head up or down.

In the rotating nut type of machine, bronze nuts are fastened in the main gears and rotate with them, pulling the screws, to which the head is attached, up and down. The gears rest on long pedestals bolted to the base plate of the machine, and in these pedestals keys are fixed which prevent the screws from turning.

The thrust, in each case, is taken on the underneath side of the cover plate by ball or roller bearings. The rotating nut machine usually requires a pit or opening in the foundation for the screws which project below the base line of the machine.

The weighing apparatus consists of a weighing table C, levers D_1 and D_2, and a graduated beam E. For tensile strain there is also a weighing or top head F and two weighing columns G_1 and G_2 attached to the weighing table.

(ii.) *Olsen's 200,000-lb. Testing Machine.*—*Fig.* 15 shows the 200,000-lb. Olsen four-screw compound-lever testing machine of the rotating nut type.

Straining Mechanism.—D, D are the straining screws which are attached to the pulling head C, to which one end of the specimen is attached. They pass through holes at the corner of the platform E and through openings in the levers F and bed-plate G, and enter the driving nuts H and H_1, situated below the latter.

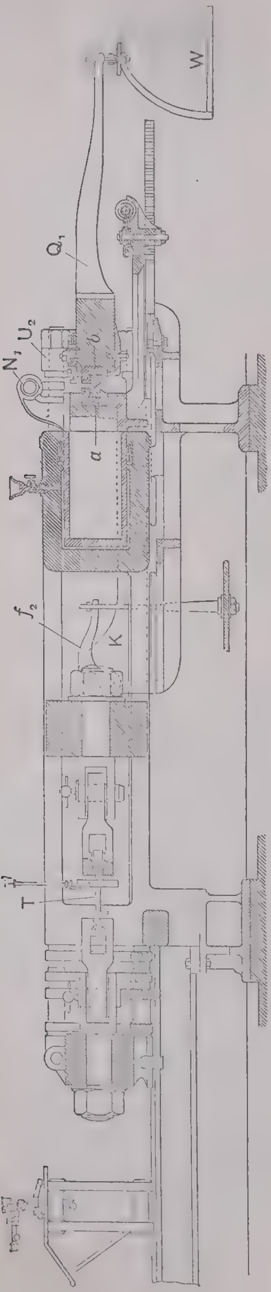
The driving nuts H and H_1, which are made extremely long to ensure a long life, are driven by means of gearing JKMN operated by pulleys and belting. As each screw is fitted with feathers, in longitudinal slots cut through the threads, to prevent them from turning, rotation of the nuts causes the screws to either rise or fall, carrying the pulling head C with them. The thrust of the nuts against the bed-plate G is taken by ball thrust washers.

(iii.) *Weighing Apparatus.*—The weighing mechanism is essentially the same as that of a platform weighing machine. The load on the test piece, applied by the straining mechanism, is communicated to the platform E either directly in a compression test, or through the medium of the upper steel plate B (to which one end of the test piece is wedged) and columns A in the tensile test.

The platform rests wholly on three main levers F so constructed as to act as a single lever, and any pressure on it is transmitted directly to them. The knife edges of only one of these levers are shown in the figure.

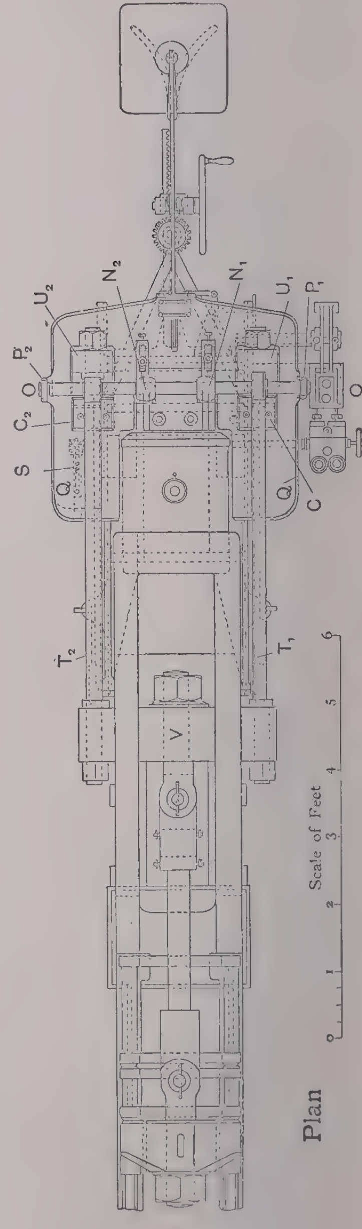
A second multiplying lever F_2 is placed above and parallel to the lever F, and is connected to it by a stirrup J_2. The reaction of the lever F_2 is taken at K on a strong iron framework which is secured to the gear box of the machine by a diagonal brace. This framework also holds the support L_2 for the fulcrum of the graduated steelyard F_3, to which the load is transmitted from lever F_2 by the link *n*.

A cylindrical weight W, which runs on a screw, adjusts the zero of the beam, while a poise *q*, which travels on wheels, balances the



Sectional Elevation

FIG. 12.



Plan

FIG 13.

load applied. The steelyard is graduated up to 100,000 lbs., and an additional weight on the end of the lever adds a further 100,000 lbs.

(iv.) *Horizontal Compound Lever Machines.*—For testing long pieces, a horizontal testing machine is essential. In order to obviate the difficulties introduced by the small knife-edge distance of the Werder machine, multiple lever arrangements are used. A bell-crank lever is adopted to convert the horizontal force into a vertical one, and this is combined with the weighing lever, either with or without the introduction of intermediate levers.

The arrangement of two machines of this type is given in *Fig.* 16.

(v.) *Large Horizontal Machines.*—In order to carry out tests on built-up structural members of a practical size, machines of large capacity are required, and for this purpose no machine of less than 300 tons is of much use. Excluding chain testing machines, the best examples of large horizontal machines built in this country are:

Kirkaldy's machine of 400 tons built in 1866.

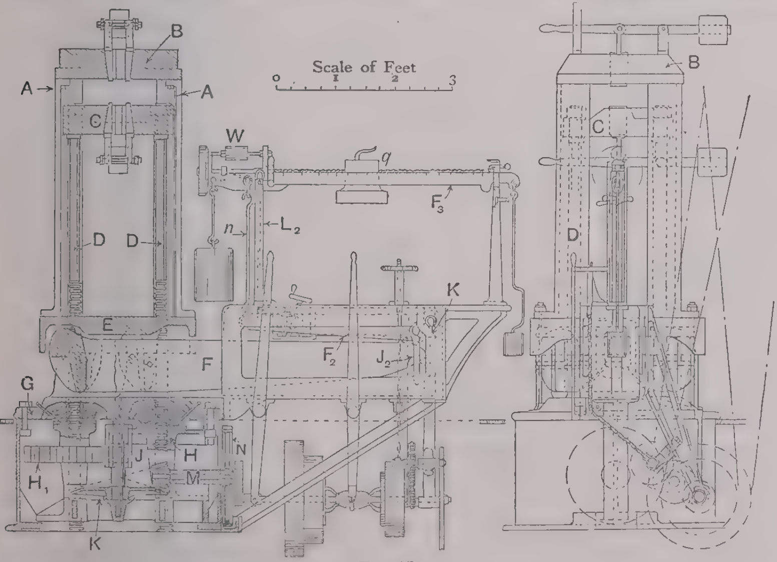


FIG. 15.

The 300 ton machine of the Conservatoire des Arts et Métiers at Paris built by Messrs. J. Buckton and Co. in 1904.[1]

The Avery Machine[2] of 700,000 lbs. installed at Birmingham University in 1909.

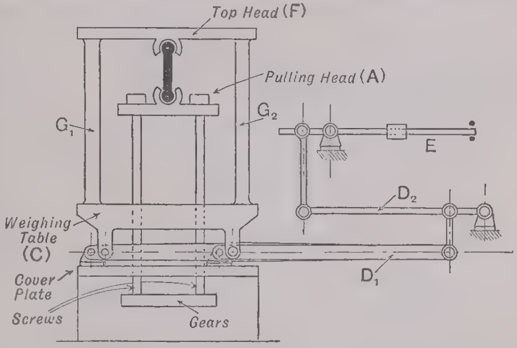

FIG. 14.

(vi.) *The Birmingham University 700,000-lb. Testing Machine.*—This is a universal machine with a capacity of 700,000 lbs. and takes tension bars 28 ft. long and columns 30 ft. long. The span for bending tests is 20 ft., and the wedge grips take a maximum size of 6 × 2½″ flat or 3¾″ diameter.

A diagrammatic view of the machine is given in *Fig.* 17 and more detailed drawings of the straining and weighing mechanism in *Fig.* 18.

The machine has a ram K at one end and the lever system D at the other. The heavy cast-iron bed XX has substantial standards HH at either end whose tops are connected by horizontal columns YY with the distance, of about 40 feet, between them without intermediate support. There is therefore a clear span along the top and sides, enabling heavy test pieces to be lowered in position by the traveller running overhead. To one standard the cylinder L is bolted, while the lever system is fixed to the other.

[2] *Engineer*, May 21, 1909.

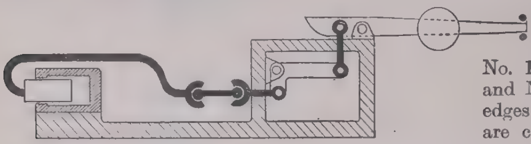

Diagram of Greenwood and Batley's Horizontal Testing Machine

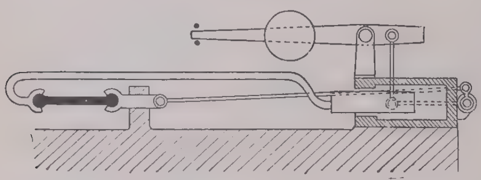

Diagram of Buckton's Horizontal Testing Machine

FIG. 16.

The load is applied by hydraulic pressure. At Birmingham the town pressure of 100 lbs. per square inch is available for low load tests and gives a total thrust of 35 tons. For the full capacity of the machine an accumulator supply of ten times the pressure is used. The diameter of the ram is 32 inches and its stroke 66 inches. The main cylinder L, bolted to the standard, forms part of the machine frame, and the main ram K, having an internal diameter of 20 inches, moves over an auxiliary fixed ram M whose function is to provide for the return of the main ram after the test is completed. The main ram is driven forward by admitting low-pressure water behind the fixed ram. The load on the ram is communicated to the travelling crosshead No. 2 by means of four notched racks N, sliding in the frame of the machine, which are fixed to the head of the ram and into which the crosshead No. 2 is keyed in any desired position.

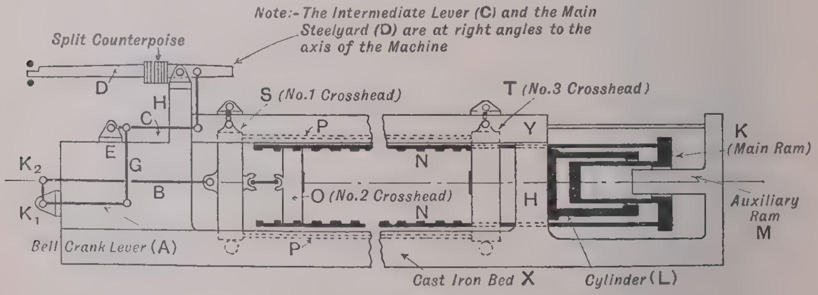

FIG. 17.

One end of the test piece is fixed to the crosshead No. 2 and the other end to the crosshead No. 3 for compression and the crosshead No. 1 for tension. Crossheads No. 1 and No. 3 are suspended from knife edges on the top of the frame Y and are connected by tension rods P, P which, when crosshead No. 3 is in use, transmits the load to the lever system through crosshead No. 1 and the main link BB. The main link BB pulls on the top knife of a bell-crank lever through a hardened steel bearing block Q. Thus, for compression, the load is communicated to the weighing apparatus from the ram by way of (1) sliding racks N, N, (2) travelling crosshead No. 2, (3) the test piece, (4) the floating crosshead No. 3, and rods P, P, (5) crosshead No. 1, and (6) main link B.

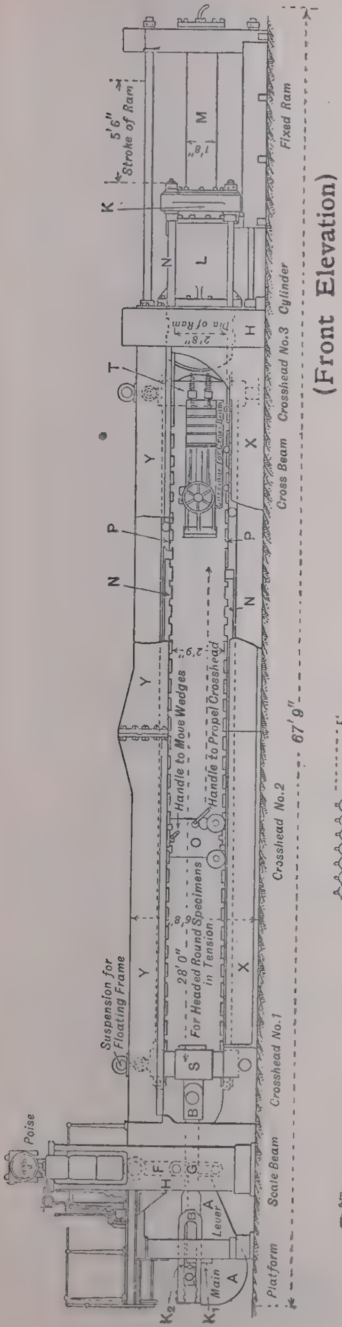
The weighing apparatus consists of a bell-crank lever A whose principal knife edge K_1, 5 feet long, thrusts against a plate fitted in the bed of the machine. The load is applied by the main link B on to a knife edge K_2 similar to the principal knife edge but a short distance above it and forming with it the short arm of the lever. The intermediate lever C and the main steelyard D are at right angles to the axis of the machine. The former has its fulcrum on a substantial casting E fixed to the bed of the machine, and the load from the bell-crank lever is transmitted to it by the link and shackles G, F while the latter has its fulcrum supported by a column H on the side of the machine.

The split counterpoise system (see § (5)) has been adopted in order to obtain an open scale for small loads. In this case it is divided into seven equal poises giving, separately, a maximum load of 100,000 lbs., and when combined the full load of 700,000 lbs.

The counterpoise can be moved by hand or operated mechanically through a screw, and all the movements are controlled by one operator at the lever end of the machine.

§ (8) Diaphragm Machines.—Diagrammatic sketches of diaphragm machines are given in *Figs.* 19A to C. *Fig.* 19A represents the Thomasset machine,[1] constructed about the year 1872, in which the load is communicated through the test piece *t* to a lever *l*, the end of which bears on to a diaphragm *d*. The pressure of the lever on the diaphragm is balanced by fluid pressure, the amount of which is measured by a gauge.

The Maillard machine (*Fig.* 19B) is similar to that designed by Thomasset except that the intermediate lever is dispensed with, the pressure being taken directly on the diaphragm, which is consequently much larger. The Maillard principle is adopted by Messrs W. H. Bailey & Co. in their 5000-lb. Ster-Hydraulic tester, and is a very convenient arrangement for small testing purposes. The



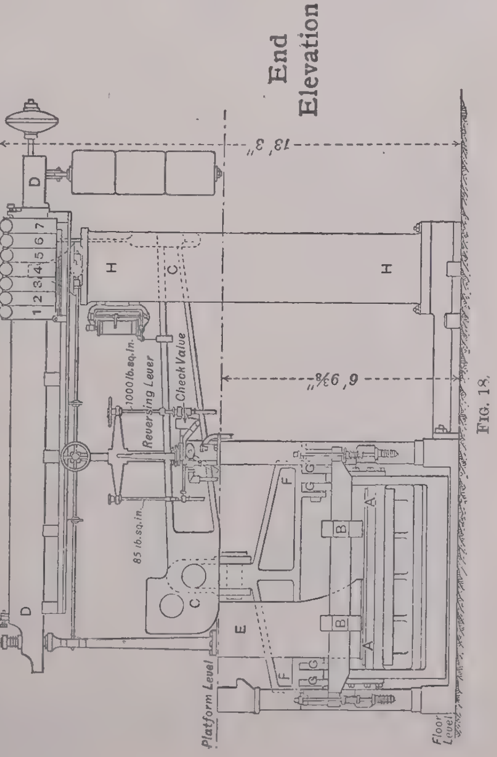


FIG. 18.

---

[1] Lebasteur, *Les Métaux*, p. 52.

load is applied to the back of the diaphragm, and the pressure in the diaphragm chamber is measured by a pressure gauge or mercury column.

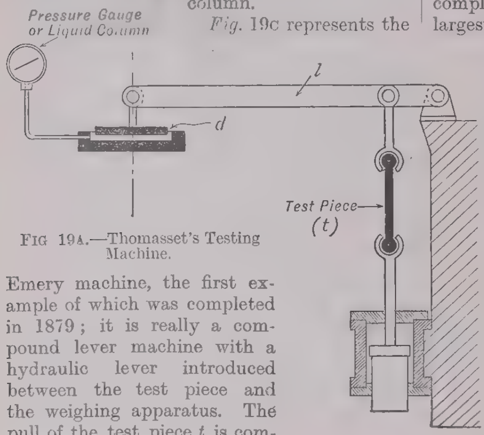

FIG 19A.—Thomasset's Testing Machine.

Fig. 19C represents the Emery machine, the first example of which was completed in 1879; it is really a compound lever machine with a hydraulic lever introduced between the test piece and the weighing apparatus. The pull of the test piece *t* is communicated to a diaphragm D. It is transmitted from this to a reducer R, the pressure on which is balanced by the lever system.

(i.) *Emery Machines.* The first Emery machine owes its origin to the United States Board for testing steel, iron, and other materials, who entered upon their work in 1875. One of the most important actions of the Board was the acquisition of an 800,000-lb. testing machine which they ordered from A. H. Emery of New York. This was completed in 1879, and is one of the largest and most accurate testing machines in the world. Unwin, after inspecting an Emery machine, said: "The merit of the Emery machine was that, while it had been made as much more delicate and sensitive than an ordinary machine as a chemist's balance was in comparison with a grocer's scales, this result had at the same time been obtained by means which rendered the more sensitive machine less liable to injury, less liable to wear, and less liable to get out of order, than the ordinary machine."

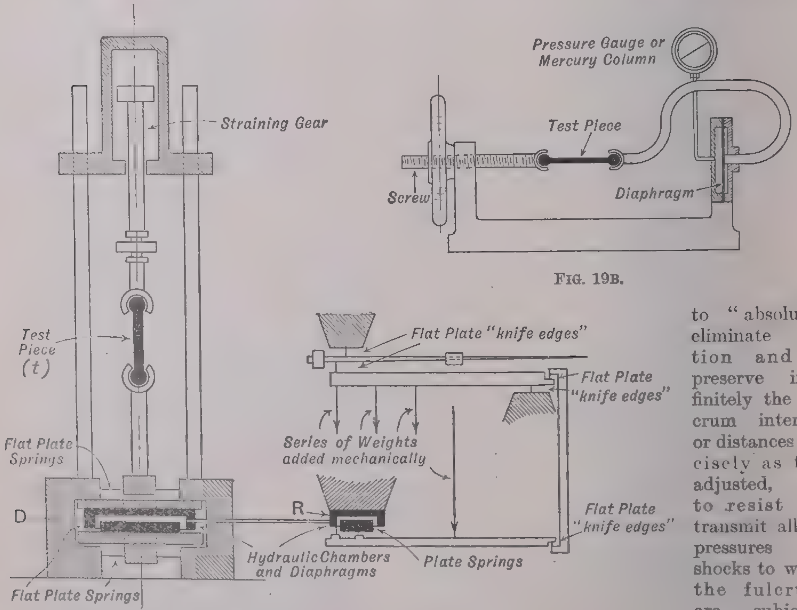

FIG. 19B.

FIG. 19C.—Diagram of Emery Machine.

The principal peculiarities of the Emery machine are: (*a*) An arrangement of hydraulic chambers and diaphragms able to receive large pressures and shocks without injury and to transmit them to a convenient point for measuring and recording.

(*b*) The replacement of knife edges with thin blades of steel. These were introduced to "absolutely eliminate friction and to preserve indefinitely the fulcrum intervals or distances precisely as first adjusted, and to resist and transmit all the pressures and shocks to which the fulcrums are subjected without in the slightest degree impairing their sensitiveness or durability."

Numerous machines have been made in the United States since 1879 on the Emery principle. *Figs.* 20 and 21 show particulars of the more important working parts of a 300,000-lb. vertical Emery testing machine; detailed drawings are given in Mr. Towne's[1] paper.

(ii.) *300,000-lb. Emery Machine* (*Figs.* 20 and 21). *Straining Gear.*—A tension test piece A (*Fig.* 21) is shown between the shackles U and L of the machine. The upper shackle U is attached directly to the ram P of the straining press, which is carried by two main adjusting guide screws M rising from the bed of the machine F. The vertical adjustment is effected by means of the nuts N, which are geared together and are rotated through a shaft and bevel gearing by a handle X.

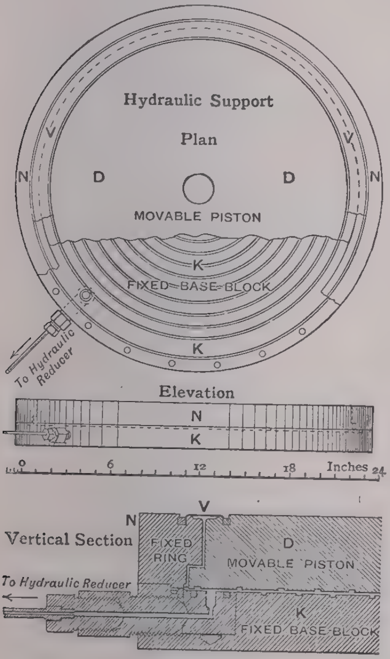

FIG. 20.

The fluid pressure is conveyed to the ram by the pipes T_1 and T_2, which have swivel joints to allow for adjustment of the straining cylinder.

(iii.) *Hydraulic Lever.*—The lower shackle L is secured to a yoke consisting of two blocks H and B connected by four steel bolts W. In this yoke the hydraulic support S is placed between the two beams G_1 and G_2. Thus the load is transmitted directly to the hydraulic support through the yoke and beams; the upper block H acting on beam G_1 for compression and the lower block B communicating the tensile load through beam G_2.

The yoke is secured in its proper position by flat plate springs I which hold it steadily laterally while leaving it free to move vertically through the small range desired. The hydraulic support S (*Fig.* 21) is shown in detail in *Fig.* 20 and consists of a piston D which can move vertically 0·001 inch in a fixed ring and base block (N and K). A space of 0·1 inch is allowed between the piston D and the ring N.

The lower surface of the piston and the upper surface of the base block are turned with annular grooves and are lined with soft sheet brass 0·005 inch thick. The linings form a sac by being interlocked as shown in the diagram. The piston D, while permitted to move vertically, is secured against lateral motion by an annular diaphragm V at its upper surface, and the exposed portion of the working diaphragm or upper portion of the brass sac at its lower face, which acts as a flexible hinge or joint. The sac is filled with alcohol and glycerine or refined kerosene oil, and the load when applied to it is transmitted to a smaller hydraulic chamber or reducer R (*Fig.* 19c), containing a similar thin film of liquid, where it is balanced by the lever weighing apparatus.

(iv.) *Weighing Apparatus.*—The maximum load of the machine is thus reduced to a maximum of 10,000 lbs. on the reducer, and this is all the load that is conveyed to the fulcrum plate of the main lever M (*Fig.* 19c) of the weighing apparatus. Thin pieces of tempered steel are used instead of knife edges, and are forced, under a pressure of about four times the working load, into the pieces that they connect. The relation of the beams, which have a total multiplication of 20,000 to 1, is shown in the figure. The total reduction of load is 600,000 to 1, so that very small weights are all that are necessary to keep the levers horizontal.

(v.) *Calibration.*—The hydraulic support is tested with known loads, applied by a "rating machine," up to the maximum capacity of the Emery machine. The exact weight required on the weigh lever to balance a known load on the machine is thus found by actual test, and the poise weights are carefully adjusted in accordance with this calibration.

The rating machine is a carefully constructed dead-weight loading appliance. The weight was produced from standard weights accurately adjusted at the Bureau of Standards, Washington.

§ (9) MACHINES WITH NO WEIGHING DEVICE.—Machines in this class are those in which the load is applied by a fluid press, and the stress in the specimen is calculated from the pressure on the plunger.

---

[1] See Towne, *Inst. Mech. Eng. Proc.*, 1888, pp. 206 and 448.

An objection to this method of test has been that errors are introduced into the results owing to the variability of the friction caused by the ram packing. This objection has now been overcome, in the machine constructed by Messrs. Alfred J. Amsler & Co., by using oil as the fluid together with an accurately fitted ram and cylinder with small clearance, thus eliminating the packing friction.

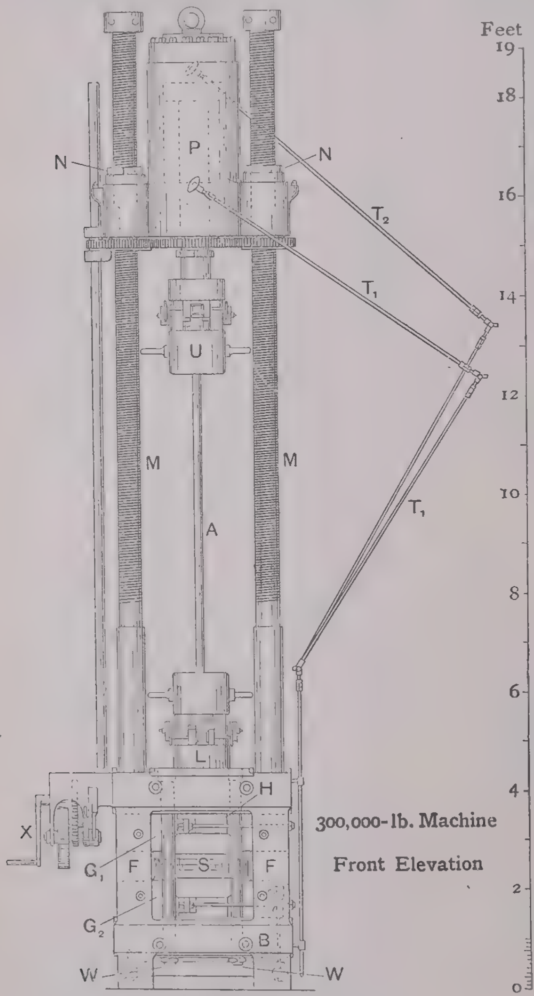

Fig. 21.

(i.) *Amsler Testing Machine.*—A 50-ton universal machine of this make is shown in *Fig.* 22. Each installation consists of three main parts:

(1) The press or actual testing machine P.
(2) The oil pump for producing the pressure C.
(3) The pendulum dynamometer D for measuring the load from the oil pressure in the pressure cylinder.

(ii.) *The Press.*—The press is fixed to the top part of the machine, and the movable cradle carrying the upper grips is freely suspended from the ram by two rods connected by a crosshead which rests on the top of the ram. The bottom of the cylinder of the press is held rigidly to the base of the machine by four round columns, which are made heavy enough to carry the superstructure and the maximum load without deformation.

The base itself does not take any of the load applied to the test bar T, it is required merely as a support for the machine and to raise the working parts to a convenient height above the floor level. It is made in the form of a hollow iron casting with an opening in the front for the recovery of the fractured test pieces.

The ram of the press is fitted in the cylinder with such precision that no collar or cup leather is required to ensure a sufficiently oil-tight working. The small amount of play which the ram has in the cylinder allows a slight percolation of oil to take place between them; this makes the movement of the ram in the cylinder very easy, eliminating friction and allowing an exact measurement of the total load to be made. The ram can be rotated by a handle, so that by occasionally moving it through a small angle the formation of ridges, etc., is avoided.

(iii.) *Oil Pump.*—The press is operated by oil pressure produced by a high-pressure pump (O, *Fig.* 22) driven by an electric motor from a countershaft (for small machines a hand drive can be employed). The arrangement of suction and delivery of the oil is such that if all the valves are kept closed the oil is automatically short-circuited back to the reservoir, which is carried on the pump stand. There are also returns for the oil to the reservoir from the top of the cylinder due to leakage, and for the released oil from under the ram.

Water pressure may be used to work the machine by making arrangements for transforming into oil pressure for working the press.

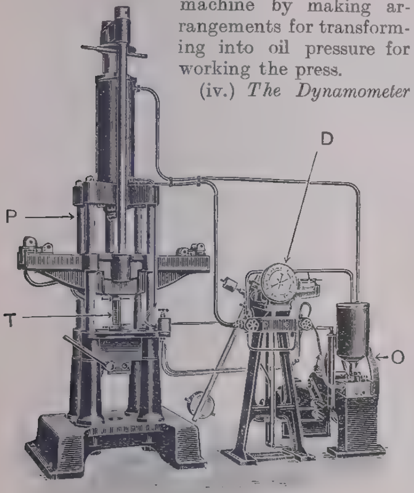

FIG. 22.

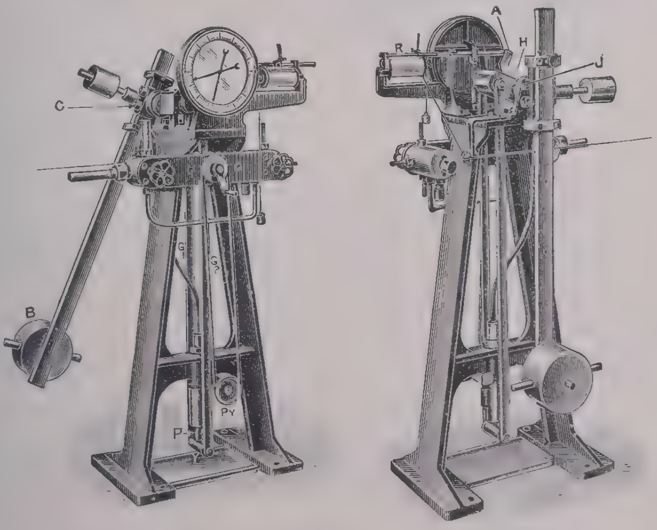
(iv.) *The Dynamometer Apparatus.*—The measurement of the load is made by means of a pendulum dynamometer D. The oil from the high-pressure pump is admitted to the straining cylinder through the dynamometer, so that the actual pressure in the cylinder is shown by the pointer which is operated by the dynamometer.

The pendulum dynamometer is a modification of the dead-weight gauge, which is used for calibrating pressure gauges, the pendulum arrangement being used to automatically balance the load on the plunger, as shown in *Fig.* 23. The oil pressure is applied to a plunger P, which is kept slowly revolving during the test by the pulley P*y*, from which it is transmitted to a yoke Y connecting two vertical rods G_1, G_2. The tops of these rods are attached through a ball-bearing coupling to a short block lever H, which is rigidly secured to a shaft J mounted in ball-bearings in the manometer frame. The depression of the block H by the pressure causes the heavy pendulum B to be deflected until it assumes a position of equilibrium. The point of suspension C of the pendulum can be altered so as to increase the sensitiveness of the machine, the connection to the recording gauge being adjusted at the same time.

The arm and rod A attached to the pendulum operates a pointer on a dial and the dynamometer is also provided with an autographic recording apparatus R.

As a rule each testing machine is accompanied by a pump and separate dynamometer, but it is possible for several machines to use a single pump, if worked in conjunction with an air accumulator, and a separate dynamometer for each machine.

For machines of large power, *i.e.* 300 tons and upwards, Amsler's measure the load by the extension of the columns which carry the top shackle. As these columns extend under the load, they are made to operate a piston in a cylinder. The shapes of the piston and cylinder are so designed that a small relative motion between the two causes a large displacement of the oil which fills the clearance separating them. The displacement of this oil is made to work an indicator which is calibrated in terms of the load.



(*a*) FIG. 23. (*b*)

§ (10) TORSION TESTING MACHINES.—Many universal testing machines of the lever type are fitted with a special shackle for applying torsional stress, as illustrated diagrammatically in *Fig.* 24, in which the torque is applied by a worm and worm wheel A and measured by running the jockey weight B along the lever arm C. It is usually, however, more convenient to use a separate machine, and *Fig.* 25 shows a machine of 250 pounds-foot capacity, made by Messrs. J. Buckton & Co., embodying the method of test mentioned above.

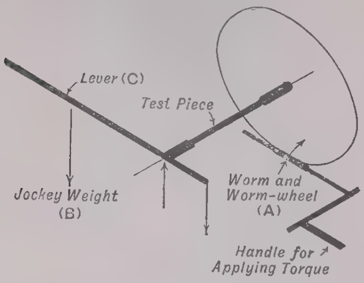


FIG. 24.

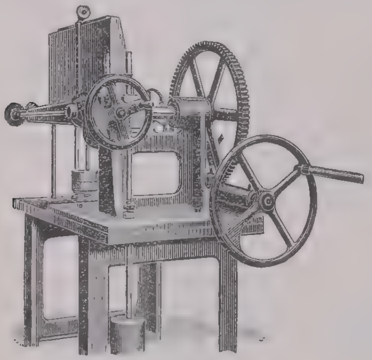

FIG. 25.

A neat little machine, designed by Professor Thurston and made by Messrs. W. H. Bailey & Co., is illustrated in *Fig.* 26. The test piece is placed between two independent jaws, one of which is rotated by hand through a worm and worm wheel. The twist is communicated through the test piece to the other jaw on which a weighted pendulum is attached. The resistance to deflection of the pendulum causes a torque to be applied to the test piece, and the angle of the deflection of the pendulum is a measure of that torque. The history of the test is recorded autographically on a chart attached to a drum which is secured to the jaw which is moved by the gear wheel. The deflection of the pendulum moves a pencil, which is secured to it, over a guide curve fixed to the frame of the machine in such a way that the movement perpendicular to the plane of rotation (that is, the height of the curve) is a measure of the torque, while the length of the curve is proportional to the angle of twist of the test piece.

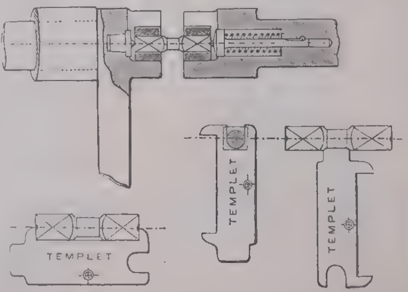

FIG. 26.

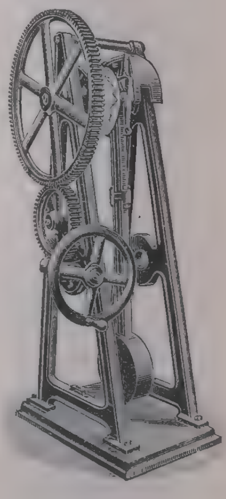
The two machines described above are typical of all of the methods employed for torsional testing machines.

§ (11) TRANSVERSE TESTING MACHINES.—Although a transverse testing shackle always forms part of a universal testing set, most testing machine manufacturers supply special machines particularly suitable for testing cast iron by cross-breaking. These machines enable cast-iron foundry bars to be tested rapidly, and give reliable information as to the mechanical properties of different mixtures.

Such a machine, supplied by Messrs. W. H. Bailey & Co., Ltd., is shown in *Fig.* 27. It is suitable for test bars up to 2 in. deep, 1 in. thick, and 36 in. between centres, and has a maximum capacity of 4500 lbs. An upward force is applied to the centre of the beam by means of a screw, turned by a hand-wheel, lifting a central shackle. The reaction is taken on the beam by two end supports and also on the lever near to the fulcrum. The load is balanced and measured by running the counterpoise along the lever while the deflection is obtained from the movement of the screw which applies the load.



§ (12) GRIPS FOR HOLDING TEST BARS.—As much care should be bestowed on the design of the grips for holding the test bars as on any of the other essential parts of the testing machine, if accurate results are required. It is important that these should be so designed that the resultant of all the forces acts along the axis of the bar, for, if this is not done, the amount of the ultimate load is affected.

The usual method of ensuring that this condition is fulfilled is by arranging for some form of spherical or swivelling seating between the test piece and the connection to the testing machine. The principal objection to most of these seatings is that they have no protection from dust, scale, or other small pieces which are apt to be scattered by the test piece on fracture.

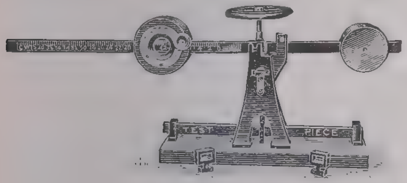


FIG. 27.

In the 100-ton Buckton machine (see § (6)) large hemispherical pieces, H_1 and H_2, are arranged in the top and bottom holders, and to these pieces the special attachments are fitted for test pieces of various kinds.

(i.) *Tension Shackles—Pin Grips.—Fig.* 28 shows the oldest method of holding the ends of plate specimens. A hole is drilled at each end of the test piece for a steel pin A, and the middle part of the plate is reduced in section. The relation of the size of the pinholes and the size of the heads of the test piece to the reduced section is such that the specimen always breaks in the reduced section. This form of holder is one of the best for small specimens, provided care is taken to ensure that the pinholes are accurately on the axis of the reduced part of the test piece, otherwise the stress across the section is not uniform and the specimen tears from the edge where the stress is greatest.

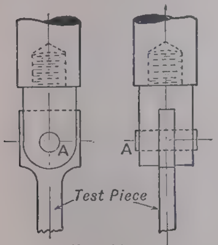

FIG. 28.

(ii.) *Wedge Grips.* — The ordinary method adopted for holding specimens of ductile materials is between two wedges with roughed surfaces, as illustrated in *Fig.* 29, but it does not necessarily ensure that the line of pull is axial. In order to obtain the best results with this method the following points must be borne in mind:

(1) The position of the wedges in the head and of the test piece in the wedges.

Fig. 29 (A) shows a sectional view of the testing machine head with the wedge grips and test piece in position. The wedge grips are bearing their full length against the head and the specimen is bearing for the full length of the wedge grips, and this is the correct condition.

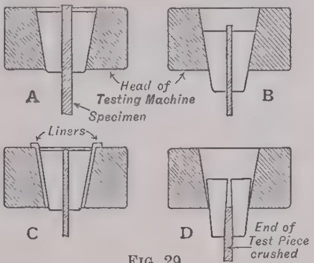

FIG. 29.

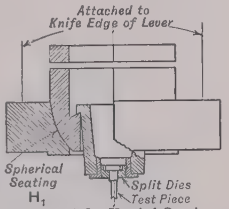
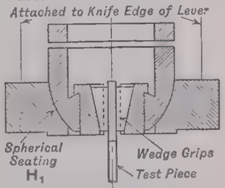
Fig. 29 (B) shows the position of the wedge grips when the specimen is too thin, and while the test piece bears the whole length of the wedge grips, the wedge grips are not bearing their full length against the head. In this case liners are used to keep the wedges back in their proper place, as in *Fig.* 29 (C), although to obviate this difficulty most testing machines are supplied with pairs of wedge grips suitable for various ranges in the thickness of the plate.

If the specimen does not bear for the full length of the wedge grips (*Fig.* 29, D) there is a tendency, on the application of the load, for the end of the specimen to be crushed and a force to be applied to the head which may split it.

(2) The tendency for the wedges to grip the test piece more on one edge than the other.



Arrangement for Headed Specimens in 100 Ton Buckton Machine

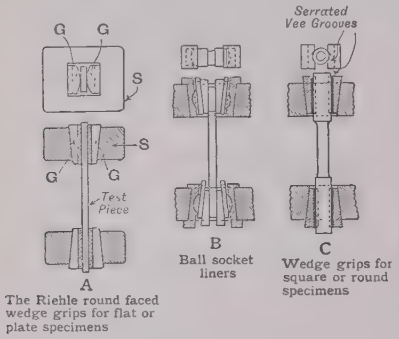


Arrangement for Wedge Grips in 100 Ton Buckton Machine

FIG. 30.

This arises if the specimen is thicker on one side or through want of proper adjustment, when the holders for the wedges are split and separate from the head, as in the Buckton

100-ton machine (*Fig.* 30). To avoid this difficulty Messrs. Riehle Bros. supply wedges with a round face. In *Fig.* 31 (A), G are the round-faced wedge grips contained in the shackle S. Another method for securing proper alignment is a form of ball-socket liner shown in *Fig.* 31 (B).



A
The Riehle round faced wedge grips for flat or plate specimens

B
Ball socket liners

C
Wedge grips for square or round specimens

FIG. 31.

For round or square ductile pieces the wedge grips are provided with serrated V-grooves, as shown in *Fig.* 31 (C).

The ends of the specimen are usually enlarged, as shown in the sketch, but with mild steel or iron this enlargement may be dispensed with.

(iii.) *Self-aligning Grips.* — When testing brittle materials or for accurate experiments the alignment of the specimen is especially of importance. It is usual in these cases to use circular test pieces with the ends to fit special spherical seated holders. *Fig.* 32 shows various methods of machining the test piece and attaching to the shackles.

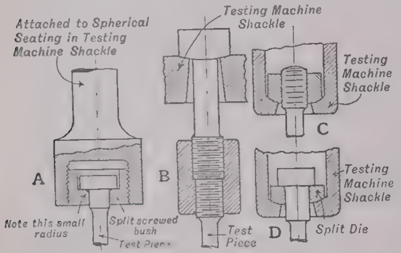


FIG. 32.

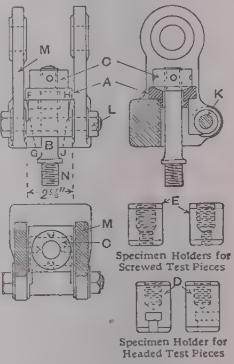
(iv.) *Avery 10-ton Shackles.*—The arrangement of Avery's 10-ton shackles is shown in *Fig.* 33. The holder M is attached to a link hanging from the beam of the testing machine by a second link. This holder consists of a forging machined to take a spherical seating A on which the pull of the test piece is taken through a tool steel stem B and nut C. The stem is screwed at N to take specimen holders of various sizes. Two forms of specimen holder are employed, viz. (1) for headed test pieces D and (2) for screwed test pieces E.

The shackle is also arranged for use with wedges. For this purpose the nut, stem, seating, and bolt L are removed and wedges are inserted, which bear along the surfaces FG and HJ. A handle works in the bearing K, and is arranged with lugs which move both wedges up or down at the same time. This facilitates gripping of the specimens and enables tests to be carried out rapidly.



Specimen Holders for Screwed Test Pieces

Specimen Holder for Headed Test Pieces

FIG. 33.

The top holder, for connection to the lever, is shown in the figure. The bottom holder, attached to the ram-straining rod, works on exactly the same principle; a slide is, however, provided for it so as to keep it parallel to the vertical testing machine guides. Both holders are given in the drawing of the testing machine in *Fig.* 6.

(v.) *N.P.L. Self-aligning 10-ton Shackles.*—The shackles given in *Fig.* 34 were designed by the author for tensile testing, more particularly for use in experiments for the determination of the elastic limit and elastic modulus. They consist of a bolt A with a spherical nut B on one end and a holder for screwed or headed test pieces on the other. The nut bears on a spherical seating G, which fits into the shackle of the testing machine. The spherical seating is kept free from dirt by being closed in at the top by a plate E and at the bottom by a piece of wash-leather F, which fits round the bolt. The wash-leather, although forming a dust-proof cover, allows free movement of the nut and bolt on the spherical seating. The space in the bush is filled with vaseline. These shackles have been in constant use and have been found to give every satisfaction.

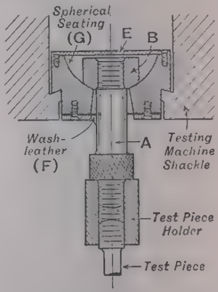


FIG. 34.

(vi.) *Grips for Testing Rope.*—The gripping of ropes or cables requires considerable care in order to obtain reliable results; it is important that the grips should not damage the ends of the rope, otherwise fracture will occur in the sockets.

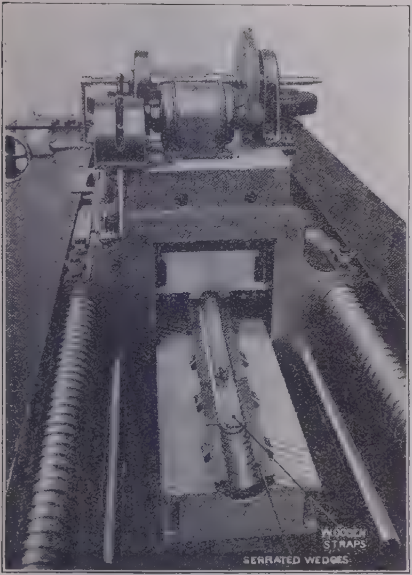

FIG. 35.

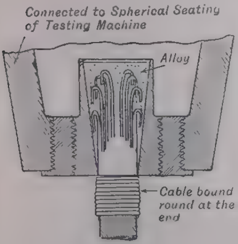
The tests are more conveniently carried out in horizontal machines, where there is plenty of available length, than in vertical machines. Serrated wedges (*Fig.* 35) are used for gripping both wire and hemp ropes, and, to prevent them from being damaged, wooden straps of a suitable thickness and length are placed between the grips and the rope. In order to seize the rope over a considerable length these special wedge grips are made very long.



Connected to Spherical Seating of Testing Machine
Alloy
Cable bound round at the end

FIG. 36.

Where only vertical machines are available a satisfactory way of holding wire rope for tensile tests is to use conical dies in the shackles and seal the ends of the wire in them, as shown in *Fig.* 36, with a low melting-point alloy. The wire is first tightly bound with fine wire at about 5 in. from each end, the end strands are then opened, bent over, and tinned. The rope is next set centrally in the dies, with a little fire-clay, and a hard alloy of lead and antimony run in forming a solid end.

For hemp rope and small cables a method which is largely used is to splice an eye on to each end and test by placing a steel pin through the eye. A more reliable method is to roll the ends round specially prepared helically grooved drums and clamp them. Such tools are supplied by Messrs. Tinius Olsen Testing Machine Co. in the United States of America, or Alfred J. Amsler & Co. (Switzerland); they are costly to build, but give accurate results in testing such materials.

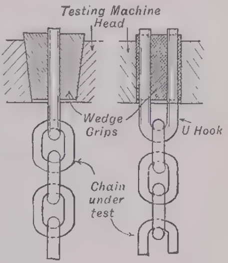


FIG. 37.

(vii.) *Grips for testing Chain in Tension.*—For testing separate chain links or complete chains a piece of steel bent into U form is passed through each of the end links. The open ends of the U-pieces are then gripped in the flat wedges used for testing flat bars (see *Fig.* 37).

Where it is necessary to carry out a considerable amount of chain testing, blocks to suit the various sizes of chain are provided, which fit into the heads of the testing machine GH (*Fig.* 38). By means of these blocks sections of a chain can be tested under a

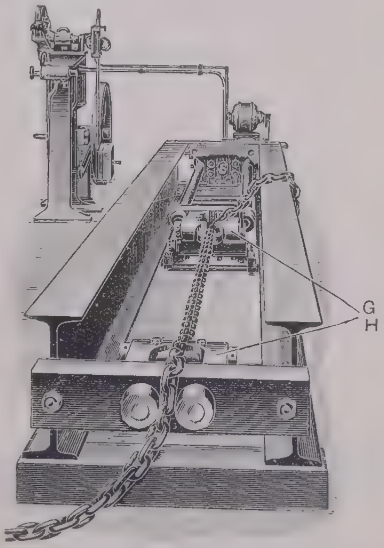

FIG. 38.

proof load; this is not possible with the U-hook method.

(viii.) *Compression Shackles.* — Spherical shackles for compression tests are necessary for accurate work. These either rest on the lower shackle or hang from the upper shackle of the testing machine. Care must be employed in using any of these arrangements to ensure that the axis of the test piece is in line with that of the bearing blocks and testing machine.

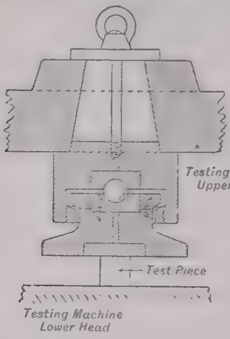

FIG. 39.

Fig. 39 shows a ball-bearing block arranged to fit the upper crosshead of an universal testing machine; this tool allows for free motion in all directions.

(ix.) *Transverse Test Tools.—Figs.* 40A and 40B show two types of shackles for transverse testing. *Fig.* 40A indicates the roller bolster supports and *Fig.* 40B the arrangement adopted with the Buckton vertical testing machine. In the latter method it will be noted that the pressure is applied in halves, at W_1 and W_2, giving a small central span D of uniform bending moment. The object of this method is to reduce local crushing of the test piece T. In both arrangements the standards A, A can be adjusted to graduations on the beam B to give different lengths of span L.

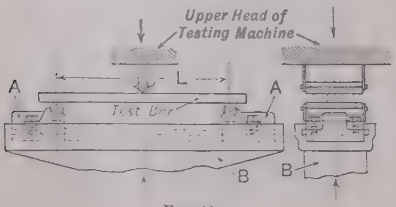

FIG. 40A.

As timber is not homogeneous, four-point loading is usually adopted (*Fig.* 41). This gives a large span over which the bending moment is uniform and in which the beam theoretically bends in the arc of a circle. *Fig.* 42 is a photograph of these shackles fitted to a 10-ton Buckton testing machine.

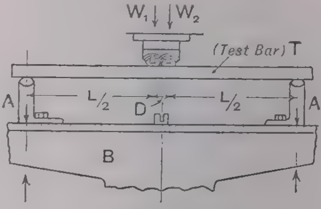

FIG. 40B.

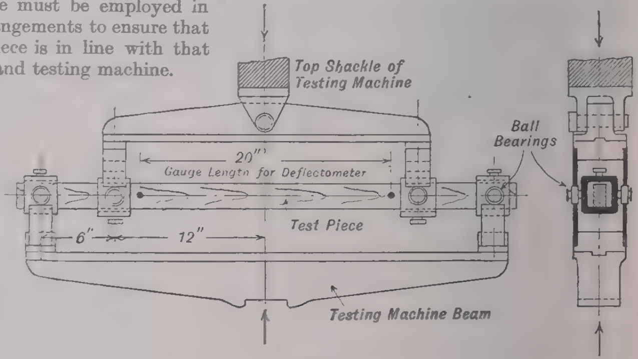
The following points in regard to apparatus for transverse tests should be observed :



Top Shackle of Testing Machine
Ball Bearings
20''
Gauge Length for Deflectometer
Test Piece
6''
12''
Testing Machine Beam

FIG. 41.

Rocking supports should be used at the ends of specimens.

Metal plates should be provided, if necessary, to prevent a high intensity of pressure under the point of loading or at the supports.

Deflectometers or deformeters should not be attached close to the points of application of the loads.

If deflections are to be observed, it is advisable that the rate of loading should be such that the readings can be taken while the load is being continuously applied. If a stoppage is unavoidable, the time intervals should be constant for the test.

(x.) *Shear Shackles.*—There are two methods of applying a shear stress to materials, one by a torsion test and the other by direct shearing or punching. The torsion formula only holds for perfectly elastic bodies, and if it is used for the breaking stress a figure greater than the real shearing stress is obtained.

Various methods for direct shear are in use, but with these the shear is always accompanied by a certain amount of bending and compression.

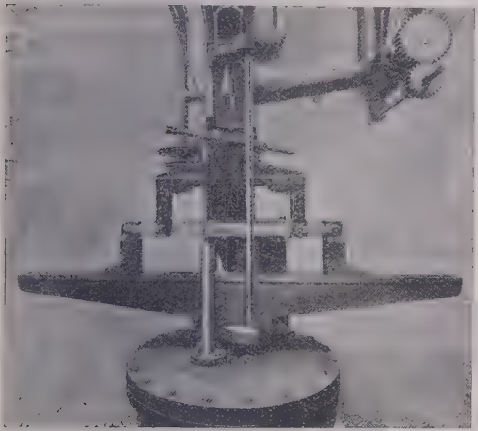


FIG. 42.

(xi.) *Tests of Bar and Plate.*—*Fig.* 43 indicates a shear test tool for round specimens. The specimen A is clamped to a block B and, with the testing machine adjusted for compression testing, the load is applied to the shearing tool C. The test can be arranged so that the specimen is broken in either single or double shear. The dies D, as well as the shearing tool, are made of tempered tool steel ground to an edge. Provision is made for wear of the tools, and they are inserted in such a manner that they can be easily removed when necessary for grinding.

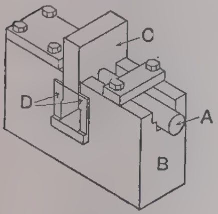

FIG. 43.

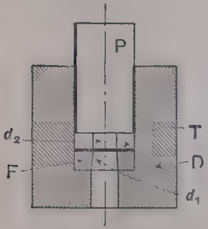

FIG. 44.

A similar method can be used for flat plate, the form of the shearing tools and dies requiring slight modification to that shown in *Fig.* 43.

(xii.) *Test of very Thin Plate.*—An arrangement for shear tests on very thin plates or slices from a bar, used at the N.P.L., is shown in *Fig.* 44. The test piece T is placed in a die D having a hardened steel facing F. A hardened steel plunger P, with a long bearing in the die, is placed on the test piece. The hole in the facing (d_1) is slightly taper (the figure is exaggerated), and the end of the plunger (d_2) is made a good fit in the hole.

The gear is placed between the compression shackles of the testing machine and the load measured, which enables the plunger to push a hole through the test piece.

If t = the thickness of the test piece and W = the load; then the shear stress = $W/\pi d_1 t$.

(xiii.) *Test of Timber in Shear* (see section on timber tests, § (127)).

(xiv.) *Torsion Shackles.*—The easiest way of holding a torsion test piece in the testing machine is to have enlarged ends, either square or round, with two keyways cut in them (*Fig.* 45).

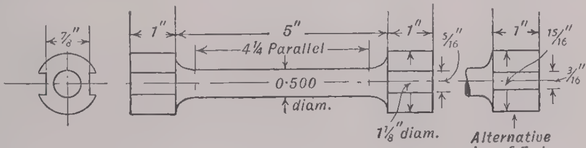

FIG. 45.

§ (13) CALIBRATION OF TESTING MACHINES.—The only satisfactory method of calibrating the readings of a testing machine is by using dead loads through the full range, such as is adopted in the Emery machines, and this method from the point of view of accuracy is above criticism.

Several devices are used to attain the same ends. If dead loads are not directly employed verification depends on a previous calibration of the device used, so that it ultimately depends on a dead-load method.

Next to loading by dead weights the employment of calibrating or proving levers is the most acceptable method. This arrangement is shown in *Fig.* 46. The levers L_1 and L_2, carefully constructed, rest on knife edges in a double chair C_1, which itself rests on the weighing table T_1 of the machine. A single chair C_2 is placed on the other knife edges and forms the fulcrum of the levers; the upper shackle C_2 of the machine is brought down on to this chair. A leverage of ten is generally adopted for calibrating machines up to ten tons capacity, and a leverage of twenty up to fifty tons capacity, which is the maximum to which this method of verification is usually carried.

Other methods of checking are as follows:

(i.) *By a standard test bar* made of steel whose modulus of elasticity is known by previous experiment. A test piece is turned to fit the testing machine, and of such a size that when the maximum load is applied to it the limit of proportionality of load to extension will not be exceeded. An extensometer is fitted to the test piece, and readings of it taken at various loads shown by the testing machine indicator. These readings are then compared with those calculated from the modulus of elasticity, and a verification of the testing machine scale obtained. This method is difficult to carry out except by persons skilled in such work.

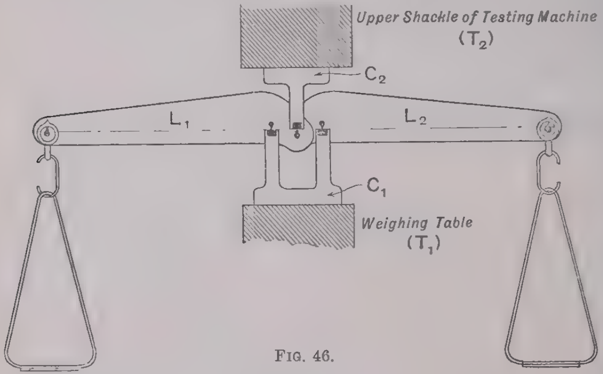

FIG. 46.

(ii.) *With Crushers.*—These are cylinders of copper whose diminution in length with load is known. A series of crushers are loaded in the compression apparatus of the machine with various values of the load, which are noted from the machine indicator. The actual forces exerted are deduced from the diminution of length of the crushers, and these are compared with the indications of the machine.

(iii.) *By a Series of Tensile Test Pieces.*—These are made in duplicate and of varying diameters, so that the largest test pieces will take nearly the full capacity of the machine.

They are all turned out of the same bar of homogeneous material, and one series is broken in the testing machine to be calibrated, and the duplicate series tested under the same conditions in a machine whose accuracy is known.

Both methods (ii.) and (iii.) are simple, but are not available for a greater accuracy than about ±2 per cent.

(iv.) *An improvement of the copper crusher method* has been suggested by Schule and Brunner,[1] who used wood in the form of slabs of small thickness (2 to 4 cm.) as crushers. Wood has the unique property of offering the same resistance to crushing whether tested as cubes or thin slabs. This method dispenses with all measurements of deformation which necessitate the use of instruments of precision, and by selecting wood well dried and without flaws, an accuracy of 1 per cent can be obtained.

Messrs. Schule and Brunner found that the wood of Coniferae is the most suitable owing to its regular structure. Five or six pieces of wood of each cross-sectional area are tested in a standard machine as well as in the machine which is under calibration.

(v.) *With a "Standardising Box."*—This is an instrument supplied by Messrs. Alfred J. Amsler & Co. for quick and accurate checking of testing machines. It is essentially a hollow test bar whose strains under loading are measured by its diminution or increase in volume. It is filled with mercury, and has a horizontal capillary tube, also partly filled with mercury, attached to it on one side, and a micrometer, working a plunger in and out of the box, on the other side. When the instrument is stressed axially the position of the mercury in the capillary tube is altered owing to the change in volume. The position of the mercury is then restored to the zero position by the micrometer. The reading of the micrometer is calibrated under known loads, and this calibration used in conjunction with the standardising box to check the testing machine.

The methods described above are applicable to most testing machines, but with single lever vertical machines a simple test can be carried out quickly and accurately in the following way:

As the load is weighed by a jockey weight, and as there is only one lever, it is only necessary to verify the weight of the jockey and the short arm-length of the lever to ensure that the machine is reading correctly.

(vi.) *Weight of the Movable Counterpoise.*—This can be found by lifting it from the lever with a suitable weighing machine suspended from a crane or, where this is inconvenient, by means of the lever itself, in the following way. First balance the beam and adjust the vernier to zero, then hang up a known weight from the beam at a measured distance from the fulcrum. This raises the beam, and the counterpoise is run along until balance is again restored.

---

[1] "A New Method of comparing the Indications of Testing Machines," *Proc. Int. Assoc. of Test. Mat.*, New York, 1912.

If W = weight of counterpoise,
w_1 = hanging weight,
l_1 = distance of hanging weight from fulcrum,
L = distance counterpoise is moved to restore balance,
then $W = w_1 \times l_1/L$.

(vii.) *Distance between the Knife Edges.*—After the beam has been balanced and the vernier adjusted to zero, a heavy weight w_2 is hung in the shackle of the machine and the counterpoise moved forward until balance is restored.

If W = weight of counterpoise,
L = distance counterpoise is moved to restore balance,
w_2 = weight hung in shackle,
l_2 = knife-edge distance,
then knife-edge distance $= l_2 = L \times W/w_2$.

(viii.) *Sensitivity.*—The sensitivity of the machine can be determined by finding the greatest weight which can be hung from the shackles without causing the beam to move after it has been balanced.

J. H. Wicksteed[1] found that with a 100-ton machine in equipoise, but unloaded, so that the dead weight of lever and poise is equivalent to 6 tons on the knife edge, a pull on the shackles applied through a silk thread breaking with a load of 3 or 4 lbs. is sufficient to raise the lever arm through its whole arc.

(ix.) *Zero Error.*—Care should be taken to see that the zero of the machine is in adjustment before commencing a test.

II. Elongation and Contraction of Area

§ (14) Ductility.—For workshop use a bend test gives much information as to the ductility of a material, and requires very little special apparatus to carry it out. The usual measures of ductility, however, are the ultimate percentage elongation or contraction of area at fracture in a tensile test.

§ (15) Distribution of Elongation in the Test Bar.—If a test piece of ductile material is marked out in one-inch lengths and then tested in tension, it is found that it breaks with a neck or waist, and that the increase in length of the section including the neck is considerably more than at any other point along the bar. Observations for some bars are given in Table 1, and results from them are plotted in *Fig.* 47, where the stretched lengths are plotted as ordinates and the original distances along the bar as abscissae. The resulting curve is seen to consist of two parallel branches connected by a S curve, and it will be evident from the curve that the vertical distance between the two parallel branches is the local extension due to the necking of the test piece.

In *Fig.* 48 the same results are plotted in another way. The increases in length in each inch are plotted as ordinates at the centre of each inch length and connected by a curve. It is seen that the rate of elongation at the fracture is very large, and that the curve is nearly symmetrical.

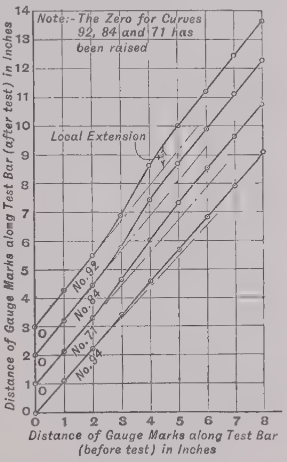

FIG. 47

From the figures in Table 1 the percentage elongations on various gauge lengths can be calculated. Taking the fracture as near to the centre as possible, these results are given in Table 2 and are calculated as follows:

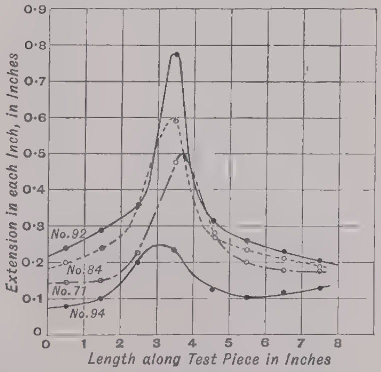

FIG. 48.

If the original gauge length $= L_1$,
the final gauge length $= L_2$,
the elongation $= L_2 - L_1$,
and the per cent elongation $= 100(L_2 - L_1)/L_1$.

---

[1] *Proc. Inst. Mech. Eng.*, 1888, p. 454.

It will be evident from the table that the percentage elongation is dependent upon the gauge length, decreasing as the gauge length increases, and that for strictly comparative results the same gauge length should be adopted for bars of the same diameter. Also, for strict comparability, the position of the fracture should be the same in each bar. If the bar breaks near to the end of the gauge length the percentage elongation is low. The formula for calculating the error involved has been expressed by Unwin [1] as follows:

"Let e_1 be the percentage of elongation in a gauge length $L+2X$, and e_2 the elongation in a gauge length $L-2X$, the fracture being at the centre in both cases. Then the elongation in a gauge length L when the fracture is at X from the centre is $e=\frac{1}{2}(e_1+e_2)$."

The results in Table 3, taken from Unwin's paper, show the magnitude of the error. Unless the gauge mark is in the part affected by the local contraction, the effect on the percentage elongation is small.

§ (16) BARBA'S LAW (ELONGATION OF GEOMETRICALLY SIMILAR TEST BARS).—The law connecting the elongation of geometrically similar test pieces was first given by J. Barba [2] in 1880, who observed that similar test bars deform similarly. It follows that, for cylindrical specimens, if the ratio of gauge length to diameter is constant, the percentage elongation is also constant. This is shown clearly by the results on a mild steel and medium carbon steel given in Table 4.

Unwin says [2] that "in plate test bars, not strictly geometrically similar, the percentage of elongation is practically constant, if the ratio of gauge length to square root of cross-section is constant. The form of cross-section within somewhat wide limits, if the area is constant, does not appear to influence the elongation."

§ (17) THE ELONGATION EQUATION. (i.) *Variation with Gauge Length.*—The elongation of a test bar is made up of two parts:

(*a*) The general extension, occurring before the maximum load is reached, which is approximately uniformly distributed along the bar and therefore proportional to the gauge length.

(*b*) A local extension independent of the gauge length occurring after the maximum load has been reached.

If L = the gauge length,
e = the total extension,

then $e=a+bL$, where a and b are constants, the former for the local extension and the latter for the general extension.

The percentage extension

$$=100\times\frac{e}{L}=\frac{100}{L}(a+bL)=100\left(\frac{a}{L}+b\right), \quad (1)$$

i.e. the percentage extension for a given sectional area decreases as L is increased.

(ii.) *Variation with Cross-section.*—Only the local extension is affected by the cross-sectional dimensions of the test piece, *i.e.* the term a in equation (1).

Since the local contraction is proportional to the *linear* dimensions of the cross-section, and the extension is not affected by the form of the cross-section,

$$a=c\sqrt{A}, \quad . \quad . \quad . \quad (2)$$

where A = the cross-sectional area,
c = a constant;

i.e. for dissimilar test bars

$$\%\text{ elongation}=100\frac{e}{L}=100\left(\frac{c\sqrt{A}}{L}+b\right). \quad (3)$$

This formula is true provided

(*a*) The gauge points are not too close to the enlarged ends of the test piece.

(*b*) The length L is not so short as to fall within the area affected by the local contraction.

Equation (3) is in agreement with Barba's law for similar test pieces that, when similarity is maintained, the percentage elongation is constant because, in that case, $\sqrt{A}/L$, and, therefore, e becomes constant.

Unwin [3] gives the following method of least squares for calculating the values of b and c, in the elongation equation, from a series of observations:

This equation is

$$e\%=\frac{c\sqrt{A}}{L}+b.$$

For simplicity, let $\sqrt{A}/L=a$, and suppose the elongations have been observed for n gauge lengths. Then the most probable values of the constants are given by the equations

$$c=\frac{n\Sigma ea-\Sigma e\Sigma a}{n\Sigma a^2-(\Sigma a)^2} \text{ and } b=\frac{\Sigma e\Sigma a^2-\Sigma ea\Sigma a}{n\Sigma a^2-(\Sigma a)^2}.$$

Applying these results to bar 84 (Table 2), whose diameter = 1·000 in. and area = 0·7854 sq. in., and percentage elongation on

$$\left.\begin{array}{ll} 3''=41{\cdot}0 & 6''=31{\cdot}8 \\ 4''=36{\cdot}5 & 7''=30{\cdot}1 \\ 5''=34{\cdot}0 & 8''=28{\cdot}8 \end{array}\right\} \begin{array}{c} \text{we have} \\ \sqrt{A}=0{\cdot}8863 \\ \text{and } n=6. \end{array}$$

A9F	·330	2·72	8·24	21·06	26·90	32·2	67·8

$$(\Sigma a)^2 = 1{\cdot}165,$$

$$c = \frac{(6 \times 37{\cdot}92) - (202{\cdot}2 \times 1{\cdot}0794)}{(6 \times {\cdot}2179) - 1{\cdot}165} = 65{\cdot}5,$$

$$b = \frac{(202{\cdot}2 \times {\cdot}2179) - (37{\cdot}92 \times 1{\cdot}079)}{(6 \times {\cdot}2179) - 1{\cdot}165} = 22{\cdot}1,$$

and therefore the elongation equation for this bar of material is

$$e\% = \frac{65{\cdot}5\sqrt{\mathrm{A}}}{\mathrm{L}} + 22{\cdot}1.$$

§ (18) CONTRACTION OF AREA AT FRACTURE.—If a is the initial area of the test bar and A the area at the point of fracture, then the reduction of area is equal to $(a - \mathrm{A})$ and the percentage reduction of area $= 100 \times (a - \mathrm{A})/a$.

If the material is perfectly plastic the percentage contraction of area is equal to the percentage elongation where the latter is calculated on the *final* length of the test bar, *i.e.* $100 \times (a - \mathrm{A})/a = 100 \times (\mathrm{L}_2 - \mathrm{L}_1)/\mathrm{L}_2$. ($\mathrm{L}_1$ and L_2 are the initial and final lengths respectively.) The proof of this is as follows:

The volume of the test piece is assumed to be constant, therefore

$$\mathrm{L}_1 \times a = \mathrm{L}_2 \times \mathrm{A}$$

or

$$\frac{\mathrm{A}}{a} = \frac{\mathrm{L}_1}{\mathrm{L}_2};$$

subtracting each from unity, we have

$$1 - \frac{\mathrm{A}}{a} = 1 - \frac{\mathrm{L}_1}{\mathrm{L}_2}$$

or

$$\frac{a - \mathrm{A}}{a} = \frac{\mathrm{L}_2 - \mathrm{L}_1}{\mathrm{L}_2}.$$

The agreement between elongation and contraction of area is only for the short part of the specimen where there is plastic deformation, and it does not apply to greater lengths.

Professor Elliot [1] has given a method of calculating the constants b and c of the elongation equation ($e = c\sqrt{\mathrm{A}}/\mathrm{L} \div b$) when the elongation is only known on one gauge length together with the contraction of area of the test bar. The method depends upon the assumption of a value for the original length of the contracted region. Taking this as $m\sqrt{\mathrm{A}}$, Elliot found that m varied from 0·9 to 2·0, and adopting the value of 1·37 he obtained very fair agreement with results previously published by Unwin.[2]

III. PROCEDURE IN ORDINARY COMMERCIAL TESTING

Commercial testing is undertaken primarily to ascertain if the material is of the quality required by a specification. These inspection or reception tests have to be made quickly, and are principally directed to giving indications of the strength and ductility of the material.

§ (19) PREPARATION AND SELECTION OF TEST PIECES.—The test pieces must be selected so as to give a reliable indication of the material as a whole. Sampling is inherently imperfect, and is therefore apt to cause difficulties. Samples should always be taken and stamped in the presence of an inspector acting on behalf of the purchaser, and there should be safeguards to avoid heat treatment or other manipulation after selection.

The number of tests should be specified, and, in order to cover errors which are likely to arise, limits should be allowed on the test results, and provision made for re-test if necessary. A usual clause is that, should the test piece fail to conform to the specification, the contractor shall have the opportunity of two further samples being selected by the inspector and tested at the manufacturer's expense. Both of these samples must pass in order for the consignment to be accepted.

Test pieces, if to be taken from a sample, such as a tyre, axle, crank-shaft, etc., should be cut out by cold sawing or drilling, and subsequently prepared by milling, turning, or planing. Should shearing be unavoidable, care must be taken to ensure that the material is not bent, and that the sheared edges are entirely removed before testing. Cutting by oxyacetylene blowpipe should not be allowed, as it alters the structure of the material for from 2 to 3 in. from the cut.

Iron or steel plates are usually tested both in the direction of rolling and across it, and with cast iron special bars are made from each cast for transverse test. For some materials special bars form part of the casting and are afterwards cut off for testing, but it is usual to specify the position of these bars and whether they are to be sand or chill castings.

For special tests some form of heat treatment, such as normalising, annealing, or tempering, may be required.

Annealing means reheating followed by slow cooling. Its purposes may be either to remove internal stresses and induce softness, or to refine the crystalline structure. In the latter case the temperature used must exceed the upper critical range, but not more than by 50° C.

Normalising means heating a steel (however previously treated) to a temperature exceeding its upper critical range (but not more than by 50° C.) and allowing it to cool freely in air. It is desirable that the steel should soak at the required temperature for about 15 minutes.

Hardening means heating a steel to its normalising temperature and cooling more or less rapidly in a suitable medium, such as water, air, or oil. Tempering is to reduce the hardness and increase the toughness, and is carried out by heating the steel (however previously hardened) to a temperature not exceeding its carbon change point.

[2] "Tensile Tests of Mild Steel," *Inst. Civ. Eng. Proc.*, 1904, clv. 175.

§ (20) TENSION TESTS.—The data ordinarily observed in a tensile test for reception purposes is

Yield load.
Maximum load.
Elongation after fracture.
Contraction of area at fracture.

§ (21) YIELD POINT AND ELASTIC LIMIT.—Very often there seems to be confusion as to exactly what is meant by the elastic limit and the yield point. It is a common practice for the elastic limit to be specified when what is actually required is the yield point. The actual elastic limit can only be obtained by the use of delicate strain-measuring instruments (see § (62)); the yield point is slightly higher than the elastic limit, and is the point at which there is an increase in the extension without a corresponding increase in the stress. This point occurs in wrought iron or mild or medium carbon steel, and is usually well marked. With hard steel, bronze, and most alloys it is non-existent, the rate of extension with load increasing after the elastic limit without any sudden jump.

For commercial testing the yield stress is the load per unit area at which there is a sudden visible increase in the extension between the gauge marks on the test piece, or it may be taken as the stress at which the beam or indicator distinctly drops when the load is applied at a uniform rate.

The author prefers to record that "there was no yield point" in cases where these conditions are not observed, but, as some specifications require an arbitrary yield point, it is taken at the point at which the test piece extends approximately 1/200 of the gauge length. With a 2-inch gauge length this, for practical purposes, is the point where the dividers, when set at 2 inches, just fail to "feel" the gauge mark.

Johnson[1] proposes that "in view of the difficulty of determining the true elastic limit an apparent elastic limit be taken as the point on the stress strain diagram at which the rate of deformation is 50 per cent greater than it is at the origin. Under this definition the apparent elastic limit would practically correspond to the yield point in materials having such a point and would give a reasonable value for such materials as cast iron, or hard steel, for which this diagram shows a very gradual curvature away from the straight line. Such a criterion has much merit and would accomplish the following results:

"(i.) It would always fix one and the same well-defined point.

"(ii.) This point would always correspond to so small a permanent deformation as to be, for many practical purposes, the true elastic limit.

"(iii.) It is equally applicable to all kinds of tests, whether on specimens or on finished members or structures, where deformations of any kind can be correctly measured.

"While the 50 per cent increase in the rate of deformation is purely arbitrary, it is not large enough to fix a point having an appreciable permanent set, but it is large enough to fix a well-defined point on the stress strain diagram."

Unwin,[2] however, says that "such a point has no significance," also "that the attempt sometimes made to define arbitrarily a yield point for materials which have no distinct yield point, and, often as manufactured, no elastic limit either, appears to him to be useless and misleading."

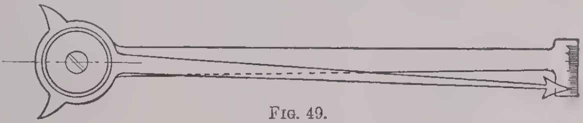

FIG. 49.

It is convenient, where a considerable amount of testing has to be done on the same size of test piece, to use a simplified extension measurer applied to the test piece instead of dividers. G. H. Roberts[3] describes and illustrates an instrument of this kind in which the extension of the test piece is communicated to the pointer on a dial. One division on the dial indicates a movement between the jaws of 0·001 inch. The yield point is seen quite definitely if it occurs, or the load for an extension of 1/200 of the gauge length can be also noted with fair accuracy.

Capp's[4] multiplying dividers answer the same purpose. They are illustrated in *Fig.* 49, and consist of two arms so pivoted that the motion of the points in which the short arms terminate is multiplied about ten times at the scale and pointer forming the ends of the long arms. To use the instrument the points of the dividers are placed in the centre punch marks on the test piece and held firmly in place when the load is applied. The pointer moves across the scale slowly until the yield point, when a sudden and marked increase in the rate is observed.

§ (22) THE MAXIMUM LOAD.—An autographic

---

[1] *Materials of Construction*, 1918 edition, p. 10.

[2] *Testing Materials of Construction*, 1910 edition, p. 266.

[3] "Engineering Research," *Inst. Mech. Eng. Proc.*, July 1913.

[4] *Proc. Amer. Soc. Test. Mat.*, 1907, vii. 624.

stress strain diagram shows that, with a test bar which "necks" before fracture, the actual load necessary to break the test piece at the neck is less than the maximum load on the bar before the reduction of area takes place. Nevertheless, the stress obtained by dividing the breaking load by the reduced area is greater than the stress obtained by dividing the maximum load by the original area of the bar, which is the figure required by specifications.

The terms breaking stress, maximum stress, and ultimate stress are applied indiscriminately to indicate the maximum load divided by the original area which is desired by specifications. It is obviously not the maximum stress, although it is calculated from the maximum load. As the term breaking stress is also liable to be misunderstood the author prefers to call it the *ultimate stress*.

§ (23) PERCENTAGE ELONGATION AND CONTRACTION OF AREA.—In specifications the elongation and contraction of area are required in order to obtain a measure of the ductility of the material. Both are empirical values, and the former, as has been shown in § (17), is dependent on the cross-section of the test bar and the gauge length. It has been suggested that the percentage general extension instead of the percentage total extension should be adopted, as this is independent of the form of test bar. It would, however, complicate the calculation of the results, and owing to the general adoption of the other method of expression would doubtlessly cause considerable confusion.

The general extension, if it is required, is obtained either

(i.) From an autographic diagram, as the extension at maximum load, *i.e.* before the necking of the test piece, or

(ii.) From the measurement of the elongation on two-gauge lengths on the same test piece.

Thus if e_1 = elongation on gauge length L_1,
e_2 = elongation on gauge length L_2,
a = total local extension,
B = the general extension per unit length,

then $e_1 = BL_1 + a$,
$e_2 = BL_2 + a$,

and the general extension per unit length

$$= B = \frac{e_2 - e_1}{L_2 - L_1},$$

$$a = \frac{e_1L_2 - e_2L_1}{L_2 - L_1};$$

e.g. with a 30-ton steel, diameter = 1·000 inch,
Extension on 8″ = 2·37 inches (29·6 per cent).
Extension on 3″ = 1·32 inches (44·0 per cent).

$$B = \frac{2{\cdot}37 - 1{\cdot}32}{8 - 3} = \frac{1{\cdot}05}{5} = 0{\cdot}21,$$

$$a = \frac{(1{\cdot}32 \times 8) - (2{\cdot}37 \times 3)}{8 - 3} = \frac{3{\cdot}45}{5} = 0{\cdot}69,$$

i.e. general extension = B = 21 per cent.

§ (24) MEASURING THE EXTENSION.—The gauge length in ordinary commercial testing is marked on the bar before it is tested, by means of either a double centre punch (*Fig.* 50) or a laying-off and per cent gauge (*Fig.* 51). It is, however, nearly as convenient and almost as quick to use a pair of dividers set to the correct gauge length. It is necessary to have a vee block to support the test piece during the marking-off process.

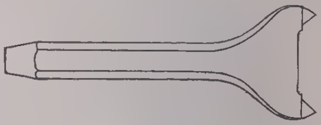

FIG. 50.—Double Centre Punch.

As long as the fracture is not less than a length equal to the square root of the area inside the gauge mark the measure of the elongation is usually accepted as satisfactory, *i.e.* 0·5 inch for a test piece of 0·25 sq. in. area or 0·7 inch for a test piece of 0·5 sq. in. area.

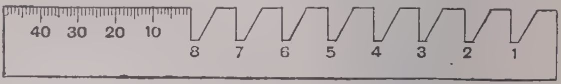

FIG. 51.—Laying-off and per cent Gauge.

Sometimes it is specified that "should a tensile test piece break outside the middle half of its gauge length the test may, at the contractor's option, be discarded and another tensile test shall be made from the same bar, billet, sheet, forging or drop forging." The middle half is defined as shown in *Fig.* 52.

§ (25) METHOD OF REPORTING RESULTS.—It is desirable that the results should be reported in such a manner that the information can be assimilated as easily as possible. It adds greatly to the facility with which the results can be compared and scrutinised if the form of report is always in the same style. The following points are also worth consideration:

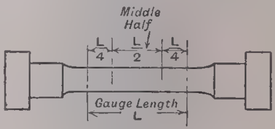

FIG. 52.

(1) The report should contain as far as possible the actual observations.

(2) The heads of information which are purely observational and those which have been reduced by calculation should be kept separate. It is convenient to have the latter on the right-hand side of the form.

A typical form for tensile tests is given in *Fig.* 53, together with the results of a few tests. It is seen that the information which is ultimately required is given in the last five columns.

REPORT.—TENSILE TEST OF MATERIAL CARRIED OUT ON BOILER PLATE SUPPLIED BY A. BROWN & CO., LTD., FOR WHOM THE TESTS WERE MADE

Test No.	Identification Marks.	Original Dimensions.			Yield Load. Tons.	Maximum Load. Tons.	Dimensions at Fracture.				Yield Stress. Tons/Sq. In.	Ultimate Stress. Tons/Sq. In.	Elongation. Per Cent.	Reduction of Area. Per Cent.	Remarks.
		Gauge Length. Inches.	Dimensions. Inches.	Area. Sq. In.			Extension. Inches.	Distance of Fracture from Gauge Mark.	Dimensions. Inches.	Area. Sq. In.					
1201	UE1	2	·563	·2489	3·4	6·57	·67	1·0	·395	·1225	13·7	26·40	33·5	50·8	Slightly laminated fracture

FIG. 53.

Example of Test Record and Calculation of Results.—

TENSILE TEST ON BOILER PLATE FOR A. BROWN & CO., LTD.
Material received July 30, 1920

	1.	2.	3.
Test No.	1201	..	..
Identification marks	UE1	..	..
Gauge length	2″	..	..
Dimensions of test piece	0·563″ diam.	..	..
Cross-sectional area of test piece	0·2489 sq. in.	..	..
Yield load	3·4 tons	3·4/0·2489	..
Yield stress	..	..	13·7 tons/sq. in.
Maximum load	6·57 tons	6·57/0·2489	..
Ultimate stress	..	..	26·40 tons/sq. in.
Elongation	0·67″	(0·67/2) × 100	33·5 per cent
Distance of fracture from gauge mark	1·0″	..	..
Dimensions at fracture	0·395″ diam.	..	..
Area at fracture	0·1225 sq. in.	$\frac{\cdot 2489 - \cdot 1225}{\cdot 2489}$	..
Reduction of area at fracture	..	..	50·8 per cent
Remarks	..	..	Slightly laminated fracture

It will be noted that, with the exception of the original area, the observed values are given in column 1 and the calculated figures in column 3. This method simplifies the typing of the report as given in *Fig.* 53.

§ (26) FORMS OF TENSILE TEST BARS.—It is shown by experiment that the form of the tensile test piece has an influence on both the elongation and the strength.

The elongation with ordinary test bars is measured on a gauge length of uniform section. The effect of the enlarged ends is to reduce the local drawing-out of the material. The parallel part of the test piece is therefore always made somewhat greater than that on which the elongation is measured. If the length of the parallel section is reduced so as to form an abrupt change in cross-section of the bar tested under tension, a concentration of stress is caused at the bottom of the groove or notch which is thus formed, while the shoulders formed by the groove prevent free elongation of the metal.

In a material which extends very little, an abrupt change of section will lower the breaking load, while with a ductile material the suppression of the local drawing-out gives an increased tensile stress.

The influence of the gauge length on the percentage elongation has been discussed in § (17).

On account of the considerations stated above, it is essential that definite types of specimen should be specified for commercial tests, in which the results of the tests decide whether the material is to be accepted.

As a result of the work of Barba, the French

Commission recommends the adoption of the relation

$$L^2 = 66{\cdot}67\ A$$

or $L = 7{\cdot}2D$ for circular specimens,
where L = the gauge length,
A = area of cross-section,
D = diameter of the test bar.

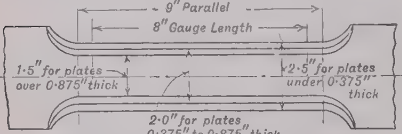
The German Commission recommends the use of the relation

$$L = 11{\cdot}3\sqrt{A}$$

or $L = 10D$ for circular specimens.

Thus while, with a test piece 10 mm. diameter, a gauge length of 72 mm. is recommended in France, a length of 100 mm. is adopted in Germany.

Owing to the practical difficulties in the way of adopting a varying gauge length for different cross-sections of test piece cut from plates and other rolled sections, fixed standards for cylindrical and flat specimens have been prescribed by the American Society for Testing Materials (A.S.T.M.) and the British Engineering Standards Association (B.E.S.A.).



9" Parallel
8" Gauge Length
1·5" for plates over 0·875" thick
2·5" for plates under 0·375" thick
2·0" for plates 0·375" to 0·875" thick

B.E.S.A. Standard Sizes of Test Plates for Plates

	d	G	P	p	l	S	L_1	L_2	D_1	D_2
×	0·977	3·50	4·00	5	8	1·5 B.S.W.	6·25	8	1·25	1·75
×	0·798	3·00	3·375	4	6·5	1·25 B.S.W.	5·25	6·5	1·0	1·5
×	0·564	2·00	2·25	3	4·5	0·75 B.S.F.	4·25	5·25	0·75	1·25
	0·358	1·25	1·50	2	3	0·50 B.S.W.	–	–	–	–
	0·125	0·443	0·625	0·875	1·5	"0" B.A.	–	–	–	–

Radius r should be as large as is consistent with the other dimensions.

× *These are B.E.S.A. Test Pieces*

Standard Forms of Cylindrical Test Bars

FIG. 54.

The sizes selected by the B.E.S.A. are given in *Fig.* 54. Those adopted for cylindrical test bars of forgings (*Fig.* 54) approximately satisfy the law of similarity, where

$$L = 4\sqrt{A},$$

viz. :

Diameter. Inches.	Area in Sq. Inches.	Gauge Length. Inches.
0·564	0·250	2
0·798	0·500	3
0·977	0·750	3½

For plates, both 10-inch and 8-inch gauge lengths were in use before the B.E.S.A. standard was published. A standard width of 2 inches was used for convenience in milling; this gave a cross-sectional area varying with different thicknesses of plate, and thus disregarded the effect of the cross-sectional area on the percentage elongation.

In order to overcome this difficulty the B.E.S.A. standardised test bars having a fixed gauge length of 8 in. and a width varying with the thickness of the plate. In order to lessen the cost of production, three widths only were chosen, viz. :

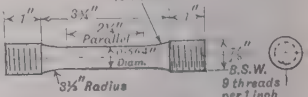
Thickness of Plate. Inches.	Width of Test Bar. Inches.	Gauge Length. Inches.
Under ⅜	2½	8
⅜ to ⅞	2	8
Over ⅞	1½	8

§ (27) ENLARGED ENDS OF TEST PIECES. (i.) *Tensile Tests.*—The design of the enlarged ends of test pieces requires care in order to be sure of satisfactory results. It has already been stated that axial alignment of the test piece is necessary for accurate work and that this is best attained by the use of spherically seated holders.

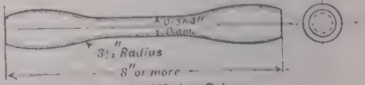
For brittle materials it is essential that the transition from the parallel part of the test piece to the enlarged ends is gradual, and that any part of the enlarged ends which is screwed, or otherwise has a sharp corner, is sufficiently large to prevent fracture at that place. Forms of ends for turned test pieces of cast materials are given in *Fig.* 55.

Test pieces may be tapered inside the gauge length towards the centre, to an amount not exceeding 0·003 in. for turned test pieces and 0·01 in. for sheets or plates, in order to induce fracture near the centre of the gauge length. If this is done the middle half of the gauge length of the test piece should be parallel.

(ii.) *Compression Tests on Metals.*—With the more plastic metals there is no well-defined point of break-down under compression, and it is usual to record the compressive strength at a given unit of deformation. The values which are obtained in this way are only



Test Piece for Screwed Grips



Test Piece for Wedge Grips

FIG. 55.

comparative and do not give results which can be used as a basis for calculating sizes of structures.

With brittle materials the ultimate stress can be obtained with precision, and the results are of value for calculating sizes of compression members.

For metals the test piece is usually a cylinder whose ratio of length to diameter is two.

It is important, especially with brittle materials, that a spherical seated shackle should be provided in order to adjust for inaccuracy of the parallelism of the shackles. A form of shackle is shown in *Fig.* 39. Care should be exercised to ensure that the pressure is applied axially.

§ (28) QUALITY FACTOR.—Various empirical means of estimating the quality of the material from the results of the tensile test have been suggested. They combine the tensile strength with either the percentage of elongation or percentage contraction of area at fracture. The only factor which has been used to any large extent in this country is a modification of one suggested by Wohler:

Wohler's quality factor $= p + c$
and the modified factor $= p + e$,
where $p =$ tensile strength,
$e =$ per cent elongation,
$c =$ per cent contraction of area.

A quality factor must be used with care, bearing in mind the use to which the material is to be put.

§ (29) BEND TESTS.—A rough workshop test of the ductility of metals is given by the bend tests of various types which are now in common use. The test is made by bending a piece of the material either by steady pressure or hammering, the former giving the more concordant results, until an angle of 180° is reached or previous rupture takes place. In the latter case the angle is noted at which fracture occurs on the outside of the bend. A large amount of experimental work has been carried out by Mr. Bernard Firth,[1] but the test has not been so carefully standardised as the tensile test.

The test is also used for ascertaining the effect of punching and drilling on the ductility, by using perforated plate specimens with the hole in the centre of the plate. The diameter of the hole, as recommended by Martens, should be twice the thickness of the plate and the width of the specimen five times its thickness.

§ (30) KINDS OF BEND TEST.—The principal types of bend test in use are:

(i.) Cold bend test (as received).
(ii.) Cold bend test (annealed).
(iii.) Quench bend test or temper bend test.
(iv.) Hot bend test.
(v.) Nick bend test.

(i.) *Cold Bend Test.*—This is the type which is most commonly used and is carried out at normal temperature. To test the ductility at low temperature the test pieces are sometimes cooled artificially.

(ii.) *Annealed Bend Test.*—For the annealed bend test the material is, previously to bending, reheated to a temperature exceeding its upper critical range, followed by slow cooling. The steel is usually very bad if it cracks after annealing.

(iii.) *The quench bend test* is used for determining the effect of alternations of high and low temperature on the ductility on such materials as boiler-rivet steel and stay-bolt iron. Before applying the bend test the material is heated to blood-red and plunged into water at a temperature of 80° F. The colour is judged indoors in the shade.

(iv.) *The hot bending test* is specified to detect red shortness or high sulphur content. The material is bent while at a temperature of about 950 to 1000° C.

(v.) *The nicked bend test* is intended to show whether the material has a crystalline or fibrous structure. The test piece is nicked all round, before bending, with a tool having a cutting angle of 60°. The depth of the notch is 8-16 per cent of the diameter of the test piece. The test piece should be placed so that the bend occurs with the minimum depth.

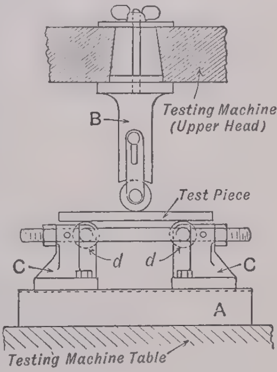


FIG. 56.

§ (31) FORMS OF SPECIMENS FOR BEND TESTS AND METHOD OF TESTING.—Rods are usually tested without machining. Plates should be planed at the sides after shearing, and the corners rounded with a file, otherwise cracks may start at the corners due to the shearing process having weakened the metal. With plates over one inch thick it is especially important that this precaution should be taken.

It is usual to bend bars, unless otherwise specified, round a mandrel of a radius equal to the diameter or thickness of the bar.

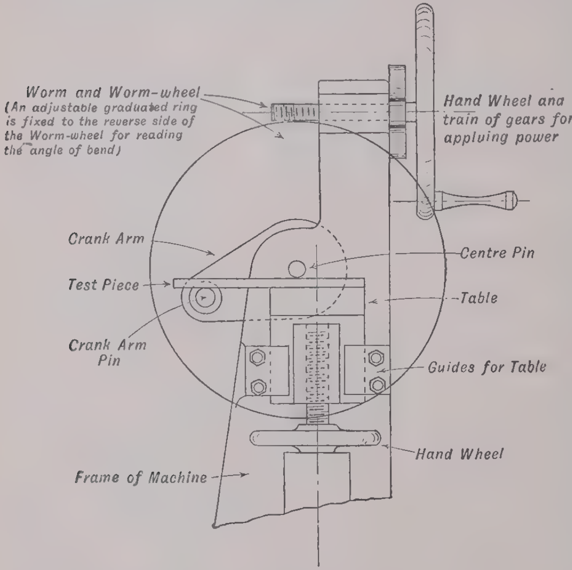
A cold bending apparatus is shown in *Fig.* 56, in which a steady pressure is applied during the test. The lower plate A rests on the table of the testing machine while the upper tool B is held in place in the pulling head by wing nuts and plate. The brackets CC are spaced sufficiently apart to allow the upper tool and twice the thickness of the specimen to easily pass between the lower rollers *dd*. The rollers can be changed so as to adapt the apparatus for either round, square, or twisted bars.

---

[1] *Inst. Civ. Eng. Proc.* clv. 254.

Where a large number of tests have to be carried out, and the testing machine or press cannot be spared, it is usual to have a special machine used exclusively for bend tests. A hand power machine for specimens up to one inch square is shown in *Fig.* 57.

The correct size of centre pin is first put in the machine, the crank arm is next rotated until the crank arm pin is below the level of the test piece, and then the table is adjusted by means of the small hand-wheel until the top of the specimen rests against the centre pin, which should be at about the centre of the specimen. The graduated ring is set to zero, and power is applied to the crank arm, which revolves until the test piece ruptures or the required angle of bend, read off on the graduated ring, is reached.



Worm and Worm-wheel
(An adjustable graduated ring is fixed to the reverse side of the Worm-wheel for reading the angle of bend)
Hand Wheel and train of gears for applying power

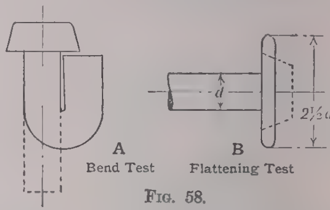
FIG. 57.

A fatigue test is sometimes used as an alternative to the bend test. The test piece is placed on bearings with a span of 6 in., and must stand without fracture twenty blows from a weight (of 1120 lbs.) having a rounded end of 1¼ in. radius and falling 6 in. The test piece is to be reversed after the first and every alternate blow. The height of fall after the twenty blows is increased to 12 in. and the test continued until fracture occurs.

Bend tests are now often replaced by single-blow notched bar tests (see § (98) to § (109)); but these require special testing plant.



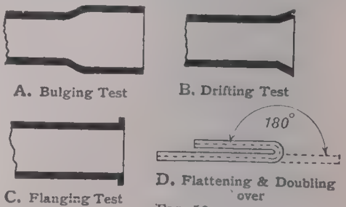
A Bend Test B Flattening Test

FIG. 58.

§ (32) TESTS FOR RIVETS.—Rivets are usually subjected to a bend test and a flattening test. For the bend test they are hammered cold without cracking until the two parts of the shank touch (*Fig.* 58 (A)) and for the flattening test the heads are hammered while the rivet is hot and must flatten without cracking of the edge to a diameter 2½ times that of the shank (*Fig.* 58 (B)).

§ (33) BULGING, DRIFTING, FLANGING, AND FLATTENING TESTS FOR COPPER AND BRASS TUBES.—It is usually specified that brass and copper tubes shall stand a certain percentage increase in the diameter (25 per cent is usual) without crack or flaw when subjected to bulging (*Fig.* 59 (A)), drifting (*Fig.* 59 (B)), or flanging (*Fig.* 59 (C)). Another test which is frequently imposed is flattening and doubling over. It is generally carried out both cold and at red heat. The tube is flattened and doubled over through 180° as shown at *Fig.* 59 (D).

§ (34) DRIFTING TEST OF METALS.—Another workshop test for ductility, which is applied with ordinary shop appliances, is to bore holes of a given diameter near to the edge of the plate and open them by means of a conical



A. Bulging Test **B.** Drifting Test

C. Flanging Test **D.** Flattening & Doubling over

FIG. 59.

drift (taper 1 in 10) until cracking occurs or a definite increase in diameter is reached. The hole is usually ⅝ inch diameter and 1½ inch from the edge of the plate.

The following table gives comparative figures for various sizes of plate:

TABLE 5

Material.	Thickness. Inches.	Original Size of Hole, in Inches.	Enlarged Size of Hole before Cracking, in Inches.
Wrought iron	0·20	0·625	1·00
„	0·25	0·625	1·20
„	0·30	0·625	1·32
Mild steel	0·30	0·625	1·50

§ (35) FALLING WEIGHT TEST (called "drop test" in U.S.A.).—The falling weight test is considered to be a most useful test for rails and is given a prominent place in rail specifications. It is made by placing a piece of the rail 4 to 6 ft. long on supports 3 ft. apart and dropping a heavy hammer, through varying distances, on to it at the mid-point of the span. The results show if the rail is brittle and the deflection gives a measure of the ductility.

TABLE 6

	U.S.A.	British.
Falling weight	Of cast iron with steel striking die having a radius of striking face of 5 in. and length of face of 12 in. Total weight 2000 lbs.	Of cast iron with steel striking face having a radius of 5 in. Weight 2240 lbs.
Anvil	Solid iron casting 15 in. thick and weighing 20,000 lbs.	Weight 26,880 lbs., area of base 45 sq. ft.
Foundation	Anvil supported on 20 springs arranged in groups of five at each corner. The springs are supported by a cast-iron base-plate which is bolted to a substructure with a timber floor in between. The floor to be 18 in. longer than the base-plate.	Anvil supported direct on 25 tons of concrete having an area of 100 sq. ft. No timber or springs between the test piece and foundation.
Supports for test piece (anvil dies)	Pieces of steel having a cylindrical bearing surface of 5 in.	Steel bearers having a radius of 3 in.
Release	A tripping device.	No automatic release allowed.

P. H. Dudley[1] of U.S.A. says: "The physical properties of different sections can be compared and their chemical compositions adjusted from the results obtained on the standard drop-testing machine."

The results are comparative only when carried out under the same conditions.

It is generally recognised that the weight of tup, distance apart of supports, height of fall, radius of striking faces and supports, and form of foundation must be specified. There is a difference of opinion however on this point, more especially in regard to the foundation of the machine.

Particulars of the standard machines usually adopted in the United States of America and in Great Britain are given in Table 6.

The atmospheric temperature is usually reported, and due allowance is made for rails tested at or below 0° C.

The falling weight test is also applied to tyres and axles. For tyres a weight of 2240 lbs. is allowed to fall freely from 10, 15, 20 ft., and upwards on the tread; the tyre being placed in its running position upon a heavy cast-iron anvil supported by a rigid concrete foundation. The tyre must deflect a given amount without fracture.

If d = internal diameter of tyre, as rolled, in inches,
t = thickness of the centre of the tread, as rolled, in inches,

deflection $= d^2/ct^2$,

where c = a constant depending on the breaking stress of the material (see Table 7).

TABLE 7

45	42-48
50	50-55
55	56-62

§ (36) DROP TEST OF TYRES.—Tyres are subjected to a drop test as well as to a falling weight test. The tyre is allowed to drop freely, in a running position from a specified height, upon a rail fastened to an iron block of not less than two tons weight. The tyre is then turned through 90° and dropped a second time. The height of fall depends upon the diameter of the tyre (see Table 8).

§ (37) TESTING CAST IRON. (i.) *Transverse Test.*—Owing to the ease with which it can be carried out the transverse, or cross-breaking test, has been universally adopted as the standard for cast iron. The test is carried out by breaking the test bar as a beam loaded centrally. The strength is measured by the centre load which the bar will carry. The deflection is also usually specified because, when taken in conjunction with the load, it gives an approximate measure of the toughness of the cast iron. It is essential that the form of the test bar should be standardised in order to obtain comparative results, but unfortunately the standards which are in use in various countries are different. Particulars are given in Table 9.

	18	1905	44,900		1·82
	24	1400	44,000		1·78

The general experience, in casting bars of the various standards in use, is that there is a little more difficulty in obtaining sound bars cast to the English section than in the case of either the American or German bars.

Machined bars are generally weaker than unmachined specimens.[1]

If W is the central load, L the span, Z the modulus of the section, and f the stress in the bar.

Then within the elastic limit,

$$\frac{WL}{4}=f\times Z, \text{ or } f=\frac{WL}{4}\times\frac{1}{Z}.$$

Above the elastic limit the stress calculated from the formula varies for the same material with the form of the section, but if the breaking load W_b is substituted for W, a value of f is obtained which is a measure of the quality of the material for bars of similar section, and is called the modulus of rupture.

G. Hailston,[2] in 1914, as a result of a series of experiments on cast iron when tested by cross breaking, finds that whereas the ratio of the breaking loads for $1\times2\times36''$ (span) and $1\times1\times12''$ (span) beams is 1·333 if the formula $W\times L/4=fZ$ is taken as applying up to the point of rupture, the actual value is 1·153 if the pieces are machined, and 1·146 when tested with the skin left on. He further finds that the best test bar to give the most consistent and comparable results, both with breaking load and deflection, is $2\frac{1}{8}\times1\frac{3}{8}\times42''$ cast on the flat and machined down to $2\times1''$ and tested on a span of 36 in. The rate of testing should not exceed 112 lbs. in less than 15 seconds.

---

[1] Segundo and Robinson, *Inst. Civ. Eng. Proc.* lxxxvi. 248.

[2] *Iron and Steel Inst. Journ.*, 1914.

The results in Table 10 of tests on grey cast iron by Mathews[1] show that the modulus of rupture decreases as the span increases; the cross-section being circular (1¼ in. diam.) and kept constant.

Table 11, compiled from figures recorded by J. E. Stead,[2] gives a comparison of results obtained on British, American, and German standard bars. His conclusion is that it is desirable that any bar for testing for deflection by transverse stress should not be less than 24 in. long, as, with shorter bars than this, it is very difficult to measure to the required degree of accuracy except with very delicate measuring instruments.

TABLE 11

EXPERIMENTS ON TRANSVERSE STRENGTH

Comparison of tests on English, German, and American Standard Bars

In commercial work a deflectometer of the type shown in *Fig.* 60 is generally used. It consists of a cast-iron base the bottom of which is carefully planed. This base carries a scale along which a lever moves a vernier reading to 0·001 in. The adjusting screw of the lever is arranged under the transverse tool so as not to be affected by the breaking of the specimen. A simple arrangement which is sometimes adopted is to use a Brown and Sharp lathe indicator under the transverse tool at the centre of the beam.

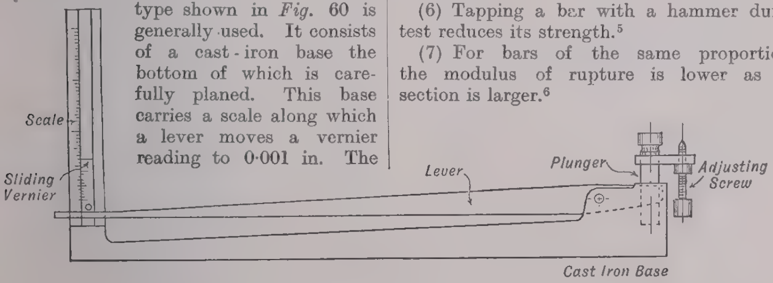

FIG. 60.

The following observations have been recorded as the result of careful experiment:

(1) Square bars, in general, exhibit a slightly higher modulus of rupture than round bars of equal area. Tests by a committee of the American Society of Mechanical Engineers[3] give an average of about 5 per cent higher.

(2) Bars cast horizontally are strongest when the load is applied against the cope face.

(3) Rough bars are stronger than planed bars.[4]

(4) Tumbling in a rattler increases the hardness of the skin and therefore improves the strength.

(5) Bars run with hot metal are weaker and deflect more than bars run with dull metal.[5]

(6) Tapping a bar with a hammer during test reduces its strength.[5]

(7) For bars of the same proportions, the modulus of rupture is lower as the section is larger.[6]

(8) A wide bar gives a higher, and a deep bar a lower modulus of rupture.[6]

(1″ wide, 2″ deep, 42″ long, and 36″ span) the strength of cast iron is usually specified by its breaking load in cwts., figures of 18, 28, and 38 (cwts.) corresponding to poor, fair, and good cast iron. A usual specification is that the cast iron shall sustain a load of 30 cwts. at the centre with a deflection of not less than $\frac{3}{8}$ in.

A form of report which is suitable for transverse tests is given in *Fig.* 61. It enables the salient points of the results to be seen at a glance, and meets all ordinary cases on the testing of cast iron.

(ii.) *Effect of Temperature on the Transverse Strength of Cast Iron.*—Cast iron loses very little of its strength or toughness up to a temperature of 400° C. The following sets of experimental results by Meyer[1] show this very clearly.

§ (38) Tensile Strength of Cast Iron.—It is important when making tensile tests on cast iron to ensure that the pull is axial, as this material is greatly weakened by oblique or eccentric loading. For accurate testing, shackles with spherical seats should be employed (see *Figs.* 33 and 34), the test bar should be cast in one with the work and turned to a suitable size, care being taken to avoid rapid changes of section near the part of the specimen under test.

The size of the bar from which the test piece is taken affects the results obtained, bars of larger section giving, as a rule, lower results.

Tables 13 and 14 give results recorded by J. E. Stead[2] on test pieces prepared from bars of various sizes which have been cast in different ways.

Table 10 gives results obtained by Mathews[3] on cast iron containing various percentages of silicon.

A comparison between the modulus of rupture and the tensile strength is given in Table 15.

§ (39) Crushing Strength of Cast Iron.—The crushing strength of cast iron is obtained on cylinders or prisms in which the ratio of the height to the least lateral dimension is between one and three.

The crushing strength is usually about five times the ultimate tensile stress, and samples of bad, good, and very good cast iron should give a crushing stress of 30, 40, and 50 tons per square inch respectively.

§ (40) Resistance of Cast Iron to Direct Shear and Torsional Shear.—As the result of experiments in direct shear by Platt and Hayward[4] it was thought that the shearing strength of cast iron was about five to six tons per square inch. Izod,[5] however, by using more perfect apparatus, has obtained much higher figures, and these are confirmed by Goodman. The results of these tests, together with the figures obtained from gun-metal and mild steel, for comparison, are given in Table 16.

The point of interest in Table 16 is the fact that the shearing strength of cast iron is higher than the ultimate tensile strength. Goodman says that, with the exception of specimens which are defective on account of blowholes or sponginess, he has never had a single instance of a specimen of cast iron giving a lower result in shear than in tension.

Fremont is of opinion that the shear test gives a very useful indication of the quality of cast iron if the sample tested truly represents the material of the casting. He has devised a special test for this purpose.[1] A small piece of the actual casting, 25 mm. diameters and 20 mm. long, is detached by a trepanning tool. The specimen is placed within a block holding a fixed blade, and is cut by a movable blade which is forced into the specimen by a weight

[1] Fremont, *Comptes Rendus*, Dec. 9, 1918.

acting on a lever. The force of rupture is estimated from the weight and leverage. Since the diameter of the hole bored in the casting is only about 1¼ in. diameter the casting is not spoiled by this method of procedure.

Under torsional shear a round bar of cast iron invariably fractures along a helix whose angle is 45°, that is to say, it occurs where the tensile stress is a maximum, and indicates that cast iron has a lower resistance to tension than to shearing. This conclusion confirms the direct shear results of Izod and Goodman. A typical torsion fracture is shown in *Fig.* 62.

FIG. 62.

§ (41) INFLUENCE OF FORM ON THE PROPERTIES OF MATERIALS.—An abrupt change in the cross-section of a tensile or transverse test bar causes:

(*a*) A diminution of the elongation at the reduced section due to the shoulders of the notch or groove.

(*b*) The stress to be highly concentrated at the periphery of the groove or notch.

There are thus two effects—the suppression of the drawing out of the material causes a gain of strength, while the inequality of the stress on the section of fracture gives a reduction in strength.

With a brittle material, *e.g.* cast iron, the elongation is negligible, and in consequence the effect of a groove is to cause a reduction of strength. On the contrary, a grooved mild steel test piece is stronger than a plain bar of the same material, because the suppression of the drawing out causes an increase in strength which is greater than the effect due to concentration of stress at the groove acting in the opposite direction.

(i.) *The Effect of Perforation on the Strength of Mild Steel Plates.*—In the discussion on a paper by W. Hackney before the Institute of Civil Engineers, Stromeyer[1] describes experiments carried out to determine the effect of perforation on the tensile strength and elongation of boiler plates. The forms of test bars that he used are given in *Fig.* 63, and the results are given in Table 17.

The test pieces are all cut from one piece of plate 12 mm. (t) thick, and the holes are all 24 mm. (d) diameter. The width (b) varies in different bars from 7·6 to 54·0 mm.

(ii.) *Strength of Screwed Bolts.*—The results of some tensile tests on four different kinds of screw threads, made by the author, are given in Table 18. The threads selected were:

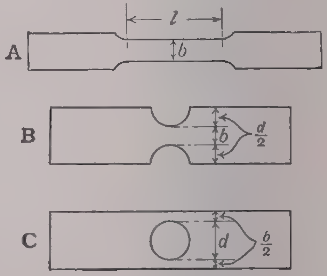

FIG. 63.

(1) British Standard Fine.
(2) British Standard Whitworth.
(3) Sellers Thread.
(4) U.S.A. 60° Sharp Vee Thread.

Four materials were used, ranging in ultimate stress from 24·0 to 52·7 tons per square inch. The bolts were ⅝ in. diameter and were all machined from 1¼-in. diameter bar.

---

[1] *Proc. Inst. Civ. Eng.*, 1884, lxxvi. 142.

From the results in Table 18 it is seen that for steel up to 40 tons per square inch the strength (per square inch of section taken at the bottom of the thread) is greater for the bolts than for the plain bar, but that for the 53-ton steel the bolts, with the exception of those screwed with B.S.W. thread, are weaker than the plain bar.

Note.—(1) Stresses are given in tons per square inch. (2) For tests on threads, the area for calculating the stress is taken as that at the bottom of the thread.

Martens[1] has carried out similar tests on ½-in. and 1-in. bolts, using steels of 27·7 and 23·9 tons per square inch respectively. His conclusions are as follows:

(1) Screw threads subjected to plain tension

---

[1] *Zeits. Vereines Deutsch. Ing.*, April 27, 1896.

are stronger than plain bars of the same net cross-sectional area, the excess of strength being approximately 14 per cent.

(2) There is no marked difference in the ultimate strength with different forms of threads—the sharp thread is slightly stronger than the others.

(3) Under repeated loads and impact it is probable that the sharp vee threads would develop cracks quicker than the other forms, and that the Whitworth thread would be the last to show this weakness, either with repeated loads using soft material or static loads with high carbon steel.

The two sets of experiments, by different experimenters, described above are in agreement. It will be seen that Martens's supposition with regard to the superiority of the B.S.W. thread with high carbon steels under static loads is shown by the author's tests to be correct.

With regard to Martens's statement of the probable weakness of sharp vee threads under impact, some tests by the author also confirm this conclusion. The tests, of which the results are given in Table 19, were made on 1-in. bolts and broken by a single blow, the energy absorbed in fracture being measured. It will be noted from the table that the sharp vee bolts are the weakest of those tested and the British standard threads the strongest.

TABLE 19

§ (42) INFLUENCE OF TIME ON TEST RESULTS.—General experience shows that elongation and contraction of area are increased by very rapid loading, but that within the ordinary limits of time occupied by a tensile test to fracture, of most materials, the rate of loading does not appear to have any effect on these results. The results from various experimenters, however, are not quite consistent.

(i.) *Effect of very Rapid Loading.*—Maitland [1] found that steel, broken in impact, gave 74 per cent more elongation than the same material broken in the static tensile testing machine.

Blount, Kirkaldy, and Sankey [2] concluded that the impact tensile test gave the ductility in the same terms as the static tensile test, but always with higher numerical values.

On the other hand, Lebasteur [3] was unable to find this difference with steel bars. His tests gave fractures which were the same in appearance in the two cases, and the elongations of similar bars were also nearly identical.

(ii.) *Effect of Variations of Slow Rates of Loading.*—Bauschinger [4] carried out a fairly complete set of experiments under slow rates of loading and showed that:

(1) The effect on the elongation of altering the rate of loading varied according to the material employed. With cast iron the effect was negligible, while with steel, wrought iron, copper, bronze, and brass it was so slight that it was masked by differences in the quality of the test bars. For lead and tin there was a marked increase in the extension with time.

(2) The ultimate stress was in some cases greater when the extension was fast than when it was slow.

Tests on iron and steel given by the Commission des méthodes d'Essai des Matériaux [5] show very little difference in the ultimate extension of the ultimate stress whether carried out in a few seconds or many minutes.

Bottomley,[6] however, when experimenting with soft iron wire, found that, generally, the contraction of area and local contraction were less if the loads were applied more slowly. His researches included a determination of

the effect of time on the breaking load of soft iron wire. He found that the wire, if loaded to just below the ordinary breaking load, increased in strength according to the time the wire was under this initial load.

A summary of the results are given in Table 20.

IV. Measuring Instruments for the Determination of the Elastic Constants of Metals

In order to obtain information as to the elastic constants of materials it is necessary to measure deformations while these materials are being strained elastically.

In commercial testing, where a measure of the ductility only is required, the final amount of deformation is all that is necessary. In a tensile test with a standard 2-in. gauge length and cross-sectional area of 0·25 sq. in., the total elongation may be 0·50 in., and as this can be measured by the aid of dividers to the nearest $\frac{1}{100}$ in. the accuracy of reading is 2 per cent.

Using the same size of test piece and gauge length, the extension at the elastic limit is of the order of 0·002 in., so that for the same percentage accuracy the measurement must be correct to 0·00004 in.; the smallness of this extension can be realised when it is considered that the thickness of a piece of cigarette paper is about 0·001 in. With the best types of mirror extensometer, alterations of length can be accurately measured to $\frac{1}{10}$ of this amount, *i.e.* 0·000004 in.

§ (43) Extensometers.—In any type of strain-measuring apparatus there are certain general principles which it is advisable should be fulfilled.

(i.) If changes in length of the axis of the test bar are to be determined, measurements should be taken on opposite sides of the specimen. Unwin[1] has shown that, if this condition is not satisfied, initial curvature of the bar will cause serious errors in the results, but "if the mean of measurements taken at points symmetrically placed on either side of the bar is adopted, the error due to curvature is nearly eliminated, the lengthening of the distance of one side being compensated by shortening on the other."

(ii.) The apparatus should be directly attached to the test piece at the gauge points only, and after the initial setting it should not be necessary to handle it during the course of the experiment.

(iii.) The instrument should be as light as possible, and designed so as to be rapidly attached to or detached from the test piece without interfering with the application of the load. It is advisable that, if possible, it should be self-contained.

(iv.) The instrument should be arranged so that its accuracy can be determined by a calibrating device, and the attachment to the test piece should be such that the gauge length is capable of determination with sufficient accuracy.

(v.) The mechanical or optical details, and the relative positions of all the parts with respect to the axis of the specimen, should be such that the "constant" of the instrument is the same throughout its range, or that any errors which are involved are so small as to be of no importance.

(vi.) The zero of the instrument should be constant for the same conditions of test; thus if, after straining the test piece, there is no permanent set the instrument should return to its initial position.

Extensions are measured in five different ways:

(i.) With a micrometer screw.
(ii.) By an indicating dial.
(iii.) With a microscope.
(iv.) By a multiplying lever (mechanical magnification).
(v.) By optical magnification.

With methods (i.), (ii.), and (iii.) the deformations are ascertained with little or no magnification, while with instruments employing methods (iv.) and (v.) the strains are considerably magnified before the measurements are made. Some extensometers use a combination of (iv.) or (v.) with (i.), (ii.), or (iii.).

§ (44) Micrometer Screw Extensometer.—These instruments consist of two clamps placed on the test bar at a distance apart which is equal to the gauge length. The movement of one clamp relatively to the other, as the load is applied, is measured by the reading of one or more micrometer screws fixed to one clamp and brought into contact with the other. The accuracy of the instrument depends on:

(*a*) The uniformity of the pitch of the micrometer screw.

(*b*) The constancy of the pressure at the point of contact.

(*c*) The care with which the micrometer screw is operated, because the instrument has to be touched by hand many times during the experiment. Care should be observed in order to ensure that the couple applied by the fingers is perpendicular to the axis of the screw.

Micrometer screw extensometers are largely used in the U.S.A. by students, and give satisfactory results when used with great care. The principal makes of instrument are divided into two sections according as to whether they have one or two micrometers.

---

[1] "Measuring Instruments used in Mechanical Testing," *Phil. Mag.*, March 1887; *Phys. Soc. Proc.*, 1887.

§ (45) DOUBLE MICROMETER SCREW INSTRUMENTS. (i.) *Professor R. H. Thurston's*[1] *Extensometer* (1875).—This was the first instrument in which two micrometer screws were used, one placed on each side of the axis of the test piece, and in which electric contact was employed in order to eliminate errors due to variation of pressure.

(ii.) *Henning's*[2] *Micrometer Extensometer.*—This instrument is shown in *Fig.* 64. Two frames A and B grip the test piece by two steel points *h*, *h* and two knife edges *c*, *c*. The lower frame B carries two micrometers *m*, *m*, and the upper frame A is provided with a pair of plugs *g*, *g* which are in line with the micrometers. As the distance between the frames increases with application of the load, the ends of the screws *f*, *f* are brought in contact with the plugs *g*, *g*. The contact is indicated by ringing an electric bell by a weak electric current, or, owing to the uncertainty of bell mechanisms, telephone receivers are sometimes substituted. The extension is read on vertical scales *e*, *e* and the graduations of the micrometer heads *m*, *m*.

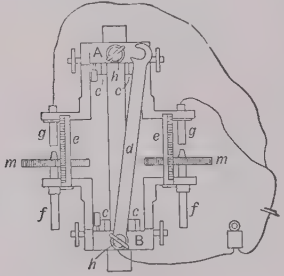

FIG. 64.

The instrument registers to one ten-thousandth part of an inch, and can be used on either round, flat, or square specimens. In order to attach the extensometer to the test piece, the frames A and B are opened. Bars *d* are used for setting the frames A and B at the correct distance apart; they are removed while the test is in progress. An instrument of this type is supplied by Messrs. Tinius Olsen Testing Machine Co., Philadelphia, under the name of The Olsen Standard Duplex Micrometer extensometer.

(iii.) The extensometer invented by C. A. Marshall, of the Cambria Iron Company, differs from Henning's in three small details. The adjusting bars *d* (*Fig.* 64) are omitted and the knife edges *c*, *c* are replaced by a spring and roller attachment which, in connection with a spirit level, assists in the accuracy of the adjustment. The micrometer screws are placed nearer the lower frame than in the Henning extensometer.

(iv.) *The Yale extensometer*[3] is a simplification of the Marshall apparatus. The spring rollers are omitted and a gauge bar introduced to keep the clamps parallel, bring the points of measurement opposite, and gauge the length. The gauge bars are made of different lengths and are removed before beginning to strain the specimen. It reads to ten-thousandths of an inch by micrometer screw.

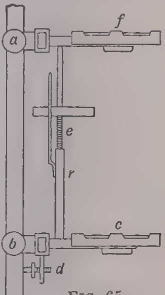

FIG. 65.

§ (46) SINGLE MICROMETER SCREW INSTRUMENT. *Unwin's*[4] *Screw Extensometer.* — This instrument is shown diagrammatically in *Fig.* 65. The two frames are clamped to the test piece at points on a plane passing through its axis by set screws *a* and *b*. The lower frame carries the micrometer screw *e*, on the hardened point of which the upper frame rests. Provided that the frames are at right angles to the axis, the micrometer screw gives the variations in the length between the two points of support on the test piece. To set the frames normal to the axis of the test bar, levels *c*, *f* are attached to them. Level *c* on the lower frame is adjusted by the screw *d*, while the upper frame is set level by means of the micrometer screw *e*. The pressure on the micrometer screw is thus constant, and equal to the weight of the upper frame.

§ (47) SINGLE MICROMETER SCREW COMBINED WITH A MULTIPLYING LEVER. (i.) *Garratt's*[5] *Extensometer.* — In this instrument (shown diagrammatically in *Fig.* 66) there is a mechanical magnification of two, combined with measurement by means of a single micrometer screw. Two pairs of steel plates B and C are attached to the test piece by screws E, E and pivoted together at F. The micrometer M is pivoted to the lower plates and carries a spindle H which passes through a guide K pivoted to the upper plates. The spindle carries a hardened pin on its upper end, and when the test piece extends, this pin, which forms part of an aneroid barometer, moves the aneroid needle. Half of the amount which

the micrometer has to be moved to bring the needle to its original position is a measure of the extension.

(ii.) *Riehle improved extensometer*, supplied by Messrs. Riehle Bros. Testing Machine Co., reads the average stretch from two sides of the test bar with one micrometer screw. The arrangement is shown diagrammatically in *Fig.* 67. The two frames A and B are each fixed axially to the test piece by two hardened steel-pointed thumb-screws S, S. The left-hand rod R is rigidly joined to the lower frame B and is pivoted to the upper one A. The right-hand rod swings from a pivot in the upper frame over the micrometer screw in the lower one. The rods are equidistant from the points of attachment to the specimen, so that when elongation occurs the right-hand swinging rod moves away from the micrometer *twice the amount of the elongation.* This extensometer can be used on gauge lengths from 2 in. upwards by having sets of rods for those gauge lengths which are required. Elongations of 0·0001 in. can be easily read, and electric contacts can be employed with the instrument.

FIG. 67.

(iii.) *The Cambridge Extensometer* (*Fig.* 68). —This simple and accurate extensometer is made by the Cambridge and Paul Instrument Co. Ltd., Cambridge, and is especially designed for use as a workshop instrument. It is composed of two separate frames, each of which is attached to the test bar M by hard steel conical points PP and P′P′ arranged in geometric slides so that, after the points are gently driven into the punch marks, they can be clamped in position by the knurled heads R, R. The lower frame carries a micrometer screw H and a vertical arm B at the top of which is a hardened steel knife edge about which the two frames work together. The micrometer screw is provided with a hardened steel point X over which a nickel-plated flexible steel tongue A, forming a continuation of the upper frame, is carried. The tongue and frame form a lever magnifying the extensions of the test piece by five.

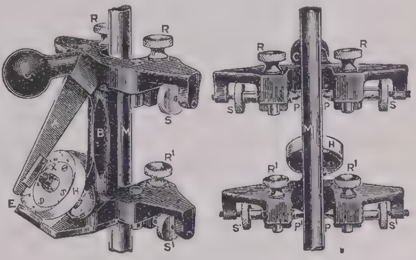

FIG. 68.

In use the vibration of the flexible tongue takes the place of the electric contact, in the instruments previously described, as a delicate means of setting the micrometer screw. The steel tongue is vibrated and the screw turned until the point X just touches the hardened knife edge of the tongue as it vibrates. Readings can be repeated by this means to 0·001 mm. under ordinary conditions of test. The standard instrument is suitable for specimens up to $\frac{3}{4}$ in. diameter on a gauge length of 4 or 2 in.

§ (48) INDICATING DIAL INSTRUMENTS.—This type of instrument consists of one or more calibrated dials with pointers on nicely mounted spindles. These take the place of the micrometer screws in the previous class of extensometers, and are self-indicating for large or small deformations. They are generally used in conjunction with some form of lever magnification.

Messrs. T. Olsen supply a dial extensometer of exactly the same form as Henning's extensometer (§ (45)) except that dials and sliding rods replace the micrometer screws. The sliding rods are attached to the lower frame in place of the micrometer screws, and spindles, carrying drums and pointers, are fixed to the upper frame with their axes horizontal. These take the place of the plugs *g*, *g* (*Fig.* 64). The friction of the sliding rods against the small drums (1 in. in circumference) cause the latter to rotate. This also rotates the spindles and pointers round calibrated discs.

§ (49) DIAL EXTENSOMETERS WITH MECHANICAL MAGNIFICATION. (i.) *University of Wisconsin Wirewound Extensometer.*[1]—This has one dial attached to the upper frame which is operated by a wire arranged to transmit twice the extension of the test piece to the dial drum.

(ii.) *Hurst-Tomlinson Extensometer* (*Combined Lever and Dial*), *Fig.* 69.—This instrument has been especially designed for use on the standard test piece (0·564 in. diameter and 2 in. gauge length); it can be used, however, on specimens up to one inch in diameter. The gauge length of 2 in. is not adjustable, but the instrument can be attached to specimens of greater length than this if required. It is provided with two forked levers, A and B, fitted at the fork with pointed clamping screws which, when tightened on to the test piece, form the pivots of the levers.

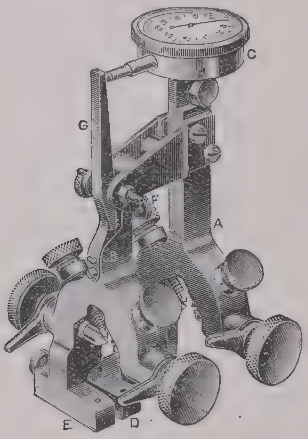

FIG. 69.

The dial indicator C is attached to one end of the upper lever, and the other end, beyond the test piece, has a stout vertical lug D extending downwards from one extremity of the fork nearly to the level of the lower lever. Here the lug bends inwards, and one arm E of the fork of the lower lever extends inwards in the same way.

The two levers are connected by a short length of piano wire which lies in the central vertical plane of the two levers.

This forms an elastic hinge, so that as the test piece stretches the free ends of the levers open away from one another.

This method of connecting the levers also permits the test piece to straighten out slightly under the load, if originally slightly bent, without straining the extensometer.

The lower lever is shorter than the upper one, and it carries at the free end a short vertical screw F with a large milled head.

The end of the screw is rounded and polished, and bears on the end of the shorter arm of a third lever G which is attached by a short length of flexible steel ribbon to a bracket which is screwed and dowelled to the upper main lever.

The end of the longer arm of this third lever bears upwards on the end of the plunger of the dial indicator.

The system of levers is proportioned so that the movement transmitted to the indicator is ten times the extension of the test piece.

By turning the milled head of the screw F the dial indicator can be brought to zero before the load is applied; a light spring maintains the end of the small lever in contact with the point of the screw. While the extensometer is being attached it is necessary for the two main levers to be rigidly locked, with the axis of the clamping points parallel and at a distance of 2 in. apart.

This is accomplished by inserting two locking pins, one of which constrains the axes to be parallel while the other fixes the distance between them.

The first pin is placed in the same horizontal plane as the wire hinge, and its axis intercepts the centre of the wire so that the insertion of this pin leaves the levers only one degree of freedom.

The second pin correctly fixes the relative positions of the two levers.

In order to ensure that the clamping points shall grip the test piece along a diameter and not along a shorter chord, two screws are placed in the forked part of each lever inclined at about 45°.

The axis of these screws intercept the axis of the test piece and the ends are rounded to bear at points on the test piece.

The usual diameter of the reduced part of the test piece is 0·564 in., which gives a cross-sectional area of 0·25 sq. in., and the length of the screws is such that when just tight the ends are 0·282 in. away from the vertical plane through the clamping points.

When attaching the extensometer it is simply held up against the test piece bearing on the ends of the four screws, and the clamping screws are tightened and the points pierce the test piece along two diameters. The extensometer is thus a self-contained marking-out jig. As soon as the instrument is fixed to the test piece the four screws are just slightly slackened so that they are just clear while the test is being made.

---

[1] See Johnson's *Materials of Construction*, 1918, p. 81.

One division on the indicator corresponds to an extension of 0·0001 in. and, by estimating, the extension can be readily measured to the nearest 0·00002 in. This instrument is made by Charles W. Cook, Ltd., Manchester.

(iii.) *Riehle Dial Extensometer.* — A similar type of dial extensometer is supplied by Messrs. Riehle Bros. Testing Machine Co. The instrument itself is not quite so elaborate, and requires a special marking-off block which forms part of the outfit.

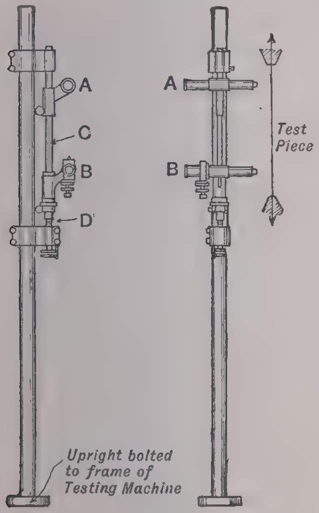

FIG. 70.

(iv.) *Berry Strain Gauge*[1] (*Combined Lever and Dial*). — This instrument measures the deformation on the surface of the test bar or structure and in principle is a pair of beam compasses, one point of which is fixed to the frame of the instrument and the other operating an Ames Dial through a five to one bell-crank lever. The points of the instrument are placed in the gauge marks and an alteration in the gauge length is shown on the Ames Dial.

§ (50) MICROSCOPE READING EXTENSOMETERS. (CATHETOMETERS.)—With this type of instrument the distance between fine scratches on the test piece is measured by sighting with a microscope on the two scratches, and reading off the distance the microscope has been moved along the slide to which it is fixed. The determination of elongations by this method is a lengthy process, and except for special purposes it has been abandoned.

Fig. 70 shows an arrangement of two microscopes which is convenient for measuring the extensions of stranded cables. Microscope A has ordinary cross wires while microscope B is fitted with a micrometer eyepiece. Both instruments are attached to a bar C which can be moved vertically by the screw D. Both microscopes are focussed on scratches on the test piece and the load applied. By means of the screw D the cross wire of the top microscope A is made to coincide again with the top scratch, while the adjustable cross wire is moved in the second microscope to the new position of the bottom scratch. The movement of this cross wire in the calibrated micrometer eyepiece gives the extension.

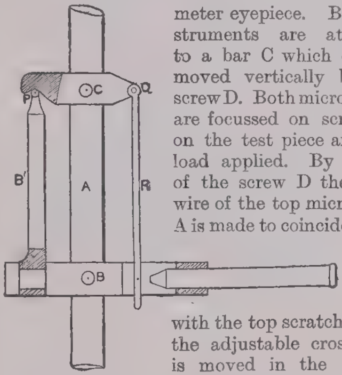

FIG. 71.

§ (51) COMBINED MICROSCOPE AND LEVER EXTENSOMETER. *Ewing Extensometer.*[2]—This instrument has been used for a great deal of the scientific work in this country. It is shown diagrammatically in *Fig.* 71, and in its latest form in *Fig.* 72. The two clips, B and C, are each attached to the test piece A by two pointed screws. Clip B carries the vertical projection B′ (*Fig.* 71) terminating in a rounded point P, which engages with a conical hole in C. The pieces B and B′ are joined to one another in such a way that the test piece may twist a little without affecting the engagement of P with C. When the test piece extends, P serves as a fulcrum for the clip C, and point Q is displaced through a distance equal to twice the extension. This displacement is measured by a microscope attached to B, sighting on a mark on the rod R hanging from the point Q on the upper clip. The readings are taken from a micrometer scale in the eyepiece of

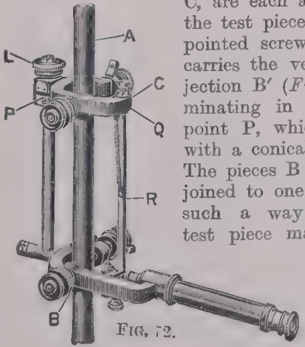

FIG. 72.

---

[1] *Engineering Record*, June 11, 1910.

[2] *Roy. Soc. Proc.*, 1895, lviii. 123.

the microscope. The screw (L, *Fig.* 72) serves to bring the sighted mark to a convenient point on the micrometer scale and also determines the scale readings which can be estimated to 0·00002 in. A clamping bar is added by which the clips B and C are held at the correct distance when fixing them on the test piece. This extensometer is made by Messrs. The Cambridge & Paul Instrument Company for gauge lengths of 2 and 8 in. and 10 and 20 centimetres.

An apparatus for marking off the gauge points (*Fig.* 72A) is supplied with the instrument.

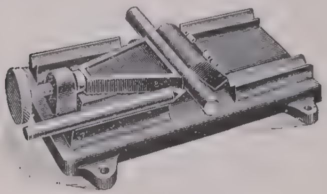

FIG. 72A.

§ (52) MULTIPLYING LEVER EXTENSOMETERS.—(i.) Kennedy [1] designed a simple lever (leverage 100 to 1) extensometer clipped to the test bar at two points.

Martens's [2] lever extensometer is a modification of the Kennedy instrument, and is arranged to take simultaneous readings on two opposite sides of the specimen. It is shown diagrammatically in *Fig.* 73, and consists of two clips D, D carrying the graduated scales C, C, and held on opposite sides of the specimen by a spring S. Diamond-shaped pieces A, A, to which the arms B, B are attached, are pivoted in shallow seats formed in the clips D, D. With a magnification of fifty, readings can easily be made to 0·002 mm.

(ii.) *Kennedy's* [3] *horizontal extensometer* is gripped on the bar at four points in an axial plane and consists of two frames, one fixed to each gauge mark, which rest on each other over the points of attachment to the test bar. A light pointer is provided with two steel points, one resting on each frame. When the test bar elongates the two points move relatively to each other in an axial direction, and this movement is magnified by the end of the pointer which travels over a scale carried by a rod attached to one of the frames.

Other instruments of this type have been designed by Stromeyer,[4] Goodman,[5] Wicksteed,[6] Ashcroft,[7] Col. W. H. Paine,[8] and Dupuy.[9]

§ (53) OPTICAL MAGNIFYING EXTENSOMETER.—For greater accuracy than 0·00002 in. in measuring deformations some form of optical lever is generally employed in which the change of length of the test piece is converted into rotary motion of a mirror which is observed by means of a telescope and scale. Some extensometers employ two mirrors in which readings are obtained from opposite sides of the test bar, while in others the mean extension is measured by the reading from a single mirror.

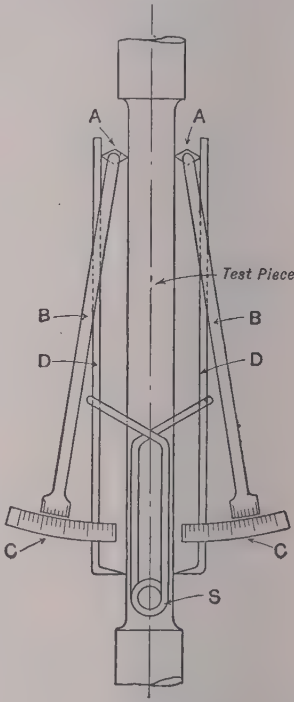

FIG. 73.

(i.) *Two Mirror Apparatus. Bauschinger's Instrument.*[10]—The introduction of mirror extensometers is principally due to Bauschinger, who designed the instrument shown in *Fig.* 74.

Two clips, *a*, *a* and *b*, *b*, are pressed against the specimen: *c*, *c* are light springs which press outwards against the rollers *d*, *d*. These rollers, which are of caoutchouc, are carried by the clip *b*, *b*, and themselves carry the mirrors *g*, *g*. As the specimen extends the rollers rotate, and these rotations are measured by means of the telescopes E, E and scales *f*, *f*. The results are recorded to 0·0001 mm.

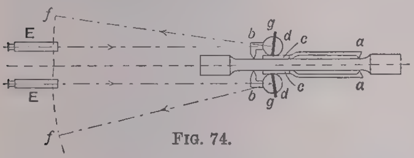

FIG. 74.

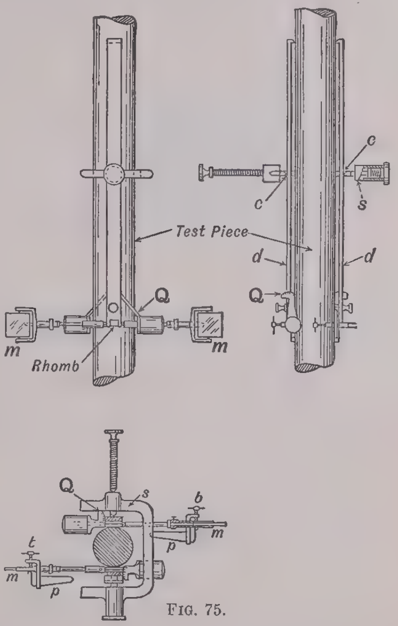

FIG. 75.

(ii.) *Martens's Mirror Extensometer.*—This is an improvement of Bauschinger's instrument and is shown in *Fig.* 75. It is extremely accurate and sensitive and is most adaptable. In this arrangement the multiplying levers of Martens's lever extensometer (*Fig.* 73) are replaced by small mirrors (*m*, *m*, *Fig.* 75) which are attached to the rhombic-shaped pieces of steel acting as fulcra, in such a way that the reflecting surface of each mirror is on the axis of the fulcrum. The two clips *d*, *d* are held on opposite sides of the specimen by a spring *s* which rests in grooves *c*, *c*. Each clip is pointed at one end which is gripped directly on the test bar, while the other end has the rhombic piece interposed between it and the bar. The mirror is mounted in a frame by means of pivots centred in small holes drilled in the glass. In order to adjust the position of the mirror the frame is free to revolve on the axis of the rhomb. An adjusting screw *b* and spring *p* are placed on opposite sides of the mirror to control its

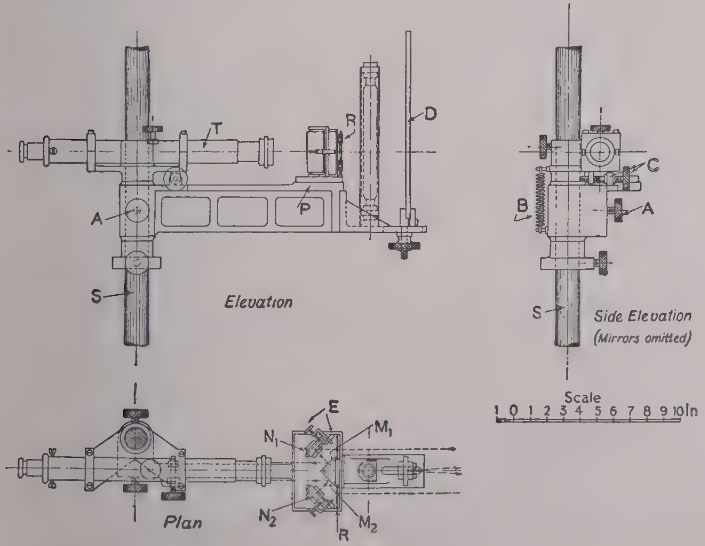

FIG. 76.

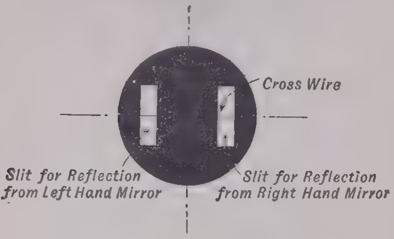
position about an axis at right angles to that of the rhomb.

A pointer Q is attached to the rhomb and arranged so that, when it coincides with a mark on the clip *d*, the instrument is set at the proper gauge length.



Cross Wire
Slit for Reflection from Left Hand Mirror
Slit for Reflection from Right Hand Mirror

FIG. 77.

Extension of the test piece rotates the rhombs, and the angular rotation is measured by a scale and telescopes as described for Bauschinger's extensometer. Two readings are necessary, one for each rhomb, and two telescopes are usually employed.

At the N.P.L. a "one telescope" arrangement has been in use for some years with complete success. This is shown diagrammatically in *Fig.* 76.

The telescope T is attached to a support S. Immediately under the telescope, and attached to the same support, is a platform P whose height from the ground can be quickly adjusted. It can be locked in any position by a knurled-headed screw A. The telescope arrangement is kept in contact with the platform by means of a spring B, and their relative position in a horizontal plane can be accurately adjusted by means of the pivoted nut and screw C.

The platform carries an illuminated scale D, two fixed mirrors M_1 and M_2, and two mirrors N_1 and N_2 pivoted vertically so that their position can be altered by means of the screw and spring E.

The illuminated scale is reflected from one of the "Martens" rotating mirrors on to the pivoted mirror N_1, and the angle of this is adjusted to bring the reflection into the telescope by means of the fixed mirror M_1. The other "Martens" mirror is made to reflect the illuminated scale on to the pivoted mirror N_2, and this is adjusted to bring the reflection into the same telescope. The difference between the lengths of the two rays is so small that the telescope can, at the same time, focus the scales reflected by each of the Martens rotating mirrors. The mirrors reflect "ghosts," and these are cut out by inserting a mask (*Fig.* 77) in the eyepiece of the telescope, and by having adjustable brass shades (R, *Fig.* 76) fixed in between the mirrors on the platform and the extensometer.

The mirrors used must be absolutely flat, and great care should be taken to see that they are not distorted when they are clamped in position.

A curved scale should be used, but readings can be taken on a straight scale and a correction applied. The illuminated scale is graduated in millimetres and readings of the scale can be estimated to 0·1 mm.

If l = the width of the rhombs,
L = distance from the scale to the axis of the test piece,
x = extension of the test piece,
X = sum of the readings from the two Martens mirrors.

$x/\mathrm{X} = l/4\mathrm{L}$.

Usual values of l and L are 0·180 in. and 45·0 in. respectively. If X is measured in millimetres we have

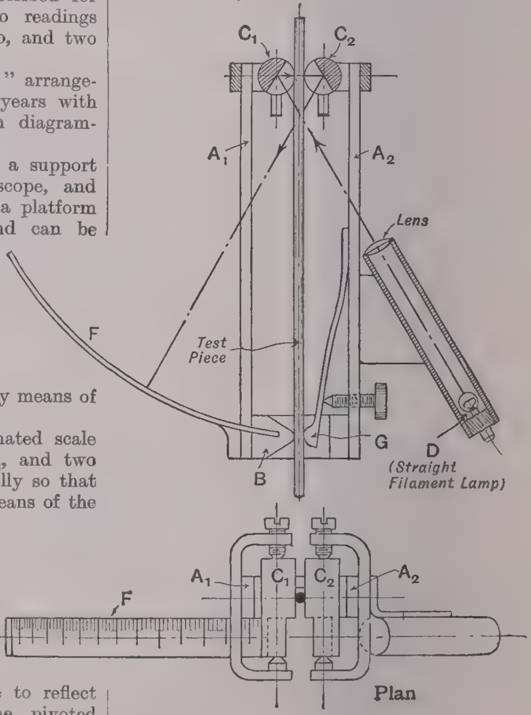


FIG. 78.

$$x = \frac{l \times \mathrm{X}}{4 \times \mathrm{L}} = \frac{0{\cdot}18 \times \mathrm{X}}{45 \times 4} = 0{\cdot}001 \times \mathrm{X} \text{ millimetres.}$$

By providing suitable clips this extensometer can be used on gauge lengths from one inch upwards and with test pieces from 0·03 to 0·8 in. diameter.

An instrument using Martens's method but of slightly different design to that shown in *Fig.* 76 is supplied by Messrs. Alfred J. Amsler & Co., Schaffhausen.

(iii.) *Westinghouse Wire Testing Extensometer.*—This instrument, designed by Lynch & Brace[1] for extensometer tests on small sections such as wire, ribbon, etc., is shown in *Fig.* 78. It consists of two clips A_1 and A_2, fastened at one end to a slotted block B, while the free ends carry hardened rollers, C_1 and C_2, which can turn in pivot bearings.

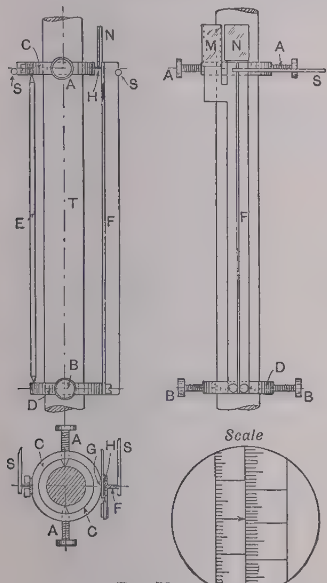

FIG. 79.

One end of the instrument is clamped to the test piece between the spring G and the block B, and the rollers C_1 and C_2 are sprung apart to take the test piece at the other end. Plane mirrors are attached to the rollers, which are arranged so that a spot of light from a lamp D is reflected from the mirror C_1 to mirror C_2, and thence to the curved scale F.

With this extensometer increases of length of 0·00002 in. can be measured.

(iv.) *Single Mirror Apparatus. Morrow's Extensometer.*[2]—This instrument is a combination of Ewing's lever arrangement for making the extensometer indicate the mean strain, with a mirror method of measuring that strain. It is shown diagrammatically in *Fig.* 79. The attachment to the test piece T is by four set screws AA and BB. AA serves as a fulcrum for the top annular ring C, and when the test piece extends, the movement between C and F (which is an extension of the bottom ring D) is approximately twice the extension. So far the principle is the same as that of the Ewing extensometer, but whereas Ewing measures this extension by a micrometer microscope, Morrow uses a "Martens" rhomb H to which a mirror N is attached in a vertical position.

A second mirror M is permanently fixed to F. The images of the scale from both mirrors are seen side by side in the telescope. An index mark is taken on the image of M for reading the movement of N. By this means allowance is made for any movement of the test piece and extensometer, as a whole, relative to the position of the telescope.

With the instrument as used by Morrow the extension of the specimen is obtained to the nearest $\frac{1}{1,200,000}$ of an inch.

Other single mirror extensometers have been designed by Unwin,[3] Martens,[4] and Hartig.[5]

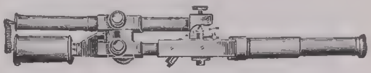

FIG. 80.

§ (54) COMPRESSOMETERS. — Most instruments used for tensile experiments can also be used as compressometers provided that the test piece is of sufficient length to take them. It is, however, often necessary to modify the method of attachment. The conditions applicable to the use of extensometers (§ (43)) apply, with just as much force, to compressometers.

The Yale extensometer (§ (45)), using double micrometer screws, and the Wisconsin (§ (49)) dial extensometer are both used in the U.S.A. for compression tests by a suitable modification of the clamps.

Ewing's compressometer for short blocks (*Fig.* 80) is on the same principle as that used for tension tests. The mechanical multiplication is, however, increased to five times, enabling readings of $\frac{1}{125,000}$ of an inch to be obtained.

Martens's mirror arrangement (*Fig.* 75) has been used by the author as a compressometer on diameters up to $4\frac{1}{2}$ in. by providing additional springs S to hold the clips on to the larger size of test piece.

Unwin[6] has designed an instrument for short blocks combining lever and microscope.

---

[6] *Testing Materials of Construction*, 1910, p. 231.

This instrument is shown diagrammatically in *Fig.* 81. The lever L_1, having a knife edge resting on the pillar P, gives a mechanical magnification of 2½. The frame L_2 is fixed to the specimen by four screws, and both frame L_2 and lever L_1 carry silver plates on their ends having a fine scratch on each. The distance between these scratches is measured by the micrometer microscope M. Alterations of this distance with load give the compressive strain as the mean of that on the two sides of the block.

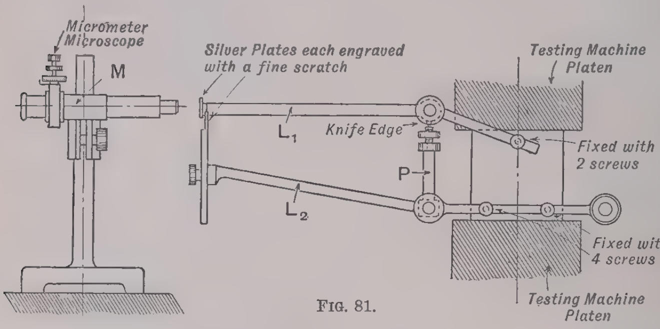

Fig. 81.

§ (55) Torsional Strain Indicators.—For measuring elastic deformations in torsion, in order to determine the coefficient of rigidity, accurate observations are necessary. All instruments for this purpose should be independently fixed on the bar with a definite gauge length.

Where a high degree of accuracy is not essential, a convenient and simple method is to clamp two long pointers on to the specimen at a given distance apart and observe their movement over a fixed scale. The difference between the readings is a measure of the torsional strain.

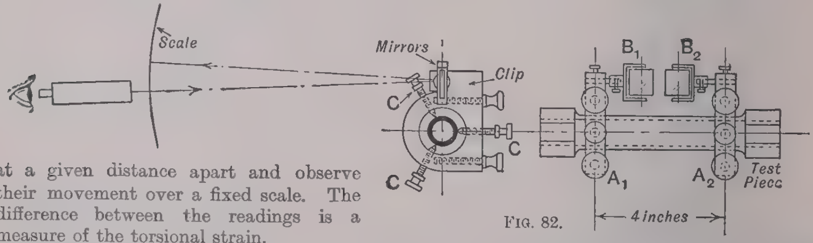

Fig. 82.

(i.) *Porter's Torsion Indicator.*[1]—In this indicator the long pointers of the above instrument are replaced by two rings clamped to the test piece at a gauge length of 3 in. by three set screws. One clamped ring is graduated in degrees and carries on it a concentric ring engraved with a vernier reading to five seconds of angle. The vernier ring is supported on ball bearings and is operated by an arm fixed to the second clamped ring. Provision is made for setting the vernier and for any change of length of the specimen during test.

(ii.) *Coker's Torquemeter.*[2]—The torsional strain is measured by this indicator on a length of 8 in. At one end of the specimen a graduated circular plate is attached to the gauge mark by three set screws. This plate carries an arm and vernier which can be moved round it, and to which is attached a frame carrying a cross-wire and a mirror. At the other gauge mark a chuck, also fixed by three set screws, supports an arm having a micrometer microscope attached to it. This microscope sights on to the cross wire of the vernier plate frame.

When the torque is applied to the test piece the cross wire moves relatively to the microscope, and the amount of this movement is measured by the micrometer eyepiece to about one second of arc. When the strain has exceeded the range of the eyepiece the cross wire can be readjusted to zero by moving the cross-wire arm round the circular plate by means of a tangent screw.

(iii.) *Unwin's Torsion Micrometer.*[3]—This instrument acts on the same principle as that designed by Coker. There are, however, one or two slight differences in detail. With Unwin's method the microscope, attached to a projection from one clip, sights on to a finely divided scale on the other clip at a gauge length of 5 in. The micrometer eyepiece reads to 0·005 degree.

(iv.) *Mirror Torquemeter.*—The method employed at the N.P.L.[4] is shown in *Fig.* 82, and consists of two small clips, A_1 and A_2, each fastened to the test piece by three pointed set screws C. Attached to these clips are the adjustable mirrors B_1 and B_2 of a Martens mirror extensometer. The mirrors are arranged, on a gauge length of four inches, so that they are in the vertical plane passing through the axis of the test piece. The method of measuring the movement of the two mirrors by the use of a single telescope has already been described (§ (53)). The difference between the readings from each mirror at small increments of the torque give, when multiplied by a constant depending on the scale distance, the angle of twist for that increment on a length of four inches.

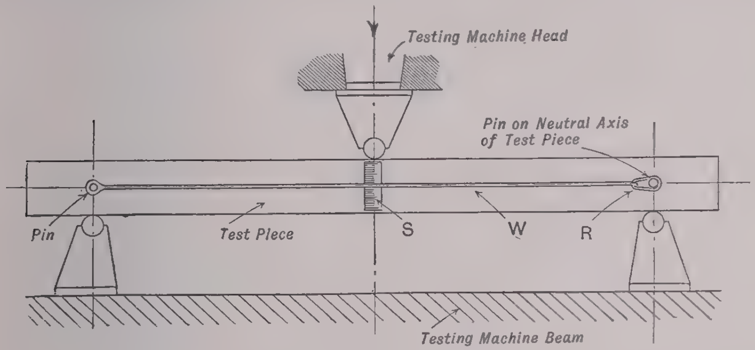

Fig. 83.

§ (56) Deflectometers.—These instruments are used to measure the amount of bending of beams, etc., during a transverse test.

Commercially a multiplying lever deflectometer (*Fig.* 60) is generally employed or a strained-wire arrangement may be used where large deflections are to be measured. This is shown in *Fig.* 83. A fine wire W is strained between two pins fixed on the neutral axis of the beam above the supports and kept taut by a rubber band R. This forms a datum line. A polished scale S is graduated either in mm. or inches and suspended from the neutral axis at the centre of the beam. The observer brings his eye to such a position that the wire and its image in the polished scale coincide, and he then reads the position of the wire on the scale.

For most work an accuracy of 0·001 in. is usually sufficient.

The methods described above do not fulfil some of the essential conditions for accuracy, which are:

(1) The apparatus should be designed to give the relative deflections of points in the neutral axis of the beam. This requirement is not fulfilled by the lever deflectometer.

(2) The mean deflection should be obtained. The apparatus should either provide for taking readings on both sides of the test piece or automatically give the mean deflection. This condition is not accomplished by the strained-wire arrangement.

§ (57) Apparatus for measuring Lateral Strains. (i.) *Coker's Lateral Strain-measuring Apparatus.*[1]—This instrument is shown diagrammatically in *Fig.* 84 and consists of two tubular arms A_1 and A_2 connected by a flexible steel plate B which forms the fulcrum. The steel plate is gripped by two collars CC, one of which carries an adjustable screw L, which bears on the test piece and keeps the instrument from turning. The arms are attached to the test piece T by two screws DD, the pressure on which is provided by the compression of a spiral spring S on the opposite side of the fulcrum.

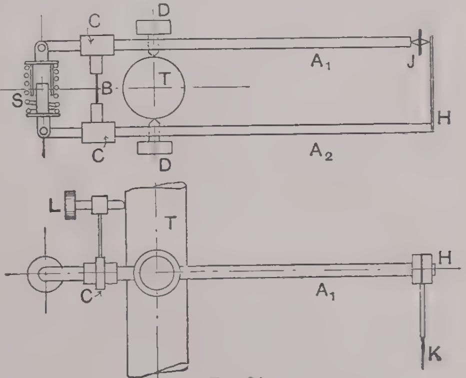

Fig. 84.

The arm A_2 has a projection H, the end of which is opposite to the arm A_1 and is arranged to spring towards it, gripping a knife edge J.

---

[1] *Roy. Soc. Edinburgh Trans.* xxv. part i. p. 452.

Any change in the diameter of the test piece causes a relative movement between the end of the arm A_1 and the projection H of the arm A_2. This movement rotates the knife edge J, to which a mirror K is attached. The rotation of this mirror is observed by a telescope and scale and gives a measure of the alteration in the diameter of the test piece.

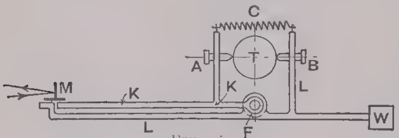

Fig. 85.

The scale distance is arranged so that each scale division represents 0·000001 in.

(ii.) *Morrow's Instrument for measuring the Lateral Contraction of Tie Bars.*—This instrument,[1] shown diagrammatically in *Fig.* 85, also uses optical means of measuring the relative displacement of two arms.

Two arms KK and LL are pivoted at F and two screws A and B grip the test piece T and are pressed inwards by stiff springs C. Alteration in the diameter of the test piece causes arm K to fall relatively to the arm L. This relative motion is measured by the tilt of a mirror M which is supported on three points, two of which rest on arm L and one on arm K. A vertical mirror, not shown, is also fixed to L at the side of the tilting mirror M and serves as an index for that mirror, thus eliminating any errors due to the instrument moving relatively to the observing telescope. The instrument is balanced by a weight W.

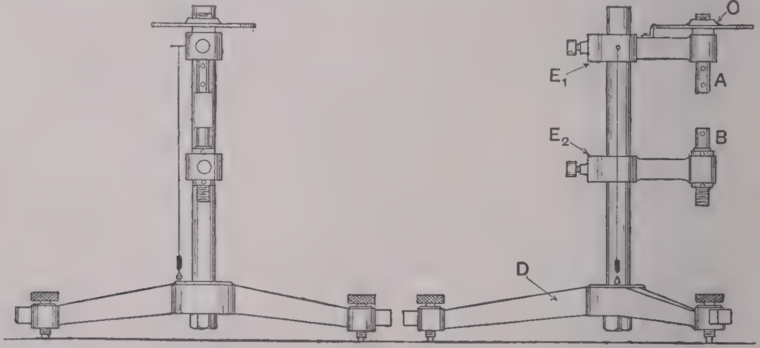

Fig. 86.

§ (58) Calibration of Deformation-measuring Apparatus.—The usual methods of obtaining the constants of extensometers, compressometers, etc., are:

(1) By measurement of the leverage of the instrument. In some types of apparatus this can be carried out successfully. With the Martens mirror extensometer the constant depends on the width of the rhombs and the scale distance. The former can be determined by an accurate measuring machine, and the latter is usually adjusted by setting the scale distance from the test piece by means of a gauge of known length.

(2) By test on a steel test piece whose elastic constants have been accurately determined. The test piece is gripped in the testing machine in such a way that the stress is distributed in the proper manner and readings of the apparatus which is to be calibrated taken at definite increments of the load. These readings are then compared with those calculated from the known elastic constants. If possible, a standardised apparatus is attached to the test piece at the same time as the one whose constants are unknown and a direct comparison made.

(3) By a calibrating instrument. An instrument used by the author is shown in *Fig.* 86 and consists of a stand D carrying two arms E_1 and E_2. These arms are movable along a feather on the stand so that their position can be adjusted. They are bored accurately in line to take two rods A and B. B is fixed, but A can be moved up and down by a micrometer head C. A also works along a feather which prevents rotation.

The apparatus to be calibrated is attached to A and B and its readings compared with the movement of the micrometer head. The pitch of the micrometer screw is 0·025 in. and the head is divided into 25 parts so that one division of the head (about ½ in. long) corresponds to a movement of 0·001 in.

It is essential that the desired reading

[1] Morrow, *Phil. Mag.*, 1903, vi. 417.

should always be approached in the same direction in order to eliminate any backlash in the screw. As the accuracy of the calibration depends upon the accuracy of the screw, this has been determined on a screw-measuring machine and a correction curve obtained for it.

§ (59) AUTOGRAPHIC RECORDING APPARATUS.—The deformation co-ordinate of the curve is always recorded directly from the test piece itself, usually with some form of multiplication. The main difference in the various types of recorders is in the method of obtaining the load co-ordinate. There are two principal ways in which this is done :

(i.) Load recorded by the movement of the counterpoise with or without automatic adjustment.

(ii.) Load co-ordinate obtained by the deformation of a calibrated spring.

The early diagramming apparatuses were applied to pendulum machines. Thurston, in 1876, designed the torsion test apparatus described in § (10), and, in 1877, Abbott constructed a recorder adapted to a machine in which the pull from a hydraulic press is transmitted through the test piece to a pendulum, the angular rise of which gives a measure of the load. An improved apparatus of the same kind was used by Pohlmeyer in 1882, and more recently by the N.P.L. for tests of copper and bronze wires fully described in the British Engineering Standards Association Report, No. 55.

§ (60) AUTOGRAPHIC APPARATUS, RECORDING POSITION OF COUNTERPOISE. — In machines having a moving counterpoise the load co-ordinate is obtained from the position of the counterpoise on the beam by moving a drum or pencil, by suitable pulleys or gearing, from the shaft or screw which drives the counterpoise. The beam is usually kept floating by moving the poise by hand adjustment. By this means, however, the reduction of load at the yield point cannot be obtained and the final reduction, when the test piece is stretching locally, is only imperfectly reproduced.

Riehle Autographic and Automatic Apparatus. — In some American machines an autographic apparatus is provided having an automatic weighing device. This device is designed to move the poise on the beam automatically to balance the load on the specimen. In the Riehle machine the scale beam on rising or falling completes an electric circuit at the top or bottom stop in the beam stand. Each circuit is separate and connected to a magnet.

The driving pulley of the machine turns a horizontal shaft which has a cast-iron disc on its end. This disc in turn drives one of two fibre wheels located equidistant on either side of the centre of the disc. Each fibre wheel has an armature controlled by one of the magnets of the electric circuits mentioned above. Thus when the beam rises and completes the top circuit, one of the magnets attracts its armature, causing one of the fibre wheels to engage with the cast-iron disc and drive the poise along the beam and so balance the load. When the beam drops and hits the lower contact, the armature of the other fibre wheel is attracted by its magnet, which brings this fibre wheel on to the cast-iron disc and drives the poise in the opposite direction.

The screw which drives the poise also, through gearing, drives the recording pencil axially along the drum, so that the reading of the load, which is recorded, corresponds directly to the load weighed.

The other ordinate is obtained by the drum revolving proportionally to the deformation. "Fingers" rest on top of U clamps fastened to the specimen by hardened steel-pointed set screws at the correct gauge distance. The lower "finger" moves downwards as the test piece extends and by means of a rack and pinion converts this motion into a rotary one revolving the drum through mitre wheels. The actual extension is magnified five times. The fingers are so arranged with clamps on telescopic tubing that only the extension between the U clamps is recorded on the diagram.

§ (61) AUTOGRAPHIC APPARATUS USING A CALIBRATED SPRING.—(i.) This method is used in two Wicksteed recorders. In the earlier apparatus [1] the measurement of the stress is entirely independent of the position of the poise on the beam, but is taken as being proportional to the compression of a helical spring acted upon by an auxiliary plunger operated by hydraulic pressure from the straining cylinder of the testing machine. As the load is applied by the straining cylinder it is balanced by running the poise along the beam, and the hydraulic pressure in both the straining cylinder and the auxiliary cylinder increases. The auxiliary plunger therefore compresses the spring, and the amount of the movement of the spring is recorded by a pencil on the recording paper in a direction parallel to the axis of the drum. The drum is also given a rotation proportional to the extension of the test piece and an automatic diagram is thus drawn.

The auxiliary plunger is rotated during the test in order to eliminate the friction as far as possible. The yield and maximum loads are noted from the position of the counterpoise, in order to fix the load scale of the diagram.

(ii.) *The Buckton Wicksteed Patent Spring Balanced Recorder* is entirely automatic, the variations in the resistance of the specimen are accurately recorded. The action of the recorder is shown diagrammatically in *Fig.* 87. The counterpoise W is placed at the end of its travel, thus extending the spring S. As the load W is applied to the test piece an equivalent load is released from the spring S, which therefore contracts. The amount of this reduction in length is proportional to the load on the test piece and is registered on the recording drum R by means of a cord C passing over fixed pulleys P_1 and P_2 and attached to the pencil D of the apparatus.

---

[1] Wicksteed, *Inst. Mech. Eng. Proc.*, 1886, p. 27.

The load is thus recorded axially, and the drum is rotated by the movement of the lower pulling head relatively to that of the upper shackle, to give the deformation co-ordinate. As the deformation is not communicated from a fixed gauge length of the test piece, it includes movement in the grips and cannot be taken as the extension of the specimen.

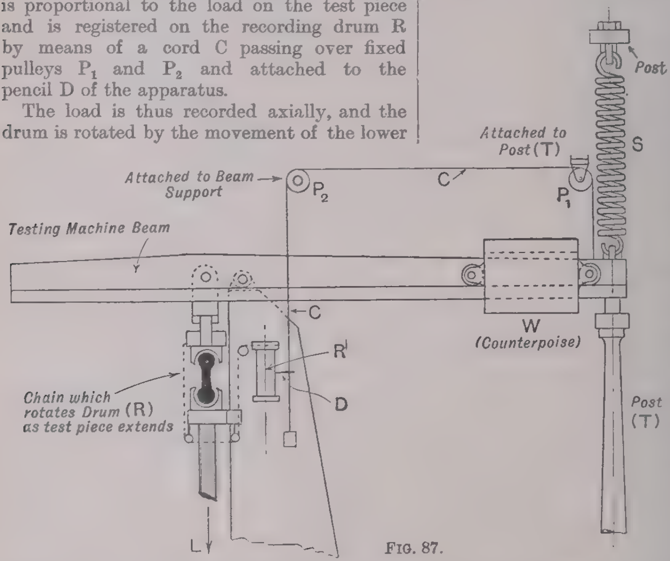

FIG. 87.

(iii.) *Moore's Autographic Recorder* [1] is very similar in action to the Wicksteed spring recorder just described, the only difference being that the spring is placed on the other side of the principal knife edge so that when the poise is run out the spring is compressed. As the load is applied to the specimen an equivalent load is released from the spring, which elongates until equilibrium is established. Moore used a steam-engine indicator; the spring of the indicator is attached to the beam of the testing machine to give the load co-ordinate, and the cord of the indicator is attached to the test piece to record the extension.

(iv.) *Kennedy-Ashcroft Recorder* [2] (*Fig.* 88).—Full details of this recorder are given in Kennedy's paper to the Institution of Civil Engineers, and the following description of the principle of the apparatus is also taken from that paper:

"The test piece '*a*' is placed in the machine in *series* with a stronger bar 'B,' called a spring-piece, and the two, which are connected directly by a simple coupling, are pulled simultaneously, the one through the other. The spring-piece is of a material such that its limit of elasticity occurs only at a load greater than that which will break the test piece. It must also be of material ascertained by previous experiment to be perfectly elastic, so that its extension is strictly proportional to the pull on it, and therefore to the pull on the test-bar. By a simple arrangement a very light pointer '*c*' is made to swing about an axis through an angle proportionate to the extension of the spring-piece, and proportional therefore to the pull on the test-bar. The end of this pointer in its motion always touches a sheet of smoked glass '*d*,' to which is given a travel—in its own plane—proportional to the extension of the test piece, and in this way the diagram is drawn. By an arrangement of differential levers it is assured that the motion of the glass depends solely on the extension between the marked points on the test-bar, so that no amount of extension of the coupling, in the ends of the test piece, or in any other part of the apparatus, can move the glass. The apparatus is also so arranged that the absolute elongation of the spring-piece does not cause any motion of the pointer relatively to the glass."

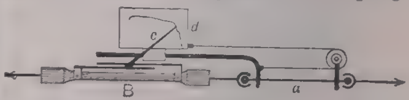

FIG. 88.

(v.) *Dalby's Optical Recorder.*[3]—This apparatus is shown diagrammatically in *Fig.* 89. It is similar to the Kennedy-Ashcroft recorder in that the load is obtained from the extensions of a bar acting as a very stiff spring, but whereas Kennedy uses mechanical means of increasing and transferring these extensions to the diagram, Dalby adopts an optical method and thus obviates the possibility of inertia errors.

---

[1] *Proc. Amer. Soc. Test. Mat.*, 1908, viii. 653.

[2] *Inst. Civ. Eng. Proc.*, 1886–87, p. 31.

[3] *Roy. Soc. Proc.*, 1912, lxxxvi.A, and 1913, lxxxviii.A.

The spring-piece W, seen in *Fig.* 90, is hollow and is connected at its upper end to the shackle A of the testing machine. A projection through the shackle is mounted in a light-tight box B. The ray from a point of light Z is reflected by a fixed mirror Q on to a concave mirror M, which again reflects it on to a third mirror N and thence to a photographic plate at F, where it is accurately focussed.

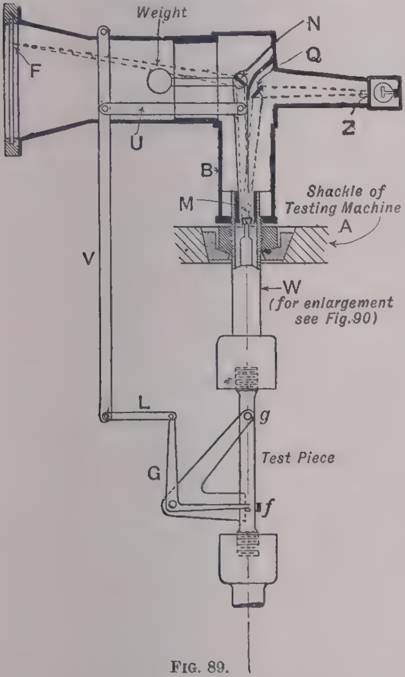

FIG. 89.

The mirror M is supported on three points; two of these, about which the mirror can tilt, are in contact with the hollow spring-bar, while the third rests on a cup on the top of the central rod T. Any stretch of the spring-bar W will cause it to move relatively to the central rod T and thus tilt the mirror M. This tilt will cause the point F to move horizontally across the photographic plate, a distance of 340 times the stretch of the bar.

The mirror N is rotated by the linkwork G, L, V, U proportionally to the stretch of the test piece between the gauge length *gf*, and this movement displaces the point "F" vertically up and down on the photographic plate. The point of light therefore traces on the plate a stress-strain diagram of the test made. After development the relation between load and extension can be measured from the plate with great accuracy.

V. DETERMINATION OF THE ELASTIC CONSTANTS

The complete load-extension diagram is drawn by means of some form of autographic diagram apparatus, but for the accurate determination of the elastic limit and modulus of elasticity it is necessary to determine with extreme accuracy the deformations produced by small loads.

§ (62) THE ELASTIC LIMIT.—The elastic limits in tension and compression obtained from stress strain curves on the first loading of a piece of material such as steel are not constant for the material but depend upon the previous treatment that the material has undergone. They are called the "primitive" elastic limits to distinguish them from the "natural" elastic limits set up in the material when it is subjected to a few alternations of stress.

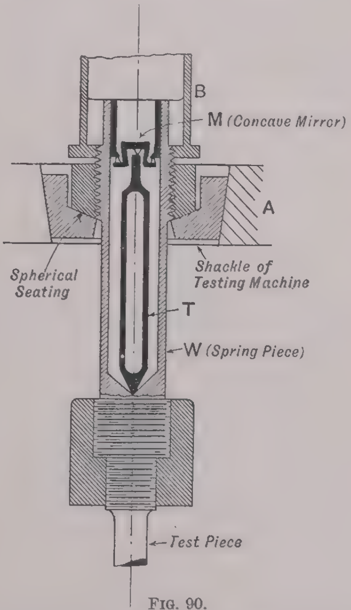

FIG. 90.

The definition of the elastic limit which has been standardised by the British Engineering Standards Association, and is commonly accepted in this country, is that it is the least stress at which Hooke's Law ceases to be exact. It is sometimes called the limit of proportionality or the "P" Limit.

With some materials there is a deviation from Hooke's Law, and a lack of proportionality between stress and strain, even for values of the stress so small that when it is removed the material regains its original dimensions (*i.e.* that there is no permanent set). Hence the elastic limit is occasionally defined as the maximum stress below which the material would fully recover its form upon removal of the load. This may be called the "R" Limit. With most materials the two definitions give substantially the same results, they both require delicate extensometers for their determination, but the method of procedure during the test is slightly different.

In the first case extensometer readings are taken with gradually increasing loads and the results plotted as a load extension diagram. The point at which there is a deviation from Hooke's Law is easily located, and the Modulus of Elasticity can be calculated from the slope of the elastic line. The increments of load taken are usually about $\frac{1}{15}$ of the estimated value of the "P" Limit, and if the value of the "P" limit is known to a first approximation, the increments are made smaller in the neighbourhood of that value and until the test is completed.

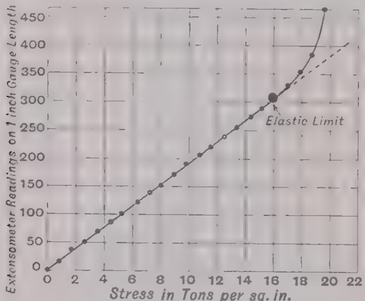

FIG. 91.

The following measurements (Table 21) are taken from a specimen machined from a piece of boiler plate and show how the "P" limit and the modulus of elasticity can be calculated.

The results are plotted in *Fig.* 91 and show that the limit of proportionality is at 16 tons per square inch.

From the elastic line it can be seen that at a stress of 13·3 tons per square inch the extensometer reading is 254; this is equivalent to an extension of 0·001 in. on 1·0 in.

The strain is therefore 0·001 and the modulus of elasticity

$$=\text{stress/strain}=13{\cdot}3/0{\cdot}001.$$
$$=13300 \text{ tons/sq. in.}$$
$$=29{\cdot}8\times10^6 \text{ lbs. per sq. in.}$$

If the readings of the extension and the applied load are known to sufficient accuracy, the limit of proportionality can be ascertained with more precision by calculating the elastic extension for the various loads applied, and plotting the difference between this and the actual extension as ordinates with the loads as abscissae. Table 21 shows this calculation, and the results are plotted in *Fig.* 92.

TABLE 21

EXTENSOMETER TEST ON BOILER PLATE

Diameter of test piece = 0·375 in.; Cross-sectional area = 0·1104 sq. in. Extensions measured on a 1-inch gauge length by a mirror extensometer.

Stress in Tons per Sq. In.	Extension Readings* on a 1″ Gauge Length. A.	Calculated Elastic Extension.* B.	Permanent Set.* A-B.

19·62	461 *	376	85

* 1 unit = 1/254,000 in.; *i.e.* 461 units = 0·0181 in.

Results of tests:

Elastic limit = 16·0 tons/sq. in.
Yield stress = 20·2 tons/sq. in.
Ultimate stress = 28·04 tons/sq. in.
Modulus of elasticity = $29{\cdot}8\times10^6$ lbs./sq. in.
Extension = 36·9 per cent.

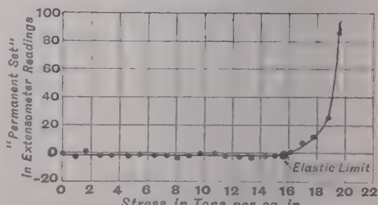

FIG. 92.

It is of first importance that shocks and vibrations should be avoided during the application of the load in an extensometer test, since actions of this kind seriously affect the sensitivity and the accuracy of the instrument.

The second method of procedure, employed to determine the "R" limit, is to apply an increment of the load and upon its release measure the amount of the permanent set, if any. The load is then doubled, and the set on release again measured. A further increase of the load is applied and released, and the operation repeated until a well-defined and increasing permanent set is obtained.

The amount of the permanent set is plotted against the load and an estimate obtained, from the curve, of the point at which the material starts to have a permanent set. From this reading the "R" limit is calculated.

Results show that the actual location of the elastic limit depends on the sensitiveness of the apparatus used, low results being obtained with instruments of high sensitivity. The determination of the "R" limit requires considerable time to carry out, but indicates plastic yielding of the material at an early point when it is properly ascertained.

(i.) *Elastic Limit by Change of Temperature.*—If a material behaves elastically, increasing load produces a cooling of the test piece, but if, however, a permanent set is produced, work is done in internal friction and the temperature of the test piece rises. E. Rasch,[1] of Gross Lichterfelde, has carried out some experiments to determine the temperature-load curve for materials. For temperature measurement he uses thermo-couples of iron-constantan, copper-constantan, or silver-constantan bound to the test piece. Alterations of the temperature are read from the movement of a galvanometer. He finds well-defined points of inflection in his curves. The loads at which these points occur give an elastic limit sometimes called the thermal or "T" limit.

(ii.) *Effect of Overstrain on Elastic Limit and Yield Point.*—Bauschinger found the effect, on the *limit of proportionality*, of overstrain to be as follows:

(1) If the limit of proportionality was exceeded but not the yield point, then the *former is raised* even if the test piece is immediately reloaded.

(2) If the yield point is exceeded, immediate reloading gives a *lower limit of proportionality*, but reloading after a long interval of time may give a *raised limit of proportionality*. James Muir[2] found that this effect can be accelerated by immersion for a few minutes in boiling water.

Bauschinger also found that the *effect on the yield point* was that if the yield point was exceeded, then subsequent reloading gave a *new yield point raised* to the stress to which the bar was loaded in the first place. This effect occurred even if the bar was reloaded immediately, but if there was an appreciable interval of time before the reloading the new yield point might be higher than the maximum stress applied in the first loading.

§ (63) THE MODULUS OF ELASTICITY.[3]—The modulus of elasticity is the number by which the amount of any specified stress or component of a stress within the limits of elasticity must be divided to find the strain or any stated component of the strain which it produces.

There is a modulus of elasticity in tension, compression, and shear.

The modulus of elasticity in tension, denoted by E, is sometimes called the modulus of direct elasticity, or Young's modulus. The value in compression is generally the same as that in tension.

The modulus of elasticity in shear, denoted by C, is called the modulus of transverse elasticity, or the modulus of rigidity.

The moduli C and E are connected by the equation

$$C=\frac{E}{2(1+\sigma)},$$

where σ = Poisson's ratio.

There is also a volumetric modulus of elasticity, sometimes called modulus of elasticity of bulk or modulus of cubic compressibility and denoted by K. It is the number by which the stress upon the exterior of the substance must be divided to give the diminution in volume or cubical strain.

If E and C are known, K can be calculated from the formula:

$$K=\frac{CE}{9C-3E} \quad \text{or } K=\frac{E}{3(1-2\sigma)}.$$

§ (64) MODULUS OF DIRECT ELASTICITY.—An example of the method of determining the modulus of direct elasticity (E) is given in § (62). Some materials, *e.g.* cast iron, mortars, and concrete, have no elastic line and therefore no definite modulus of direct elasticity. It can, however, be considered to be the reciprocal of the slope of the stress-strain curve at zero stress, but where the curvature near the origin is sharp this value of the modulus is of little use except as a comparative value of stiffness.

An example of a stress-strain curve with no definite elastic line is given in *Fig.* 93. The initial modulus of direct elasticity is obtained from the slope of the tangent (OA) to the curve at the origin.

For concrete, an empirical modulus is sometimes used for design calculations. The value is obtained in one of three ways:

(i.) The "tangent" modulus (E_t) is obtained from the slope of the tangent to the stress-strain curve where the ordinate is the working stress—25 per cent of the compressive strength is usual for the working stress—that is, from the tangent CD (*Fig.* 93).

---

[1] *Proc. Int. Assoc. Test. Mat.*, 1909, Article vii$_3$.

[2] *Roy. Soc. Phil. Trans.*, 1900, cxciii. 1.

[3] See "Elasticity, Theory of," § (5).

(ii.) The "secant" modulus (E_s) is obtained from the slope of the line OB, where Bb = the working stress of the material.

(iii.) The "chord" modulus (E_c), determined by the ratio of stress to deformation, is given by the chord drawn between two points on the curve, defined by the limits of stress for working loads, *i.e.* from the chord EF (*Fig.* 93).

The tangent and chord methods give moduli of approximately the same value, which are higher than the secant modulus.

Stanton Walker[1] has shown, from a study of curves which he obtained from various samples, that the stress-strain curve is represented by a curve of the type

$$S = Kd^n,$$

where S = unit stress in concrete,
d = unit of deformation,
K = constant depending on strength,
n = an approximately constant exponent,

and the relation between modulus of elasticity and strength of concrete is

$$E = CS^m,$$

where E = modulus of elasticity,
C = constant depending on conditions of test,
S = compressive strength of concrete,
m = an exponent.

Similar equations were suggested by Bach and Morsch.[2]

Effect of Overstrain on the Modulus of Direct Elasticity.—If the limit of proportionality is exceeded the value of E for steel is lowered, in some cases as much as 20 per cent. Recovery, however, is effected by rest or immersion in boiling water.

Marshall[3] showed that if steel is initially strained to a point within the limit of proportionality, a second loading may give slightly higher values of E.

§ (65) VALUES OF THE MODULUS OF DIRECT ELASTICITY (*Young's Modulus*).—For carbon steels the value of E in lbs. per square inch varies between $28{\cdot}5 \times 10^6$ and 31×10^6, with an average value of $29{\cdot}5 \times 10^6$. It is nearly the same in tension and compression, and is practically independent of the carbon content and of the heat treatment.

For low percentage nickel steels (3 to $4\frac{1}{2}$ per cent) the average value of E is $28{\cdot}5 \times 10^6$ lbs. per square inch, while the value of E for high percentage nickel steels (30 to 35 per cent) is low, being about 23×10^6 lbs. per square inch.

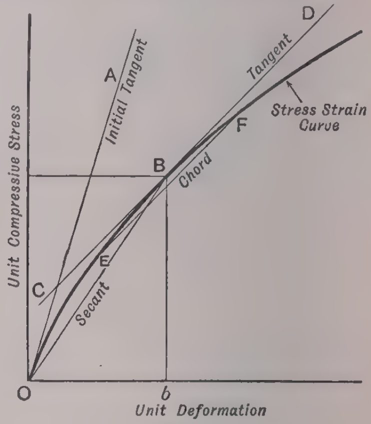

FIG. 93.

With cast iron there is no definite modulus of elasticity. Using a working-stress figure of 10,000 lbs. per square inch, the "secant" modulus for cast iron varies from 12×10^6 to 20×10^6 lbs. per square inch for grey cast iron, and from 20×10^6 to 25×10^6 lbs. per square inch for white cast iron.

Further values of E are given in Table 22.

TABLE 22

VALUES OF THE MODULI OF ELASTICITY

Material.	Value of E. Lbs./Sq. In.	Value of C. Lbs./Sq. In.
Carbon steels	29,500,000	12,000,000
Low percentage nickel steels .	28,500,000	11,200,000
Cast iron (grey) . . .	12,000,000 to 20,000,000	4,800,000 to 8,000,000
Cast iron (white) . . .	20,000,000 to 25,000,000	7,500,000 to 9,500,000
Copper (rolled) . . .	15,000,000	5,600,000
Copper (hard drawn wire) .	17,000,000	6,400,000
Copper (annealed wire) . .	16,000,000	6,000,000
Aluminium	10,000,000	3,800,000
Phosphor bronze . . .	14,000,000	5,200,000
Lead	2,500,000	880,000
Timber (English oak) . .	1,300,000	..
,, (Russian fir) . .	2,500,000 to 3,000,000	..
,, (Christiania spruce) .	1,500,000	..
,, (hemlock) . . .	2,500,000	..

§ (66) MODULUS OF TRANSVERSE ELASTICITY, OR MODULUS OF RIGIDITY (C).—The easiest method of determining the value of C is by means of a torsion test. The strain is measured by some form of torquemeter such as is described in § (55).

---

[1] "Modulus of Elasticity of Concrete," *Proc. Amer. Soc. Test. Mat.*, 1919, xix. 512.

[2] Goodrich, *Concrete Steel Construction* (translation of Morsch's *Der Eisenbetonbau*).

[3] *Amer. Soc. Civ. Eng. Trans.* xvii. 62.

A stress-strain diagram is drawn in the same way as for direct stress but having torsional stress as abscissa and torsional strain as ordinate. The value of C is then calculated from the slope of the elastic line. The elastic limit in shear is also easily located from the curve.

A series of observations by the N.P.L. mirror torquemeter (§ (55)) on a piece of a shaft are given in Table 23 and the diagram shown in *Fig.* 94. From this diagram the limit of proportionality in shear is seen to be with a torque of 1350 lbs.-in. corresponding to a stress of 24·0 tons per square inch, and the modulus of rigidity (C) = 11·9 × 10⁶ lbs. per square inch.

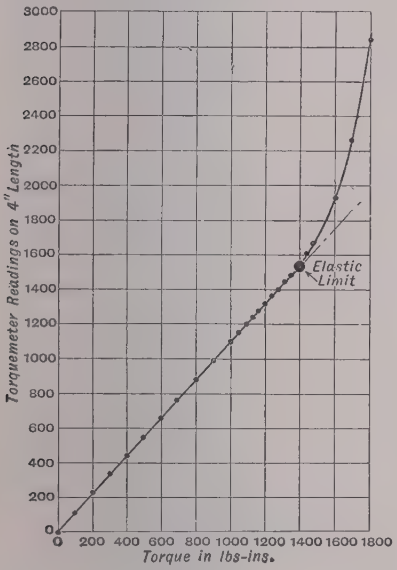

FIG. 94.

$$C = \frac{\text{stress}}{\text{strain}} = \frac{53{,}800}{0{\cdot}00453} = 11{\cdot}9 \times 10^6 \text{ lbs. per sq. in.}$$

Note.—Stress $= 24{\cdot}0 \times 2240$ lbs. per sq. in.
$= 53{,}800$ lbs. per sq. in.

$$\text{Strain} = r\theta/\text{L} \left\{ \begin{array}{l} \text{where } r = \text{radius of the test piece,} \\ \theta = \text{angle of twist on length L in radians.} \end{array} \right.$$

$$= (0{\cdot}25 \times 4{\cdot}15)/(4 \times 57{\cdot}3) = 0{\cdot}00453.$$

For wire the value of C is determined from the time of a single torsional oscillation.

Bauschinger[1] found the value of C for Bessemer steel of carbon content varying from 0·19 per cent to 0·96 per cent to range from 11·9 × 10⁶ to 12·7 × 10⁶ lbs. per square inch.

Platt and Hayward[2] give values varying from 12·3 × 10⁶ to 14·0 × 10⁶ lbs. per square inch.

Average values of C are given in Table 22.

§ (67) POISSON'S RATIO.—Poisson's ratio is the ratio of lateral to longitudinal deformation, and is usually denoted by σ.

An extensometer when used in conjunction with an apparatus for measuring lateral strains, such as are given in § (57), gives the value of σ for any material in the most direct way possible.

TABLE 23

TORSIONAL STRESS-STRAIN OBSERVATIONS

Diameter of test piece = 0·500 inches.
Gauge length = 4 inches.

1320	1446	4° 7′
1360	1497	4° 15′
1400	1550	4° 25′
1500	1699	4° 50′
1600	1919	5° 26′
1700	2249	6° 20′
1800	2859 *	7° 58′

* A reading of 2859 = an angle of twist of 7 degrees 58 minutes on a length of 4 inches.

Both instruments are fixed on the test piece at the same time and measurements are obtained, of both lateral and longitudinal strains, for equal increments of load. The results are then plotted as stress-strain diagrams, and the ratio of the slopes of the elastic lines is equal to σ (Poisson's ratio).

The figures in the following table are taken from results obtained by Coker.

---

[1] *Civilingenieur*, 1879.

[2] *Inst. Civ. Eng. Proc.* xc. 409.

TABLE 24

MEASUREMENTS OF LATERAL AND LONGITUDINAL STRAINS

Diameter of the test piece = 1·01 inches.
Length under test = 8·00 inches.

Load in Lbs.	Lateral Strain Reading.	Longitudinal Strain Reading.
1,000	0	0
3,000	20	34
5,000	42	66
7,000	63	99
9,000	85	132
11,000	106	165

From the plotted values of these results given in *Fig.* 95 it will be noted that the curves do not pass through the first point, but the remainder of the observations lie on straight lines. The slope of the longitudinal stress-strain curve $= 408{\cdot}7 \times 10^{-10}$, and the slope of the lateral stress-strain curve $= 107 \times 10^{-10}$, therefore $\sigma = 107/408{\cdot}7 = 0{\cdot}262$.

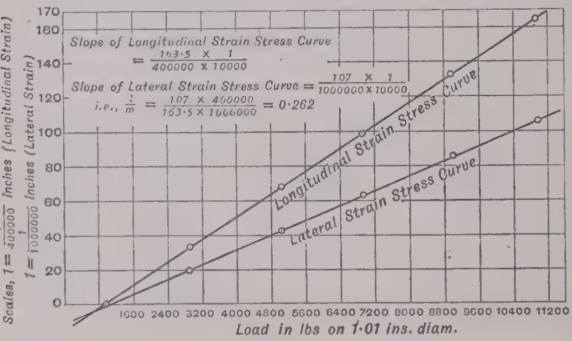

FIG. 95.

Average values of Poisson's ratio for various materials are as follows:

TABLE 25

Material.	Value of Poisson's Ratio.
Glass	0·25
Steel	0·27 to 0·30
Copper	0·33 (0·31 to 0·34)
Brass	0·33 (0·32 to 0·35)
Delta metal	0·34
Muntz metal	0·34
Lead	0·43
Stone	0·20 to 0·34
Concrete	0·08 to 0·18
Cast iron	0·23 to 0·27
Wrought iron	0·27 to 0·29

VI. SPECIAL FORMS OF TEST

§ (68) EXPERIMENTS ON THE REPETITION OF STRESSES.—It has been shown by experiment that materials fail under stresses considerably lower than the ultimate when those stresses are repeated many times.

Stanton and Bairstow[1] have shown microscopically that this deterioration is due to "slip lines being set up at the point of maximum stress in the cleavage planes of the crystals and due to unequal distribution of stress among the crystals." These slip lines broaden out and develop into actual cracks under repetition of stress. This type of failure is sometimes called "fatigue," but is perhaps better described as a "repeated stress failure."

In many cases the stress does not alternate between zero and a maximum in tension; there may be an initial tensile or initial compressive stress. For the purpose of a consideration of this subject compressive stress is taken as a negative tensile stress, and the range of stress as the difference between the maximum and minimum stresses.

Alternating stresses are usually considered as being those in which the maximum and minimum stresses are equal but of opposite sign.

Since 1864, when Fairbairn published results in the *Roy. Soc. Phil. Trans.* on riveted wrought iron girders subjected to repeated stresses, many important researches on this subject have been undertaken. As a result of his work, Fairbairn recommended that the safe repeated stress should be not more than one-third of the ultimate stress.

In 1871 Wöhler published the results of an exhaustive series of repeated stress experiments in direct stress, bending, and torsion which had been carried out during the previous twelve years. A full description of these tests is given in *Engineering* of 1871, and a good account by Unwin.[2] The most important deductions from these experiments on wrought iron and steel are:

(*a*) A stress below the ultimate will fracture wrought iron and steel if it is repeated many times.

(*b*) The range of stress, and not the maximum stress, determines within certain limits the number of repetitions before fracture.

(*c*) For a given maximum or minimum stress the number of repetitions before fracture increases as the range of stress is diminished, and there is a range of stress called the *limiting range* at which the number of repetitions is infinite.

---

[1] "Resistance of Iron and Steel to Reversals of Direct Stress," *Inst. Civ. Eng. Proc.* clxvi. 78.

[2] *Testing of Materials of Construction*, 1910, p. 371

(*d*) The limiting range of stress diminishes as the maximum stress increases.

Wöhler's work was continued on the same machines and confirmed by Spangenberg, whose results, however, were not so consistent as the original work by Wöhler.

Results published in 1886 by Baker,[1] who had experimented with soft and hard steel (28 and 54 tons per square inch respectively) and 27-ton rivet iron, were in complete agreement with Wöhler's researches.

A considerable number of experiments on the effect of varying values of the minimum stress on the limiting range of stress have been carried out by Haigh.[2]

In 1915 he reported a series of tests on mild steel to the British Association. These are summarised in Table 26.

TABLE 26

REPEATED STRESS TESTS ON MILD STEEL

Ultimate Static Stress. Tons/Sq. In.	Limiting Minimum Stress. Tons/Sq. In. A.	Limiting Maximum Stress. Tons/Sq. In. B.	Limiting Range of Stress. Tons/Sq. In. B-A.
26·0	+ 4·05	+21·55	17·5
	− 0·88	+20·62	21·5
	− 7·3	+17·20	24·5
	−13·0	+13·00	26·0
	−16·96	+ 6·54	23·5
	−20·10	+ 1·40	21·5
	−21·95	− 2·45	19·5

The results are plotted in *Fig.* 96, from which it is seen that—

(1) When the minimum stress is zero, the range of stress is approximately 21·0 tons per square inch, *i.e.* a tensile stress of 80 per cent of the ultimate stress is sufficient to fracture the material when repeated a considerable number of times.

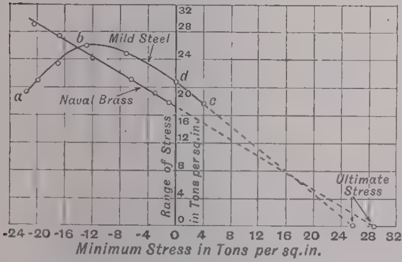

FIG. 96.

(2) When the minimum stress is less than half of the range (*i.e.* from 4·05 to −13·0) the curve approximately follows Gerber's parabola (see § (70) (ii.), otherwise there is a noticeable deviation from the parabolic form.

Results in Table 27 give details of the observations on mild steel when the stresses are alternating (*i.e.* equal tension and compression). These confirm Wöhler's deductions *b* and *c*, given above.

	26·4	5·90
	25·4	7·20 †

* 39·3 (range) = +19·65 to −19·65. † Unbroken.

Tests on Naval Brass by Haigh are summarised in Table 28 and plotted in *Fig.* 96, and show that for the brass under consideration the equation connecting minimum stress and range of stress is that of a straight line passing through the point where the minimum stress is equal to the ultimate stress. Haigh says that, as a rule, metals which give a considerable reduction of area at fracture have a high value of the ratio of alternating stress range (with equal tension and compression) to the ultimate stress. This usually varies between 1·20 in ingot iron and the best mild steel and 0·80

in high tensile and tool steels in the annealed condition.

§ (69) BAUSCHINGER'S THEORY OF FAILURE. —Bauschinger's theory of failure due to repeated stresses is the only one which has received serious consideration. He shows that, with bars subjected to cyclical variations of stress, the elastic limits in tension and compression take up new positions, the range between the two limits depending on the material and the stress at the lower limit of elasticity. Thus if the elastic limit is raised in tension by overstrain it is simultaneously lowered in compression, so that for that condition of loading two new limits are set up, which Bauschinger calls the *natural* elastic limits. He showed, further, that the range between these limits was the same in magnitude as the maximum range of stress which could be applied to the material an infinite number of times without causing fracture.

Bairstow,[1] in an important paper communicated to the Royal Society from the N.P.L., has given experimental results which constitute the first strong support of Bauschinger's hypotheses.

In the testing machine used by Bairstow for the purpose of the experiments, cyclical variations of direct stress are automatically produced at the rate of two per minute in such a manner that the extensometer, which is of the Martens mirror type, is fixed to the specimen throughout the test, and in this way the whole history of the progress of fatigue is observed.

When the limits of stress are tension and compression of equal values it is found that, if the range of stress is above a definite value, the stress-deformation curve forms a closed loop, which is called the hysteresis loop, consisting of two parallel straight lines, corresponding to the variation of stress from the limits of stress towards the mean stress, and two curved portions, corresponding to the variations of stress from the mean value to the extreme values (*Fig.* 97). The width of this loop, which is the permanent set of the specimen per cycle, increases as the range of stress increases, but for a definite range of stress tends to a limit which is not greatly exceeded by subsequent repetitions of loading, even when this is the range at which fracture under fatigue eventually takes place. Under these conditions of stress the mean length of the specimen remains constant.

When the limits of stress are unequal the hysteresis loop is formed as before, but is not closed, owing to the fact that the mean length of the specimen gradually changes because of the continued repetition of the same cycle of stress, *i.e.* the change of mean length of the specimen per cycle is the amount by which the hysteresis loop is enclosed. The amount of the permanent extension during the earlier stages of the breakdown becomes considerable as the superior limit of stress approaches the static yield point, and if its value, after the first considerable stretch has occurred, be plotted against the corresponding values of the superior limit, it is found that the curves gradually come into coincidence with the ordinary static "stress-elongation" curve at the yield point. FEABC (*Fig.* 98) shows such a curve, in producing which no cyclical variations of stress are concerned.

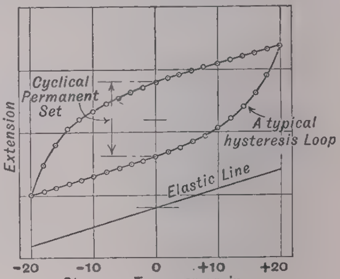

FIG. 97.

The principal conclusions arrived at by Bairstow are summarised thus :

(*a*) The "natural elastic range" is the value to be used in design, and, with equal compressive and tensile stresses, this value is identical with the "Wöhler safe range."

(*b*) The natural elastic range depends upon (1) the material and (2) the lower limit of stress. The elastic range when the lower limit is zero is less than that with equal tensile and compressive stresses (about 15 per cent with axle steel and 6 per cent with Bessemer steel).

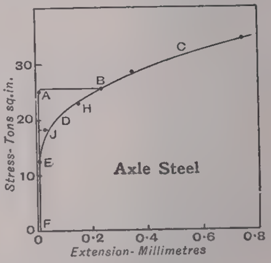

FIG. 98.

(*c*) If a stress-extension curve is plotted, the extension being the value of the permanent extension reached after repeated alternations, it assumes the form found with hard drawn copper wire, which has no yield point but corresponds with the curve FEJHBC of *Fig.* 98 produced back to the "natural" elastic limit.

---

[1] *Roy. Soc. Phil. Trans.* Series A, ccx. 35-55.

(*d*) Recovery due to stoppage of the alternations of stress is appreciable, being somewhat rapid for some materials. Recovery reduces the permanent extension at a given load and can be greatly accelerated by immersing in boiling water for a few minutes, as suggested by Muir.[1]

If an inclined line e_1a (*Fig.* 99) is taken to represent the limiting minimum stresses, and the limiting maximum stress corresponding to each limiting minimum stress is plotted on the corresponding ordinate, a curve of maximum stress *ea* is obtained. The vertical distance between the two curves represents the limiting range of stress and it will be observed—

(1) That as the limiting minimum stress increases the range decreases.

(2) That if both the maximum and minimum stress applied to the material fall between the two curves, then the material will not fail under a repeated stress having those maximum and minimum values.

§ (70) FORMULAE FOR REPEATED STRESS TESTS.—Various empirical formulae have been suggested to connect the limiting values of the maximum, minimum, and range of stress.

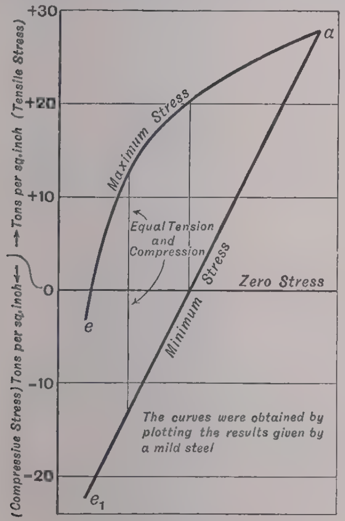

FIG. 99.

(i.) *Weyraugh and Launhardt's Formulae.*—

If $f_{\text{max.}}$ = limiting maximum stress,

$f_{\text{min.}}$ = limiting minimum stress,

f = ultimate static stress,

Z_1 = limiting range of stress when $f_{\text{min.}} = 0$,

$2Z_2$ = limiting range of stress when $f_{\text{min.}} = -f_{\text{max.}}$

Weyraugh[2] suggested the formula

$$f_{\text{max.}} = Z_1 - \frac{f_{\text{min.}}}{f_{\text{max.}}}(Z_1 - Z_2),$$

where the stress is wholly or partly reversed. Launhardt[3] suggested the formula

$$f_{\text{max.}} = Z_1 + \frac{f_{\text{min.}}}{f_{\text{max.}}}(f - Z_1),$$

where the stress is applied without reversal.

Fig. 100 is drawn plotting the values of $f_{\text{max.}}$ from the above formulae assuming the values of $f_{\text{min.}}$ to lie on the inclined line RS and

$$Z_1 = \frac{f}{2} \text{ and } Z_2 = \frac{f}{3}.$$

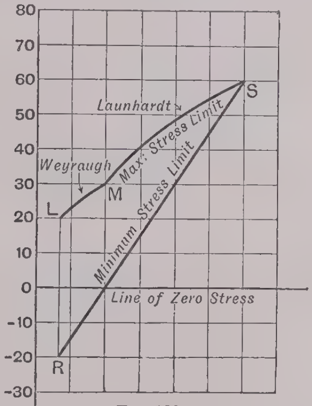

FIG. 100.

The latter have been found to be average values for a variety of materials.

The curved line for the maximum stress limit derived from Weyraugh and Launhardt's formulae is sometimes assumed to be straight, in which case one formula covers the whole field of repeated stresses.

(ii.) *Gerber's Parabolic Relation.*—Gerber showed that, by plotting the limiting minimum stress as abscissa and the corresponding safe range as ordinate, a curve was obtained which, to a first approximation, was parabolic.

Using the previous notation, Gerber's parabolic relation is expressed by the formula

$$f_{\text{max.}} = \frac{f_{\text{max.}} - f_{\text{min.}}}{2} + \sqrt{f^2 - nf(f_{\text{max.}} - f_{\text{min.}})},$$

n being a constant for the material.

§ (71) REPEATED STRESS TESTING MACHINES.—All Wöhler's tests were carried out at a speed of less than 100 reversals per minute, and a determination of the fatigue range occupied a very long time.

---

[1] *Roy. Soc. Phil. Trans.*, 1900, cxciii. 1; also *Roy. Soc. Proc.*, 1900, lxvii. 461.

[2] *Inst. Civ. Eng. Proc.* lxiii.

[3] *Zeitsch. des Arch.- und Ing.-Vereins zu Hannover*, 1873; also, *Inst. Civ. Eng. Proc.*, 1880–81, lxiii. 280.

Various machines have been constructed to accelerate the test.

Before describing those machines which are in constant use for this branch of testing, it is advisable to explain the usual procedure which is adopted in the determination of the limiting range of stress.

Starting with an unknown material and a machine giving 2000 reversals per minute, two methods of attacking the problem are used :

(*a*) If the amount of the material is small and only a limited number of test pieces can be prepared, a low range is applied to the first test piece, which is increased by about 30 per cent after ten million reversals. Increments of the same value are added to the stress range after each additional ten million reversals until the test piece fails. (If the test piece is hollow the number of reversals can be reduced to five million.) The range is then known to be between two values (assuming the material to be homogeneous). A second test piece is then inserted in the machine and a range applied slightly higher than the lower of the two previous values. This range is increased by small increments (depending upon the accuracy with which the results are desired) after each ten million reversals, until failure occurs.

Operates a trip gear working an Electrical cut out
S
W
S
W

FIG. 101.

(*b*) Where at least four test pieces are available, the limiting range is approached from the opposite direction. The first test piece has a high range of stress applied to it, and from the number of reversals required to fracture an estimate can be obtained as to the probable range. The next specimen is tested under a range still believed to be on the high side, and this process is repeated until a range is obtained under which the material does not break. A stress-reversals curve can then be drawn, from which the range of stress can be estimated with whatever accuracy is required consistent with the homogeneity of the material.

The method of procedure adopted will depend on

(*a*) The amount of material available.

(*b*) The relative cost of preparation of test piece and running of the testing machine.

(*c*) The importance of the time of duration of test.

With machines of higher speed than 2000 reversals per minute it is usually considered that a larger number of reversals is required in order to be satisfied that, if the test piece does not break, the range applied is within the safe range.

The machines which are in common use can be divided into four main types :

(i.) Rotating cantilever machines.

(ii.) Rotating bar machines with a short length under a constant bending moment.

(iii.) Direct stress machines. Load applied by an unbalanced revolving weight.

(iv.) Direct stress machines. Load applied by the pull of an electromagnet excited by an alternating current.

(i.) *Rotating Cantilever Machines for Reversals of Bending Stress.*—This type of machine has been run successfully at 3000 revolutions per minute and is shown diagrammatically in *Fig.* 101. It consists of a test piece A held in a rotating chuck B driven either direct or through gearing by an electric motor C. The test piece is loaded by weight W on a scale pan S, which is attached to the test piece through the ball bearing D. The connection between the ball bearing and the scale pan is such that the latter can adjust itself in a vertical direction without putting any constraint on the ball bearing.

The number of alternations is recorded by a counter driven by a worm wheel from a worm cut on the machine shaft. The breaking of the test piece usually operates a switch and stops the motor ; by this means the machine can be run continuously with but little attention.

A slight modification of the counting and stopping method is in some cases adopted. The counter is attached to the ball-bearing holder (by which the load is applied) and is driven by the inner race of the ball bearing. The breaking of the test piece causes the counter to cease recording, and the machine continues to run, without a test piece, until the next period of inspection.

A rotating cantilever machine which has

been running successfully at the N.P.L. is shown in *Fig.* 102.

With a bending test the stress distribution over the cross-section is unknown if the elastic limit is exceeded, and the maximum stress only falls on the outer fibres of the test piece. The test piece is often made hollow, as in *Fig.* 103, the part under test being only a thin shell.

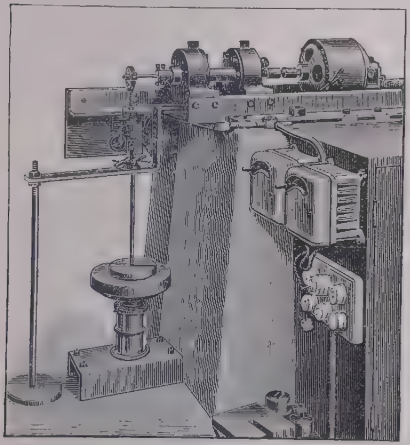

FIG. 102.

Machines of the rotating cantilever or Wöhler type have been used for researches described by Wöhler,[1] Stead and Richards,[2] C. B. Dudley,[3] F. Rogers,[4] Stanton and Pannell,[5] J. O. Roos,[6] C. E. Stromeyer,[7] and A. Martens.[8]

FIG. 103.

They are made commercially by Alfred J. Amsler & Co., and Tinius Olsen Testing Machine Co. The latter company call them "White-Souther endurance testing machines."

(ii.) *Rotating Bar Machines.*—This type of machine was first used by Sondericker[9] in 1892. The method of test is shown diagrammatically in *Fig.* 104. The test specimen ABCD is subjected to a uniform bending moment while revolving on its axis. It is supported on swivelling bearings at A and D, and the central portion between B and C is reduced in diameter. The maximum stress ($f_{max.}$) on the test piece is calculated from the formula

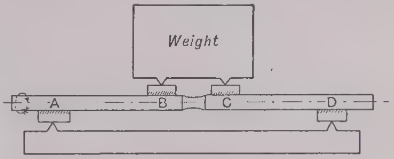

FIG. 104.

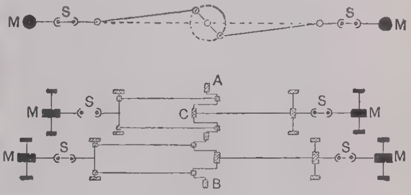

FIG. 105.

$$f_{max.} = \text{Bending moment} \times \frac{32}{\pi d^3},$$

where d = the diameter of the reduced portion. Besides Sondericker this method of test has been used by J. E. Howard[10] and Eden, Rose, and Cunningham.[11]

(iii.) *Direct Stress Machines.*—Load applied by an unbalanced weight.

In 1902 Osborne Reynolds and J. H. Smith[12] described a throw testing machine, for reversals of stress in which simple direct stresses were produced on a test piece by the inertia forces of reciprocating weights driven by a crank and connecting rod from a rotating shaft.

A machine of the same type was designed by T. E. Stanton[13] and used for his work on the resistance of iron and steel to reversals of direct stress. A diagram of the mechanism is shown in *Fig.* 105, which also explains the method of balancing the cranks.

[13] *Engineering*, Feb. 17, 1905.

Four masses M reciprocating horizontally are operated by four cranks C. There are therefore two independently perfectly balanced systems with cranks set 180° apart on the same shaft AB. The cranks of one system are at right angles to the cranks of the other system, so that the kinetic energy of the moving parts is thus approximately constant. There are four test pieces S, one stressed by each reciprocating mass.

Machines of this type, however, suffer from the disadvantage that the inertia forces vary with the square of the speed. It is therefore necessary to control the speed very carefully if reliable results are expected.

(iv.) *Direct Stress Machines.*—Load applied by pull of an electromagnet excited by an alternating current.

This method has been successfully applied by G. Kapp,[1] B. Hopkinson,[2] and B. P. Haigh.[3]

Haigh has introduced several new features into his latest design. *Fig.* 106 shows a machine installed at the N.P.L. and *Fig.* 107 illustrates the principle adopted.

The test piece S is connected at its upper end to the frame of the machine in such a way that its height can be adjusted to allow for elongation, while the lower end is attached to a frame carrying the armature A of a two-phase electromagnet M_1 and M_2.

The electromagnet is excited by an alternating current from a generator giving a sine wave E.M.F., so that the pull is almost proportional to (voltage/frequency)^2, nearly independent of the air gap, which is small and pulsates with twice the frequency of the electric current.

Two small secondary coils wound on frames are fixed close to the pole faces, and the voltage induced in these coils is measured by a voltmeter and used for calculating the stress.

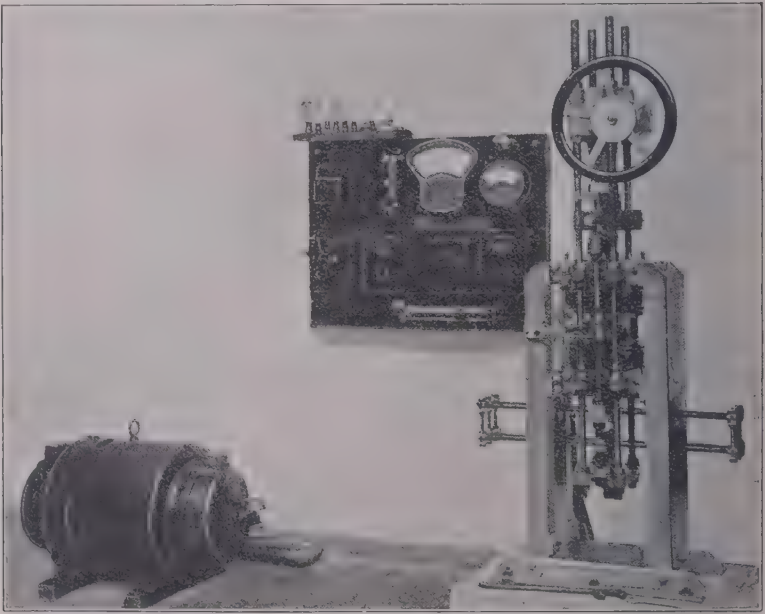

FIG. 106.

In order that the pull of the two magnets shall be of the same amount it is necessary that the air gaps shall be equal. A fine adjustment is provided with the machine to enable the test-piece frame and armature to be raised or lowered during a test until the current in the two coils and therefore the air gaps are equal. The coils are connected to a differential ammeter which reads zero when this condition is fulfilled.

By the use of a choking coil the voltage readings are rendered nearly independent of the frequency over a fairly large range, so that slight alterations of frequency during a test do not alter the range of stress.

---

[2] *Roy. Soc. Proc.* A, Jan. 31, 1912, lxxxvi.

[3] *Engineering*, Nov. 22, 1912; also *Inst. of Metals J.*, 1917, No. 2, p. 55.

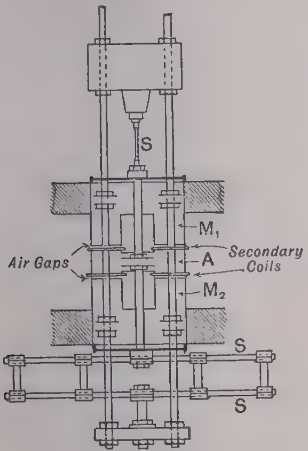

FIG. 107.

The frame carrying the test piece and armature is also attached, below the latter, to standard springs S, S. The stiffness of these springs is adjusted to counterbalance the inertia of the armature, etc., a precaution which is very desirable, as it eliminates a correction which would amount to 5 per cent of the stress range. This adjustment is effected by setting the springs, so that the moving system, without the test piece in place, vibrates in resonance with the magnetic pull.

By extending or compressing the springs an initial pull or push can be applied to the test piece so as to alter the magnitude of the minimum stress.

Thus if f_e = the alternating stress applied electromagnetically,
and f_s = the stress applied by the springs,
then the maximum stress $(f_{\max.}) = f_e + f_s$
and the minimum stress $(f_{\min.}) = -f_e + f_s$.
Range of stress $= Z = f_{\max.} - f_{\min.} = f_e + f + f_e - f_s = 2f_e$,

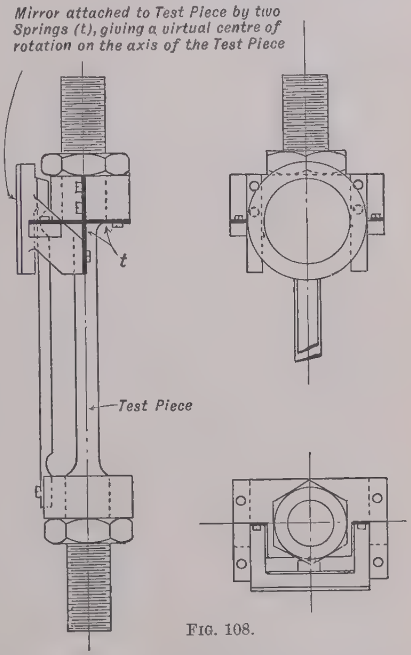
i.e. the range is not affected by the load applied by the springs.

The voltmeter is calibrated by measuring the range of stress (photographically) by a special form of optical extensometer. This is shown diagrammatically in *Fig.* 108.

§ (72) EFFECT OF SPEED ON THE LIMITING RANGE OF STRESS.—Reynolds and Smith[1] found that the limiting range of stress was smaller at speeds of 1300 to 2500 per minute than at 60 to 80 cycles per minute. Their conclusions have not, however, been confirmed by subsequent experiments.

Stanton and Bairstow,[2] using a machine of the same type, found that a change of speed from 60 to 800 did not seriously affect the range, and later, using a machine of the same type as Wöhler, they found that there was no evidence at all of any reduction in fatigue strength due to a rate of alternations of 2200 when compared with 200.

With respect to Reynolds and Smith's results Stanton says, "It seems probable that the reduction in fatigue strength noted by Reynolds and Smith as due to high rate of alternations is a characteristic of the particular mechanism used for their experiments." Bairstow[3] says, "It may possibly be that the decreased range of stress found by Reynolds and Smith has some relation to the question of recovery, but further experiments are necessary to decide the question, as the effect of the rigidity of the testing machine has not yet been fully investigated. In two instances, at least, low ranges of stress have been traced to natural periods of vibration in the testing machine agreeing approximately with the period of repetition."



Mirror attached to Test Piece by two Springs (t), giving a virtual centre of rotation on the axis of the Test Piece

§ (73) EFFECT OF RAPID CHANGES OF SECTION AND SURFACE CONDITION ON THE LIMITING RANGES OF STRESS.—Stanton and Bairstow have shown that rapid changes of section have a marked effect on the resistance of materials to repeated direct stresses.

The standard test piece that they used had a fillet of ⅜ inch, and for comparison with this they made experiments when (1) the fillet was reduced to 0·062 inch, (2) the specimen was screw cut with a Whitworth vee thread, and (3) the corners were left sharp.

TABLE 29

EFFECT OF RAPID CHANGES OF SECTION ON THE LIMITING RANGE OF STRESS

Material.	Percentage Reduction of the Limiting Range of Stress.		
	Specimen Screw cut with a Vee Thread.	Specimen having a Fillet 0·062 in. Radius	Specimen left with perfectly Sharp Corners.
Swedish Bessemer steel No. 3 .	31	32	52
Swedish Bessemer steel No. 2 .	30	28	53
Swedish Bessemer steel No. 1 .	33	32	52
Swedish charcoal iron . . .	32	35	46
Piston-rod steel	33	29	40
Mild steel No. 2	29	28	45
Mild steel No. 1	26	28	36
Wrought iron No. 1 . . .	23	19	40

The results are given in Table 29 and show—

(1) That the resistance of all these forms are, in every case, far below the corresponding maximum limiting resistances of the materials.

(2) That the resistances of forms (1) and (2) are practically the same for any given material, and that the ratio of these resistances to the corresponding maximum limiting resistances does not vary greatly for the different materials.

TABLE 30

EFFECT OF RAPID CHANGES OF SECTION ON THE LIMITING RANGE OF STRESS (USING THE WÖHLER METHOD)

Material.	Ultimate Static Stress. Tons per Sq. In.	Limiting Range of Stress. Tons per Sq. In.			Maximum Reduction in Range. Per cent.
		Fillet ⅝ in. Radius.	Fillet ⅛ in. Radius.	Sharp Corner.	
Nickel chrome shaft No. 1 .	61·9	57·0*	48·0	31·0	46
Nickel chrome shaft No. 2 .	45·2	46·0	..	29·4	36
Boiler Plate	27·9	27·6	..	16·0	42

* 57·0 = +28·5 to −28·5.

(3) That in the case of the specimens having a sudden change of section, the percentage reduction of the limiting range appears to depend on the hardness of the steel, being approximately 52 per cent for the hard steels and 45 to 35 per cent for the wrought irons and mild steels. It is, however, worthy of notice that even under the circumstances supposed to be most fatal to hard steels, *i.e.* a sudden change of section, these steels are very appreciably stronger than wrought irons and mild steels.

The results of some experiments, made by the author using the Wöhler rotating cantilever method of test, are given in Table 30. The standard test piece shown in *Fig.* 103 has a radius of 0·625 inch.

The percentage reduction in the range is seen to agree with the results obtained by Stanton and Bairstow.

The injurious effect of scratches in parts of machinery subject to variations of stress is now recognised. Haigh says that cracks develop from surface scratches under stresses perceptibly lower than the normal. In some experiments carried out by the author the alternate stress range of some aero crankshaft material was reduced from 56·0 (+28 to −28) to 49·0 tons/sq. in. by a sharp scratch 0·003 in. deep.

There seems to be no doubt that many

fatigue failures attributed to faulty material are really due to unsuitable fillets, sharp corners, or surface scratches left during the process of machining.

§ (74) RESISTANCE OF MATERIALS TO COMBINED STRESSES.—Frequent cases of the combination of stresses are met with in engineering practice, and the question of the resistance of materials to those stresses is now recognised as being of considerable importance.

Stress applications may be of three types:

(i.) Simple stress or stress in one direction.

(ii.) Biaxial stress or two stresses acting in directions at right angles to each other in the same plane.

(iii.) Triaxial stress or the application of three stresses at right angles to each other.

With simple stresses, direct tension or compression, the practical constants (modulus of elasticity, elastic limit, yield stress, ultimate stress, Poisson's ratio) are taken as a basis for design. With complex stress distribution the question arises as to the way in which these constants are to be used, and several different theories have been expounded to account for the method of failure of materials under combinations of stresses.

The more important cases of compound stress, considered from an engineering standpoint, are biaxial.

Shear is an example of biaxial stress because it is equivalent to the combination of two equal principal stresses,[1] one compression and the other tension, acting in directions at 45° with the shearing stress. Thus, in *Fig.* 109, the stress on the plane AB, at right angles to the axis, is pure shear, the intensity of which depends upon the diameter of the bar and the torque applied. This shear is a combination of tension along the 45° plane CD and compression along the plane EF. It is well known that mild steel and wrought iron fracture, in a torsion test, across the plane AB, *i.e.* a shearing failure, while cast iron breaks along the plane EF (*i.e.* fails in tension) because it is stronger in shear than in tension.

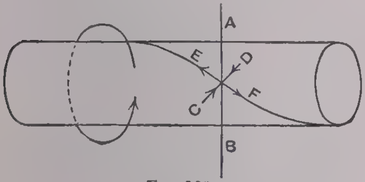

FIG. 109.

Other combinations of biaxial stress are:

(*a*) The crank-shaft which is bent and twisted at the same time. This can be reduced to a case of tension combined with compression owing to the torque producing tension and compression on two planes at right angles as described above.

(*b*) The shell of a steam boiler, which has to resist circumferential and longitudinal stresses, is an example of the combination of two tensions.

(*c*) Plates, concrete slabs or floors supported round the edges and loaded in the centre, are further examples of biaxial stress distribution.

Three-dimensional stress is found in thick steel cylinders under internal pressure accompanied by a longitudinal tension, also in concrete columns with spiral reinforcements, and in hooped guns.

§ (75) CAUSES OF FAILURE IN COMBINED STRESS.—Investigators in the "combined stress" field of research have first of all to decide upon what they consider the point of failure of a material. The elastic theory, being based on Hooke's law, is reliable up to the elastic limit (limit of proportionality or P limit), and therefore, considered mathematically, the elastic limit is the point of failure. This limit is dependent on the previous history of the material, and is therefore variable and indefinite. For experimental purposes the yield point is used, in a good many instances, as the criterion of failure; this is no doubt due to the method of testing which does not allow the tests to be continued to the point of failure.

The most important theories advanced to account for the failure of materials under combined stresses are:

(i.) *Maximum Stress Theory* (Rankine).—This theory is that the material yields when one of the principal stresses reaches a certain amount. (The stress determined by a simple tensile test.) It assumes that a second stress, at right angles to the first, neither weakens nor strengthens the original stress.

(ii.) *Maximum Strain Theory* (St. Venant).—By this theory failure is assumed to occur when the maximum strain reaches a value equal in magnitude to that at the yield point stress of the simple tension or compression experiment.

If a material is subjected to two or three stresses at right angles to each other, the maximum strain theory assumes that the strength is lowered if the stresses are opposite in sign and increased if they are of the same sign.

Thus if S_1, S_2, and S_3 are three stresses at right angles to each other, and e_1, e_2, and e_3 are the unit strains in the direction of each of the respective stresses, also

$E =$ the modulus of elasticity (assumed to be constant)

and $1/\sigma =$ Poisson's ratio;

---

[1] See "Elasticity, Theory of," § (5).

then
$$Ee_1 = S_1 - \frac{1}{\sigma}(S_2 + S_3),$$
$$Ee_2 = S_2 - \frac{1}{\sigma}(S_3 + S_1),$$
$$Ee_3 = S_3 - \frac{1}{\sigma}(S_1 + S_2).$$

For simple tension S_2 and S_3 may be taken as zero and

$$Ee_1 = S_1, \textit{ i.e. } E = \frac{S_1}{e_1} = \frac{\text{stress}}{\text{strain}},$$

which is the expression of the modulus of elasticity.

The maximum strain theory is mathematically correct if it is assumed

(*a*) to hold within the elastic limit.

(*b*) that Hooke's law is absolutely correct.

(*c*) that the material is isotropic.

(*d*) that the effect of temperature is negligible.

By taking the yield point as the criterion of failure, the variation of "E" between the limit of proportionality and the yield point is assumed to be without effect on the results.

(iii.) *Maximum Shear Theory.*—This theory assumes that the condition for initial yielding of a uniform ductile material corresponds to the existence of a specific shearing stress, the intermediate principal stress being without effect.

This theory as originally proposed, by Coulomb in 1776, refers to rupture of the material. It is adopted in Guest's[1] well-known work (1900) where it is used in conjunction with the yield stress. It is approximately verified by W. Scoble[2] and W. Mason.[3]

We can assume that simple tension is a case of combined triaxial stresses where two of the principal stresses are zero. Applying Guest's law, the bar must fail in shear, and in this case the maximum shear occurs in a plane at 45°, and the shear stress intensity is 50 per cent of the tensile unit stress. Seely and Putnam[4] find that the correct ratio of elastic shearing strength to the elastic tensile strength is 0·55 to 0·65, and therefore state that Guest's law which assumes the value to be 0·5 is not a correct statement of the law of elastic breakdown. Becker[5] found this ratio to be 0·56, and the author[6] obtained a ratio of 0·63 to 0·68 for steels with ultimate strengths of 23 and 30 tons per square inch respectively.

Becker,[7] as the result of experimental work, proposes two laws of strength under combined stress, viz.:

(1) That the strength at the yield point follows the *Maximum Strain* theory until the shearing stress reaches the value of the shearing yield point.

(2) After this point failure occurs according to the *Maximum Shear Theory.*

This suggestion appears to fit in very well with existing experimental work.

The maximum shear stress theory has been modified by Perry to include a frictional term proportional to the stress and perpendicular to the plane of shear. He noticed that brittle materials fracture at angles greater than 45° with the cross-section and assumes that this is due to internal friction.

If θ = the angle found experimentally, μ (the coefficient of friction) = tan ϕ, then $\theta = 45° + \phi/2$ for tension and $\theta = 45° - \phi/2$ for compression.

For cast iron the angle (θ) is found to be $54\frac{3}{4}°$, which gives a value of μ of 0·35.

If $\phi = 0$, this theory is the same as the maximum shear theory, and Perry suggests that this is the case for wrought iron and mild steel.

(iv.) *The Maximum Resilience Theory.*—Haigh[8] proposes that the elastic limit of a material under complex stress is reached when the energy per unit volume attains a certain definite value. He bases this view on thermodynamic considerations, and also finds that, when considered from the experimental aspect, the results fit in with this theory better than they do with either the maximum stress, maximum strain, or maximum shear theories.

Mallock[9] considers the volume extension limit or the limit of shear as the fundamental limits of a material, and assumes that the material will fail when either limit has been reached.

§ (76) EXPERIMENTS ON COMBINED STRESS.—Most experimental work has been carried out on ductile materials. Only a few experiments have been made with brittle materials and further research in this direction is needed.

Test on thin tubes in combined tension and torsion have been carried out by Guest,[1] Hancock,[2] Turner,[3] Mason,[4] and Becker.[5]

Hancock and Turner used the limit of proportionality as the point of breakdown, Guest and Mason took the yield point, while Becker adopted the "apparent" elastic limit. This is a point between the limit of proportionality and the yield point where the slope of the tangent to the stress-strain curve is 50 per cent greater than it is at the origin. Seely and Putnam[6] also used the "apparent" elastic limit in their experiments.

Guest, Turner, and Becker added internal fluid pressure in order to obtain an additional stress.

Solid round specimens under tension or compression and torsion have been used by Hancock, Scoble,[7] and Smith,[8] while the strength of thick cylinders under internal pressure has been determined by Turner,[9] Cook and Robertson,[10] and Bridgeman.[11]

Crawford[12] used flat steel plates clamped at the edges and subjected to fluid pressure on one side.

§ (77) REPEATED APPLICATIONS OF COMBINED STRESSES.—With repeated stress tests the limiting range of stress in fatigue is a value that can be definitely taken as the one at which the material fails.

Although Wöhler made tests under repeated tension and repeated torsion, his results are difficult to compare owing to lack of specific information regarding the material used in the tests.

Both Turner and Stromeyer[13] have experimented with alternating torsion; the former found that the more ductile materials approximated to the maximum shear stress law, while the more brittle samples were more nearly in agreement with the maximum strain theory.

The only experiments so far carried out on combined torsion and bending were those by Stanton and Batson.[14] A diagrammatic sketch of the arrangement which was adopted is given in *Fig.* 110. In the position shown the cross-section of the specimen at S is subject to a twisting moment WD, and to a bending moment W*d*. When the head had turned through 180° the moments were equal in amount but opposite in sign. When the head had turned through 90° from the position shown the maximum stress was that due to a bending moment WD plus that due to the direct loading, but as in all cases this stress was below the known fatigue limit of the material under reversals of simple bending, its effect was taken to be negligible, and the specimen was assumed to be subject to reversals of the combination of bending and twisting alone.

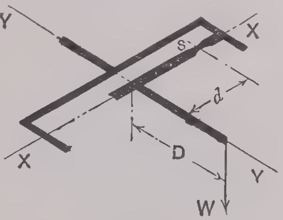

FIG. 110.

§ (78) ALTERNATING BENDING TESTS BEYOND THE YIELD POINT.—The principal objection to the commercial adoption of repeated stress tests is the time and expense of conducting tests in which millions of applications of stress are required in order to obtain the result.

Many machines have been designed in which the test piece is broken rapidly under alternating stresses which exceed the yield point. Such tests do not give information as to relative "fatigue" strength of materials, but have been found useful as indicating mechanical defects, incorrect heat treatment, and brittleness.

(i.) *Arnold Testing Machine.*[15]—In this test, in its latest form, a test piece $\frac{3}{8}$ in. diameter and 5 to 6 in. long is firmly fixed at one end in a vertical position in the vice of the machine. It is bent backward and forward, through a distance of $\frac{3}{8}$ in. on either side of the vertical at a height of 3 in. above the face of the dies, by a slotted steel head fixed to the reciprocating part of the machine. The length of slot is larger than the diameter of the test piece (usually $\frac{3}{4}$ in. with a stroke of the machine of $1\frac{1}{8}$ in.), so that an impact or shock is introduced at each alternation of stress. The standard speed adopted is 650 alternations per minute. The number of alternations to fracture is recorded. Arnold and other investigators improvised shaping or slotting machines to perform the test.

[15] "Factors of Safety in Marine Engineering," *Engineering*, 1908, lxxxv. 598.

It should be noted that, in his earlier work, Arnold[1] used a test piece $\frac{3}{8}$ in. *square* with the force applied 4 in. above the line of maximum stress. The deflection was $\frac{1}{2}$ in. or $\frac{9}{16}$ in. on either side of the vertical, and the number of alternations was 168 to 266 per minute.

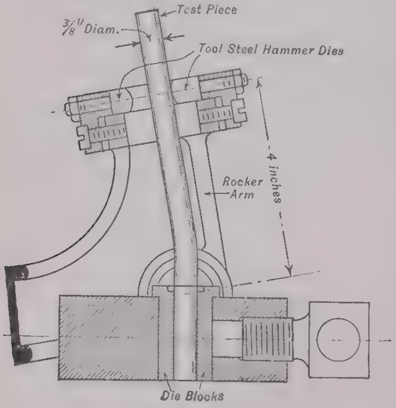

FIG. 111.

(ii.) *Landgraf-Turner Alternating Impact Machine.*—This machine is especially designed and constructed to carry out the Arnold test in order to standardise the conditions employed. In place of the straight line movement of the shaping machine a rocker arm is substituted (*Fig.* 111) to economise space and, by reason of its radius being equal to the free length of the test piece, maintain a constant leverage during the whole stroke.

The number of alternations are recorded by a veeder counter which stops registering when the test piece breaks. The test piece is $\frac{3}{8}$ in. diameter, but, with this machine, the distance from the top of the vice to the striking point of the hammer is 4 in. instead of 3 in. as used by Arnold in his latest experiments.

This machine is manufactured in the U.S.A. by Queen & Co., Philadelphia.

J. B. Kommers[2] of the University of Wisconsin has carried out an investigation with a Landgraf-Turner machine. He summarises his results as follows:

(*a*) A very important factor in a repeated stress test similar to that performed by the Landgraf-Turner machine is the amount of deflection which the specimen receives. When the deflections are less than 0·30 in. the change in the number of cycles required for rupture is very great even for small changes in the amount of deflection.

(*b*) Impact applied to the specimen has *practically no effect* upon the number of cycles required for rupture.

(*c*) At speeds of about 700 cycles per minute the number of cycles for rupture is slightly less than at speeds of about 150, but for small changes of speed this effect is practically negligible. When the deflection is small the results on the same material do not seem to be as uniform as when the deflection is about 0·30 in. or more.

(*d*) The condition of the surface of the specimen has an important effect upon the number of cycles required for rupture.

(iii.) *Sankey Hand Bending Test.*[3]—The principle on which the test is based is to bend backwards and forwards a test piece $\frac{3}{8}$ in. diameter and 4 in. long through a fixed angle until failure, the number of bends and energy required for each bend being recorded. The test is carried out on a machine, manufactured by C. F. Casella & Co., Ltd., and shown diagrammatically in *Fig.* 112. A flat steel spring B has one end gripped in a vice A which forms part of the bedplate, and the other secured to a holder C in which the test piece D is fixed. The test piece is also held in a handle E, 3 feet long, by which it is bent backwards and forwards through an angle of 91½° located by the indicators F and F.

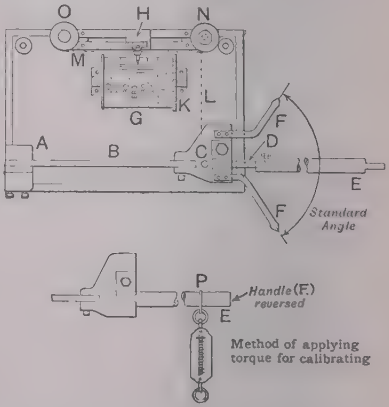

FIG. 112.

The energy required to bend the test piece is measured by the deflection of the spring B, which is recorded on the paper attached to the drum G. The horizontal motion of the pencil H is actuated by the holder C through wires L and M and the multiplying pulley N. The wire is kept taut by a spring box O, but this is sometimes replaced by a weight hanging from the wire M which then passes over a vertical pulley. The motion of the pencil is proportional to the energy required to bend the test piece. The diagram is calibrated by noting the length which corresponds to a measured pull at a known leverage from the point of bending of the test piece. The movement of the pencil holder H moves the drum through one tooth of a ratchet wheel K, which is attached to it so that a diagram is drawn such as is shown on the drum in the illustration.

---

[1] *Inst. Civ. Eng. Proc.* (supplement), 1903, and *Engineer*, Sept. 2, 1904, p. 227.

[2] "Repeated Stress Testing," *Int. Assoc. Test. Mat. Proc.*, 1912, ii. part ii. Paper V_{4a}.

[3] *Engineering*, Feb. 15, 1907, p. 209, Dec. 20, 1907, p. 829, and Dec. 27, 1907, p. 882.

The practical value of the Sankey test is stated by Hatfield,[1] who carried out an extensive series with it, to be as follows:

"The energy absorbed in breaking the Sankey test piece is practically proportional to the product of the average bending moment and the number of bends withstood. These two items may be compared roughly to the maximum stress and reduction of area in the tensile test, *i.e.* for conditions of increasing hardness in general, the maximum bending moment increases and the number of bends decreases. It is necessary that we should point out that in a number of instances we have obtained high absorptions of energy with high tensile.

"The maximum bending moment in the Sankey test follows the maximum stress in tension fairly closely, so that the latter values can be predicted within a few tons per square inch from the Sankey values. The variation found in the values of the number of bends in the Sankey are rather wider and of a less predictable nature. In this respect the Sankey test discriminates and emphasises a certain quality of the material in a manner not similarly brought out in other tests, except perhaps to some extent in the Arnold test. From a knowledge of the quality of the steel, its analysis, etc., experience has shown that fairly definite values of ductility in the tensile test, as measured, for example, by the reduction of area, can be expected in conjunction with given values of tensile strength if the steel is free from defects. Similarly the number of bends in the Sankey test should reach such values which with experience of the test may also be fairly definitely established. There are, however, several outstanding exceptions. It certainly appears that samples, which gave Sankey values well below what has been predicted from an average good steel of the same tensile strength, were in nearly all cases also somewhat inferior in reduction of area."

The diameter of the Sankey test piece is $\frac{3}{8}$ in. and its free length $1\frac{3}{4}$ in. Owing to the fact that the machine, as supplied, is not suitable for steels of higher tensile strength than 50 to 60 tons per square inch, Hatfield suggests a test piece 0·3 in. diameter and free length $1\frac{3}{4}$ in. for these steels.

Sankey[2] gives the following constants for inferring static test results from those obtained on his hand bending machine:

Yield point (tons per sq. in.)

$$=\frac{\text{initial bending effort in lbs.-ft}}{\mathrm{C}},$$

where C=2·1 for steels up to 0·3 per cent carbon and 2·7 for medium carbon steel.

Ultimate strength (tons per sq. in.)

$$=\frac{\text{maximum bending effort in lbs.-ft.}}{1{\cdot}54}.$$

Elongation (on gauge length $=4\sqrt{\text{Area}}$) × reduction of area

$$=\frac{\text{number of bends}}{1{\cdot}9}.$$

(iv.) *The Upton Lewis*[3] *toughness testing machine*, manufactured by Tinius Olsen Testing Machine Co. (English agent, Edward G. Herbert, Ltd., Manchester) is very similar in principle to the Sankey machine. It is, however, operated by a motor or belt-drive giving 250 alternations per minute instead of by hand, and the method of measuring and recording the energy absorbed is slightly different. Referring to *Fig.* 113, where the machine is shown diagrammatically, the test piece C is bent backwards and forwards by an arm operated from the adjustable crank M. The energy is measured by the amount of the compression of the springs EF, which is

recorded by the bell-crank indicator G marking on a continuous recording paper H. The form of diagram is shown in *Fig.* 113A.

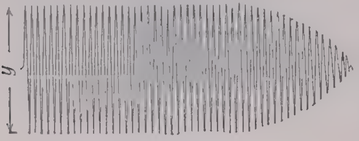

FIG. 113A.

(v.) *Other Investigators and Machines.*—Boudouard [1] used a machine in which one end of the specimen was clamped in a vice and the free end vibrated. The vibrations were maintained electromagnetically, and the oscillations were recorded optically and photographically.

Schuchart [2] tested wire under repeated bending. The wire was gripped in curved-faced jaws and bent backwards and forwards into contact with the curved faces.

Huntingdon [3] applied alternate bending by means of an attachment to a shaping machine.

§ (79) HARDNESS AND ABRASION TESTS.—An examination of the methods employed in hardness testing shows that each of them falls into one or other of two distinct categories. These are:

(i.) Indentation tests, in which the surface of the material under test is permanently distorted by the pressure of a hard steel ball, cone, or knife edge.

(ii.) Abrasion or scratch tests, in which particles of the material whose "hardness" is to be determined are torn away from its surface by sliding contact with some other substance whose corresponding resistance is so high that its surface remains unimpaired by the action.

If each of these methods were a measure of the same definite property of the material which is as characteristic of it as, say, its elasticity, it is evident that the ratio of the results of any two of the methods would be the same for every material tested. Comparisons between the results of these various tests have formed the subject of several researches which have been published during recent years. The general conclusions as summarised by Turner [4] appear to be that, although an approximate agreement may seem to exist between the various methods when applied to the case of relatively pure metals in their cast or normal state, yet when the resistance to deformation is due to tempering or to mechanical treatment no comparison is possible.

That this should be so would seem to follow from the consideration that the resistance which any so-called hardness is supposed to measure is that which the body under test exerts against a complex distribution of stress over its surface which has partially deformed or disintegrated it, and it is evident that its value will depend, not on the stress constants of the material such as its yield point, ultimate tensile and shear stresses, but on intermediate stresses, the precise nature and distribution of which are unknown and whose ratio to the stress constants may not be the same for the same method. If, therefore, such resistance, without qualification, be defined as the hardness of the material in its broadest sense, it is clear that hardness is no more a definite quality of a material than is the strength of a piece of steel of definite dimensions. In the latter case, if the nature, amount, and distribution of the stress are known, its resistance has a definite value which can be calculated. The only difference between this case and that of the hardness test is that, since in the determination of hardness there is no possibility of estimating the stress magnitude and distribution, we are driven more to direct observation of the consequences of such distribution than to a calculation of these consequences from the known characteristics of the material. Mechanical phenomena of this kind are familiar to engineers under other aspects, such as in the case of the resistance of ships and aircraft to propulsion; but whereas in these latter cases the problem is to determine the resultant force exerted by the unknown pressure distribution, in the present case, as in the corresponding one of the resistance of materials to impact, the unknown quality is the ultimate resistance of the material to the unknown stress distribution. In all the cases, however, the practical method of solution is an experimental one, and consists of setting up a similar, or nearly similar, state of stress on a specimen of the material whose behaviour is under investigation, and noting its effects.

H. Le Chatelier says, "The problem therefore seems to be to establish two or three methods of reference for hardness, giving as widely different results as possible, so that hardness (which is an essentially complex phenomenon) may be studied under all its phases. Afterwards, for each particular application the reference method which is most applicable to the conditions may be used."

That this view is now being accepted is indicated by the development, in recent years, of what are called wear tests. For example, there are wear tests for measuring the particular form of disintegration which takes place on the surface of steel rails due to the rolling abrasion of heavily loaded wheels. The characteristics of this kind of wear are the extremely small amount of the relative movement between rail and wheel and the high intensity of the compressive stress at the line of contact. On the other hand, there are wear tests of lubricated surfaces in which the pressure is relatively small and the rate of slipping large, and the same conditions of wear occur, without lubrication, with pins and check gauges.

§ (80) Indentation Tests.—The indentation method of determining hardness has been applied in three ways:

(i.) By testing the material with itself.

(ii.) By pressing (statically) a harder material into the material under test.

(iii.) By producing the indentation by dropping a ball- or cone-pointed hammer on to the material and measuring the rebound of the hammer or size of the indentation.

(i.) *The Material tested with Itself.*—Reaumur[1] in 1722 shaped right-angled prisms from two materials which were to be compared and pressed them together. The axes of the prisms were at 90°, and the right-angled edges came into contact, forming a cross. The relative hardness was measured by the depths of the indentations.

A. Foeppl[2] used two cylindrical test pieces of the material whose hardness was required. They were placed one on the other, with their axes at right angles, and were pressed together in a testing machine. Foeppl used the pressure per unit of flattened surface as a measure of the hardness, because he found that the surface of indentation was proportional to the pressure applied.

Haigh[3] has recently re-introduced the test with the substitution of square for cylindrical or triangular prisms. He gives the hardness number as $=L/R^2$,

where L = the load
and R = the length of damaged edge of prism.

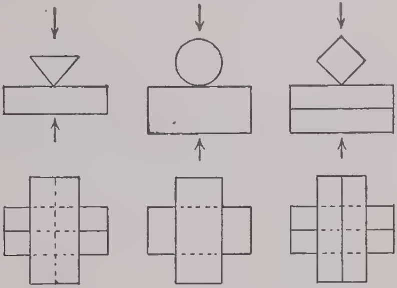
Reaumur, Foeppl, and Haigh's methods are shown diagrammatically in *Fig.* 114.

The necessity for the use of *two* test pieces is probably the reason why this method of test is not commonly applied. There is, however, no limit to the hardness of the material which can be tested, as the test is independent of the use of a harder material as an indenting tool.

(ii.) *The Material tested with an Indenting Tool (statically).*—Many different kinds of indenting tool have been tried and many ways have been suggested to express the relative indenting hardness.

Calvert and Johnson[4] and Kirsch[5] determined the load required to produce a permanent indentation of a given depth, but, whereas Calvert and Johnson used a truncated cone and a depth of 3·5 mm., Kirsch employed a cylindrical plunger of 5 mm. diameter and a depth of 0·01 mm.

The test adopted in 1856 by the United States Ordnance Department[6] was a determination of the volume of the indentation produced by a pyramidal point under a load of 10,000 lbs. A volume of 0·5 cubic inch was taken as unit hardness.



Reaumur (1722) Foeppl Haigh (1920)

Fig. 114.

Middleberg[7] used an indenting tool, in the form of a curved knife edge, for studying the hardness of tyres. The knife edge was $\frac{3}{4}$ inch long, had an angle of 30°, and was formed with an edge curved to 1 inch radius. The reciprocal of the length of the indentation under a load of 6000 lbs. was taken as a measure of the hardness.

Unwin[8] also employed a knife edge, but in his case it was straight and consisted of a piece of hardened and ground $\frac{3}{8}$-inch square steel, $1\frac{1}{2}$ inches in length. Each tool thus had four indenting edges having angles of 90°. The material tested was formed into test bars $\frac{1}{2}'' \times \frac{1}{2}'' \times 2\frac{1}{2}''$, and the knife edge was placed on the bar at right angles to its length, overlapping it by $\frac{1}{2}$ inch on each side. The hardness number was taken as P/H,

where P = the load in tons
and H = the depth of the indentation in inches.

(iii.) *Brinell Hardness Test.*—The method of test devised by J. A. Brinell[9] in 1900 is now extensively employed. A hardened steel ball is pressed under a known load into the material to be tested, and the hardness number is taken as the stress per unit of spherical area. The reason why Brinell used the spherical area is not clear, as there does not appear to be any advantage gained by using it instead of the projected area ($\pi d^2/4$).

[9] "Methods of Testing Steel," *Inter. Assoc. Test. Mat. Proc.*, 1901 (Paris), ii. 81.

If P = pressure in kilograms,

D = diameter of the ball used in millimetres,

d = diameter of the indentation in millimetres,

h = the depth of indentation in millimetres (see *Fig.* 115),

then $$h = \tfrac{1}{2}(\mathrm{D} - \sqrt{\mathrm{D}^2 - d^2}) \text{ mm.},$$

and the spherical area of indentation

$$\mathrm{A} = \pi \mathrm{D}h = \frac{\pi \mathrm{D}}{2}(\mathrm{D} - \sqrt{\mathrm{D}^2 - d^2}) \text{ sq. mm.}$$

The Brinell Hardness Number = H = P/A.

The diameter (d) is usually measured by a micrometer microscope. By the use of some forms of Brinell instruments the depth (h_1) of the indentation is taken as the test proceeds (see § (87)). With these instruments the depth which is measured is h_1, and not h (see *Fig.* 115). It should be noted that, owing to the rising of the edges of the Brinell indentation, h_1 is not equal to h, and, as the amount of this side extrusion is not the same with different materials[1] under similar conditions, the ratio of h_1/h is not always constant. It therefore follows that the hardness number obtained in this way is not the hardness number as defined by Brinell.

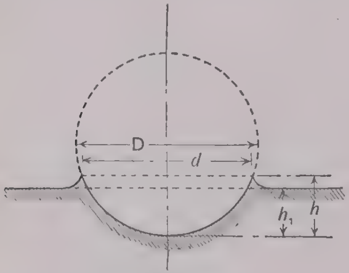

FIG. 115.

It is found that the hardness number varies with the diameter of the ball, and pressure employed. For strictly comparable results fixed values must be used for D and P. The values standardised by Brinell are:

D = 10 mm. and P = 3000 kilograms except for soft materials, when a value of P = 500 kilograms may be used.

(iv.) *Variation of Brinell Hardness with Pressure and Diameter of Ball.*—C. Benedick[2] of Upsala showed that within the range of his tests the value of $(\mathrm{P} \times \sqrt[5]{\mathrm{D}})/\mathrm{A}$ was nearly constant, and that with a ball of diameter $= \mathrm{D}_1$ and load of 3000 kilograms Brinell's hardness number $= (\mathrm{P} \times \sqrt[5]{\mathrm{D}_1/10})/\mathrm{A}$.

In order to allow for variation of pressure, H. Le Chatelier[3] proposed the further modification

$$\mathrm{H} = \frac{\mathrm{P}_1}{\mathrm{A}_1} \times \sqrt[5]{\frac{\mathrm{D}_1}{10}} \times \frac{20{,}000}{17{,}000 + \mathrm{P}_1},$$

where H = Brinell hardness number,

P_1 = load employed in kilograms,

A_1 = spherical area of the indentation (calculated from the diameter) in sq. mm.,

D_1 = diameter of the ball used.

Both the equations suggested by Benedick and Le Chatelier are empyrical and only give approximate values.

E. Meyer[4] in some published results in 1908 showed (1) that $\mathrm{P} = ad^n$, where n is a constant depending on the material, and a is a constant for a given material and given ball diameter; (2) that the mean pressure per unit area ($4\mathrm{P}/\pi d^2$) is constant for a given angle of indentation, whatever the diameter of the ball.

It follows from Meyer's law of comparison that, as d/D and $\mathrm{P}/\frac{1}{4}\pi d^2$ are constant for similar indentations on the same material, P/D^2 is also constant,

where P = pressure,

d = diameter of impression, and

D = diameter of the ball.

This relationship is useful where the piece of material is so small that a pressure of 3000 kilograms cannot be applied with a 10 mm. ball. It is then only necessary to use a smaller ball and a load determined by the above relationship to obtain the standard hardness number required; thus, if a ball 5 mm. diameter ($= \mathrm{D}_1$) is used, the load to be applied is

$$= \frac{\mathrm{P} \times \mathrm{D}_1{}^2}{\mathrm{D}^2} = \frac{3000 \times 5^2}{10^2} = 750 \text{ kilograms.}$$

Some results obtained by Baker[5] and given in Table 31 show remarkably good agreement of the hardness numbers obtained in this way.

TABLE 31

COMPARISON OF BRINELL HARDNESS NUMBERS WHEN USING BALLS OF DIFFERENT DIAMETERS

Steel.	Diameter of Ball in mm.	Diameter of Impression. mm.	Load. kg.	Brinell No.
A	10	6·3	3000	85
	7	4·4	1470	85
	5	3·13	750	87
	1·19	0·748	42·5	86

(v.) *Size of Test Piece and Effect of Time on the Results and the Applications of the Brinell Hardness Test.*—H. Moore [1] found that

(1) The depth of the indentation in a Brinell test should not be greater than 1/7 of the thickness of the test piece.

(2) The centre of the indentation should not be less than 2½ times its diameter from the edge of the test piece.

The time during which the pressure is applied is important. It is found that the time effect is most marked up to about 10 seconds' application of the load, but after about 10 seconds the effect is very small. Consequently it is usual in specifications to draft the Brinell hardness test clause as follows:

"The Brinell hardness test, where specified, shall be made with a 10-mm. diameter ball and a load of 3000 kilograms, *which shall be maintained for not less than* 15 *seconds.* Prior to testing, the skin of the sample shall be removed by filing, proper grinding, or machining at the point to be tested."

Among the most important applications of the Brinell test are the following:

(i.) For rapid control of chemical carbon determinations during iron and steel smelting.

(ii.) For testing finished articles without damaging the same, such as rails, tyres, armour plates, gun-barrels of all kinds, structural steel, etc.

(iii.) For examining the nature of the material in entire or broken parts of machinery where the making of a tensile test bar is impossible.

(iv.) For testing the degree of hardness and softness obtainable by the thermal treatment of any steel.

(v.) For testing uniformity of temper.

(vi.) For ascertaining the effect of the nature and temperature of various hardening fluids.

(vii.) For studying the effect of cold working.

It has been shown by numerous observers (Ast, Breuil, Brinell, Charpy, Dillner, Le Chatelier, etc.) that there is a close relationship between the Brinell hardness number and the ultimate tensile strength of a material.

Dillner [2] finds that, in the case of steel, tensile strength in tons/sq. in. $=C\times$ Brinell hardness number. The values of "C" are as follows:

Brinell Hardness No.	Value of "C." Ball Pressure normal to the Direction of Rolling.	Value of "C." Ball Pressure in the Direction of Rolling.
Below 175 .	0·230	0·225
Above 175 .	0·219	0·206

Unwin [3] deduced the following constants from a table compiled by Hadfield:

$$T=0{\cdot}2H+6,$$
$$Y=0{\cdot}23H-13{\cdot}5,$$

where H is the Brinell number (in kilogrammes/sq. mm.),
T = Ultimate tensile strength in tons per square inch,
Y = Yield stress in tons per square inch.

§ (81) BRINELL HARDNESS TESTING MACHINES.—The Brinell hardness test is quite conveniently carried out in any machine in which a pressure of 3000 kilograms can be accurately applied, such as a universal testing machine having a compression attachment, by the use of a special tool for holding the ball.

Special machines have, however, been developed for the purpose, and these are of two main types:

(*a*) In which the load is applied by oil pressure and measured by a pressure gauge or dead-weight control.

(*b*) Dead-weight or lever machines.

(i.) *Jackman's Oil Pressure Brinell Machine.*—An example of the first type of machine is shown in *Fig.* 116. This is the apparatus supplied by J. W. Jackman & Co., Limited, Caxton House, Westminster, of the Aktiebolaget Alpha (Sweden) design.

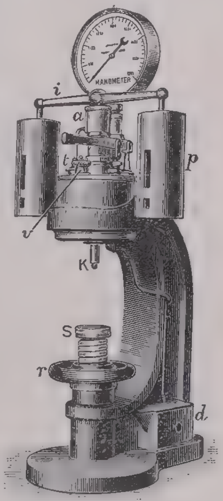

FIG. 116.

The ball K is attached to the downwardly acting ram of a hydraulic press. The test piece is placed on the adjustable table S, and is raised into contact with the ball by the hand-wheel *r*. The pressure is produced by a small hand-pump, and may be read directly in kilograms on a pressure gauge. The machine is also provided with a dead-weight control consisting of a piston, accurately fitted without packing, carrying a cross bar *i*, small cylinder *a*, and weights *p*. The small cylinder is connected to the top of the press so that the intensity of pressure is the same on the piston as on the ram. The maximum pressure is regulated by the weights *p*, and when this pressure is reached the piston rises in the cylinder. The pressure remains constant as long as the piston "floats," forming a small hydraulic accumulator.

---

[1] "Investigation on the Brinell Method of determining Hardness," *Inter. Assoc. Test. Mat. Proc.*, 1909, No. 9.

[2] "Researches concerning the Relation between Hardness Number and Tensile Strength," *Engineering*, Nov. 9, 1906, p. 638.

[3] "Mechanical Properties of Materials," *Inst. Mech. Eng. Proc.*, Oct. 1918, p. 432.

The small piston is formed by a steel ball, and the piston rod has a cup-shaped end which presses on the ball. Any leakage of oil past the piston is collected in a receptacle *d*, from which it is returned to the reservoir through the funnel *t*.

The pressure is released by opening a valve *v* which connects the top of the pressure chamber with the reservoir.

(ii.) *Avery's Dead-weight Brinell Machine.*—The arrangement of this machine is shown in *Fig.* 117. The specimen is placed on the weighing platen *s*, and if of any considerable size its weight is "tared off" by moving one of the sliding poises *c* upon the weighing steelyards until the weighing system is balanced. The ball *k* is then brought into contact with the test piece by lowering the screw by which the pressure is applied. This is done quickly by unscrewing the thumb-screw A at the top of the standard, and revolving the screw by the small hand-wheel *d* which is keyed to it. The thumb-screw is then screwed up tightly, to secure the locking plate *f* and prevent the rotation of the screw. The pressure is then applied, by means of a worm and worm-wheel *h* operated by the large hand-wheel *g* at the side of the machine. The weights *p* are "set" for the prescribed load, and the lifting of the steelyards indicates that this load is applied.

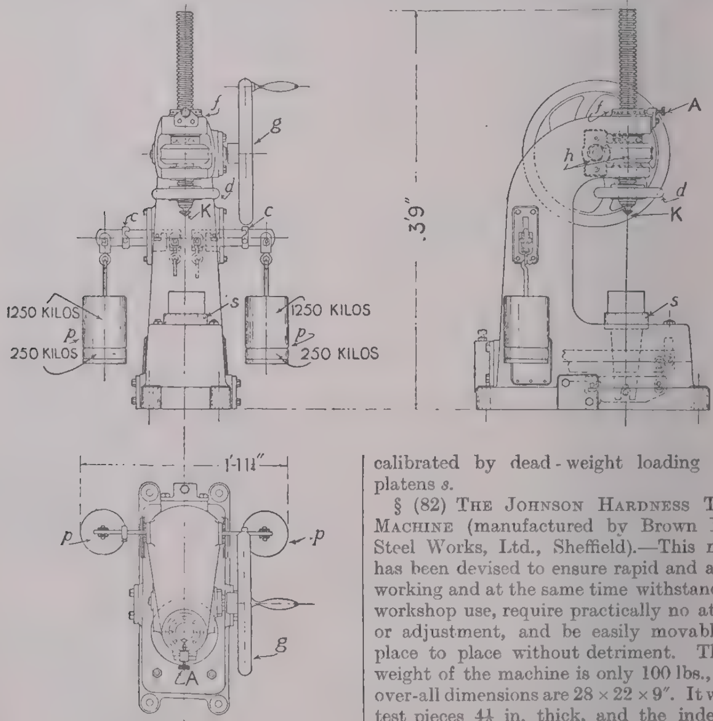

FIG. 117.

The system of levers for measuring the pressure is that adopted by W. & T. Avery, Ltd., Birmingham, in all their platform weighing machines, and is found to be extremely sensitive to small differences of load.

The leverage of the machine can be obtained directly by measurement, but it is also calibrated by dead-weight loading on the platens *s*.

§ (82) THE JOHNSON HARDNESS TESTING MACHINE (manufactured by Brown Bayleys Steel Works, Ltd., Sheffield).—This machine has been devised to ensure rapid and accurate working and at the same time withstand rough workshop use, require practically no attention or adjustment, and be easily movable from place to place without detriment. The total weight of the machine is only 100 lbs., and its over-all dimensions are 28 × 22 × 9". It will take test pieces 4½ in. thick, and the indentation can be made at distances up to 3½ in. from the edge. The arrangement of the machine is shown in *Fig.* 118.

(i.) *Description of the Machine.*—Pressure is applied to the steel ball A by means of the lever B and ball-bearing eccentric C through the single lever D and screw E. The other end of the lever D is held by an eccentric in ball-bearings F, to one of which is attached the lever G and weight H. The weight H is raised by the eccentric F when the pressure on the ball A reaches 3000 kilos, and any further movement of the operating lever B tending to apply further pressure on the ball only results in raising the weight still more.

(ii.) *Method of making Test.*—The specimen to be tested (which must have a smooth *flat* surface) is placed on the table I. The adjusting screw E is then brought down until the steel ball A rests on the prepared surface of the specimen. The lever B is then pulled forward until the weight H rises, allowing the pawl J to fall into the toothed sector K, which will automatically prevent any further movement of the lever B. The load may be kept on for any desired length of time by means of the retaining pawl L, which is moved in and out of position by means of the knurled handle M. In order to release the pressure the lever B is replaced to its original vertical position and the adjusting screw E raised.

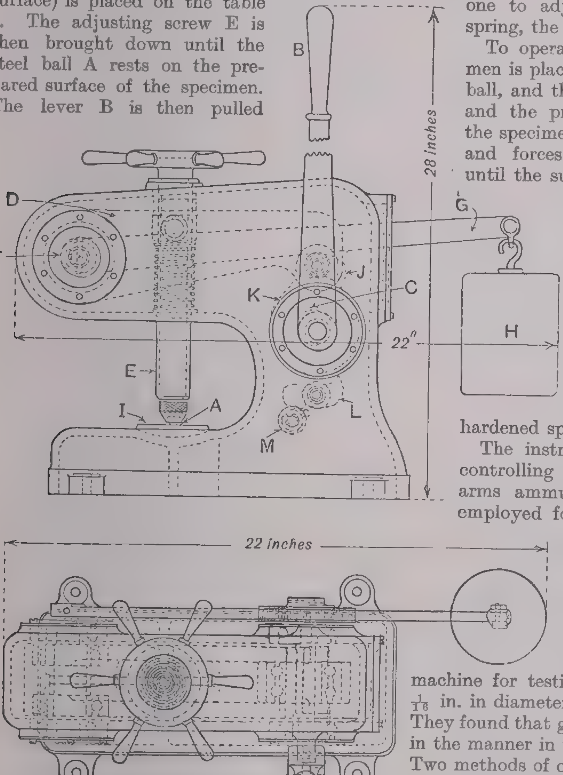

FIG. 118.

§ (83) Brinell Pliers.—For ascertaining the Brinell hardness of small and thin specimens, such as cartridge cases, Rudge Whitworth, Ltd., have devised a hand instrument which they call Brinell pliers. They are shown in *Fig.* 119 and consist essentially of a pair of pliers one nose of which serves as an anvil for supporting the cartridge case C or specimen to be tested, the other nose carrying a cylinder fitted with a piston, at the back of which is a spring. The end of the piston stem projects a short distance and carries a small hardened steel ball B $\frac{3}{64}$ in. diameter. A locking arrangement L enables one to adjust the compression on the spring, the usual pressure being 22 lbs.

To operate the instrument, the specimen is placed between the anvil and the ball, and the plier handles are grasped and the pressure applied. This brings the specimen into contact with the ball, and forces the ball and piston back until the surface of the specimen comes into contact with the face through which the ball projects. Consequently, the actual pressure between the ball and the specimen is quite independent of the pressure exerted by hand.

The diameter of the indentation is measured microscopically and the readings are quite definite, even on hardened spring steel.

The instrument found extensive use controlling the manufacture of small-arms ammunition. It has also been employed for measuring the skin hardness of many varieties of hardened steel articles.

§ (84) Small Machines for testing the Brinell Hardness of Thin Sheet.—Goodale and Banks[1] developed a "Baby" Brinell machine for testing thin sheet, using a ball $\frac{1}{16}$ in. in diameter and a load of 15 kilograms. They found that great care had to be exercised in the manner in which the load was applied. Two methods of operation were tried, viz. :

(1) The test piece was placed on the anvil and the ball pressed on to it until sufficient pressure was exerted to raise the balance beam.

(2) The test piece was forced, under a given load, into contact with the ball. The ball remained in a fixed position.

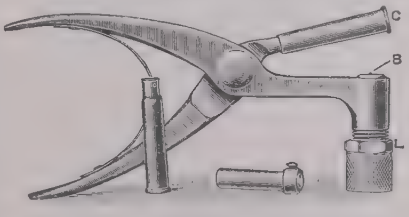

FIG. 119.

The second method gave smaller and more

---

[1] "Development of Brinell Hardness Tests on Thin Brass Sheet," *Amer. Soc. Test. Mat.* xix. 758.

consistent results than the first, and was therefore incorporated in the design of their final machine. The load was applied by a dead weight of 15 kilos, and the diameter of the impression was measured with a metallurgical microscope with a 16-mm. objective and a filar micrometer type of eye-piece.

Similar work has been carried out in England;[1] the ball used, however, was 1 mm. diameter.

It is essential for the measurement of small indentations that there should be vertical illumination.

§ (85) The Ludwik Hardness Test.—In order to overcome the variation in the Brinell hardness number with load and size of ball, Ludwik[2] proposed substituting a 90° cone for the ball, and this form of indenting tool is now often used on the Continent for the softer metals. The hardness number is obtained by means of this test in the same way as with the Brinell Test, *i.e.* the test load in kilograms is divided by the surface of the conical indentation in sq. mm., so that if

P = the load,
and d = diameter of indentation,

$$\text{Hardness number} = \text{H} = \frac{\text{P}}{\pi(d/2) \times (d/\sqrt{2})}$$
$$= 0\,9(\text{P}/d^2) \text{ approximately.}$$

With this apparatus the hardness number is the same whatever the load chosen, if the material is homogeneous.

§ (86) Measuring Microscopes for Hardness Tests.—For commercial work the diameter of the indentation is measured to the nearest 0·05 mm., and for this purpose a microscope with a scale in the eye-piece is usually supplied with the Brinell apparatus. To facilitate the reading of impressions made in corners or below the general surface of the specimen, the microscope is sometimes provided with a special adaptable piece.

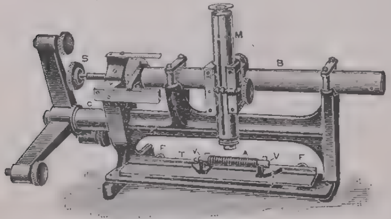

Fig. 120.

For research work an accuracy of 0·001 mm. is essential, and an instrument such as is supplied by the Cambridge & Paul Instrument Co., Ltd., and shown in *Fig.* 120, is necessary for the purpose. It consists of a microscope M clamped to a tube B which is supported by the framework of the instrument and can be traversed by the milled-headed screw S having a pitch of one millimetre. The microscope is fitted with an eye-piece containing cross-wires and is provided with a special focussing mechanism.

§ (87) Depth Indicators for Hardness Tests.—In order to dispense with the use of a microscope the depth of the indentation can be measured during the test by means of some form of depth indicator. Instruments of this type, which can be used in any compression machine, are supplied by Alfred J. Amsler & Co., Schaffhouse,[3] or the Scientific Materials Company, Pittsburgh.

The depth h_1 (*Fig.* 115) is measured relatively to the original surface of the test piece. This excludes the effect of the extrusion round the indentation, and as the amount of plastic flow varies with different metals and different pressures the hardness numbers found in this way are not proportional to the Brinell numbers obtained in the usual way from the diameters.

§ (88) Impact of Dynamic Hardness.—Numerous methods have been devised for measuring indentation hardness by the size of the indentation produced by energy of known amount. This method is complicated by a consideration of the effect of the rebound of the indenting hammer, and there is a difference of opinion as to whether the initial energy of the blow or the net energy absorbed in producing the indentation should be considered in calculating the results.

Edwards and Willis[4] used the initial energy in calculating the results in their research on impact hardness. Unwin,[5] on the other hand, is of opinion "that there should be a single impact and that the energy of rebound should be deducted from the energy due to the height of fall in calculating hardness. He doubted the method of permitting successive impacts till the energy was expended."

A dynamic hardness test was propounded by Martel[6] in 1895. He used a pyramidal point as the indenting tool, and produced the indentation by the fall of a ram on to the tool. Martel found:

(1) That the work of the falling ram was proportional to the volume of the indent, and he therefore expressed hardness as the work required to produce unit volume of indentation.

(2) That for equal energies of blow the volume of the indentation was nearly the same,

[5] "Hardness Tests," *Inst. Mech. Eng. Proc.*, 1918, p. 578.

[6] *Commission des Méthodes d'Essais des Matériaux de Construction*, Paris, 1895, Sect. A, p. 261.

when using indenting tools of slightly different form.

The author carried out a series of experiments[1] which confirmed the first of Martel's conclusions. He showed further that, when using a 10-mm. diameter ball, the ratio of the dynamic hardness number to the Brinell hardness number was approximately 1·5 over a range of Brinell hardness from 20 to 680. The dynamic hardness number was taken as being equal to the net energy in kilogram metres divided by the volume of the indentation in cubic centimetres.

The dynamic method is useful for determining the indentation hardness values of metals at high temperatures, under which conditions the standard Brinell Test cannot be conveniently carried out. The indenting tool in the dynamic test is in contact with the specimen for such a short interval of time that it is not appreciably affected by the heat.

§ (89) DYNAMIC HARDNESS TESTING MACHINES.—A moving anvil block is supplied by W. & T. Avery[2] to adapt their Izod pendulum impact machine (see § (100)) for dynamic hardness tests.

§ (90) THE PELLIN HARDNESS TESTING APPARATUS[3] is made in Paris by Ph. & F. Pellin, and is specially designed for determining the hardness of thin materials. The indentation is produced by a falling bar of known weight having at the lower end a steel ball 2·5 mm. in diameter. The release of the indenting tool is arranged electromagnetically.

§ (91) THE AUTO PUNCH, designed by Rudge Whitworth, Ltd., and shown in *Fig.* 121, is a convenient and serviceable form of impact hardness tester. It was originally designed for testing case-hardened surfaces, but has proved valuable in testing materials of every grade of hardness, even pure lead.

It consists essentially of a knurled hollow cylinder C, from one end of which projects a plunger P which ends in an adapter and cap for carrying a ¼-inch hardened steel ball B. The other end of the Auto Punch is closed by a screw-in end, in which is fixed centrally a pawl-operating rod ¼ × 3 in. long, the object of which will appear shortly. Behind the sliding hammer is a spring which, in the case of the 12-inch Auto Punch, requires about 150 lbs. pressure to compress it. A 6-inch Auto Punch spring requires about 40 lbs. The internal mechanism is shown in *Fig.* 121A. The plunger is reduced to about ¼ inch diameter for about 1·7 inches at its inner end. This part of the plunger is small enough to pass right through the hole in the sliding hammer, and will do so when the sliding pawl is moved sideways by the pawl-operating rod already referred to.

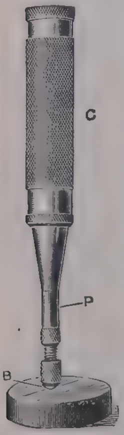

FIG. 121.

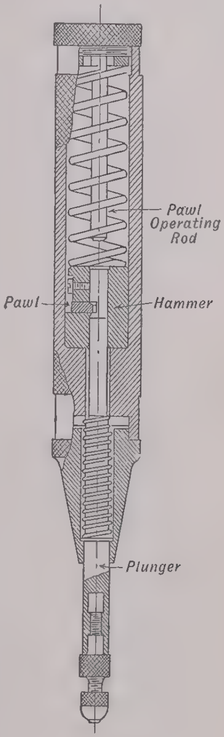

FIG. 121A.

When the Auto Punch is not in use the inner end of the plunger rests on the pawl in the sliding hammer. When the ball is applied to the article to be tested, and the knurled barrel of the Auto Punch is pressed towards the article, the hammer is forced back, compressing the spring, and continuing to compress it until the taper end of the pawl-operating rod presses the pawl to one side, and allows the compressed spring to drive the hammer forward until the front face of the latter strikes the end of the larger diameter part of the plunger. The kinetic energy of the hammer is, of course, *nil* up to the moment of its release, so that however rapidly or slowly the Auto Punch may be worked, the energy of the sliding hammer will be the same. This energy will be used up in deforming and heating the hammer and plunger where these strike one another, also the specimen and ball. Although the energy of the hammer is practically constant, the proportion of the total energy delivered to the specimen varies according to the hardness of the specimen. The softer the specimen, the greater is the proportion of the total energy spent in deforming it.

The diameter of the indentations produced by the Auto Punch follow those produced by the Brinell tests on the same class of material. If a Brinell Standard Block is employed to check from time to time the readings of the Auto Punch, the latter instrument can be used as a quick way of ascertaining the approximate Brinell hardness. In cases where an Auto Punch is used to ascertain whether deliveries are to the specified Brinell hardness, it is wiser to use the Auto Punch as a "workshop" gauge, and to employ the Brinell machine as an "inspection" gauge on all specimens which the Auto Punch shows to be near one or other of the limits of hardness.

§ (92) THE SHORE SCLEROSCOPE [1] is a rebound instrument for measuring hardness. A small diamond-pointed hammer about $\frac{3}{4}$ inch long and $\frac{1}{4}$ inch diameter, weighing $\frac{1}{12}$ oz., is allowed to fall freely from a height of 10 inches. The height of rebound of the hammer is measured against a scale, graduated into 140 equal parts, and is taken as a measure of the hardness. The shape of the diamond striking point is slightly spherical and blunt, being about 0·020 inch in diameter.

The instrument is one which depends on the production of a permanent indentation by this point, the rebound being diminished by the work expended in producing the indentation. With rubber no permanent indentation is produced, and the height of rebound is the same as that from a moderately hard steel.

The instrument is provided with an ingenious automatic head by means of which the hammer is lifted and released by air pressure from a bulb.

The Scleroscope and Brinell hardness scales [2] have been shown to be generally closely related throughout the hardness range. The Brinell hardness number divided by six is approximately equal to the Scleroscope number; the ratio appears to increase from 5·5 for soft steels to 8·0 for materials of over 700 on the Brinell scale. The applications of the Scleroscope are therefore similar to those enumerated for the Brinell test in § (80).

The Scleroscope readings have been found to be slightly dependent on the size of the piece tested. This variation can be considerably reduced by clamping the test piece to a firm foundation. Most materials are mechanically hardened by indentation. It is therefore important to ensure that the material is not tested twice on the same place, otherwise high results are obtained.

§ (93) ABRASION OR SCRATCH TESTS.—The abrasion test has been applied in three ways:

(1) As a scratch test.

(2) By drilling or grooving with a hardened steel tool or diamond.

(3) By wearing away with or without an abrasive.

§ (94) THE SCRATCH TEST.—The scratch test has been frequently used in conjunction with an indentation hardness test. In 1722 Réaumur [3] used both methods. As an indication of scratch hardness he tested metals against a bar whose hardness increased from one end to the other; the position on this bar which the metal under test would scratch indicated its hardness. Mohs [4] was the first to give a scratch hardness scale, which is still largely used by mineralogists. Ten minerals were arranged in order from 1 to 10 in such a way that each would scratch the one next below it on the list. Talc was taken as having a hardness of "one" and diamond a hardness of "ten."

(i.) *Turner's Sclerometer.*[5]—In this device a balanced lever is—

(1) Provided at its free end with a diamond point fixed in a vertical pencil.

(2) Loaded with a sliding weight and calibrated in order that the sliding weight can be set to represent known weights at the point.

(3) Supported in such a way that it can be rotated.

The hardness number is the smallest weight in grammes which will produce a scratch just visible to the naked eye on the smoothed and polished surface of the specimen.

A series of scratches are made with diminishing weights, and the hardness is taken as the mean between the least weight which will produce a scratch and the greatest weight which will not produce a scratch.

A. Martens,[6] in order to make the test more definite, defined the scratch hardness number as the load in grammes under which a conical diamond (90°) produces a scratch 0·01 mm. in width.

(ii.) A. L. Parsons [7] further modified the Sclerometer by applying the load on the diamond point by a spring in such a way that the pressure increased as the point was drawn across the test piece. The place at which the scratch commenced was noted, and the corresponding load was taken as the hardness number.

(iii.) *The Quadrant Sclerometer.* — This instrument has been devised in the Rudge-Whitworth Laboratory. The method employed is to apply a hardened edge or series of hardened edges to the surface of the test piece in such a direction that slipping ensues until they "bite" the surface of the article.

The instrument is made in various types for testing either flat surfaces, pins, or the inside of cylindrical surfaces. *Fig.* 122 shows a pin under test.

[7] *Amer. Journ. of Science*, Feb. 1910.

Two specially cut flat rods or files F_1 and F_2 are employed, and the upper one is raised until it makes an angle of about 80° with the lower. The pin P is then placed between them and the "file" lowered until it "bites" the pin. The angle at this point is an index of the scratch hardness of the article.

The theory of the instrument has been worked out by H. L. Heathcote,[1] who has shown that the angle is practically independent of the weight and size of the article to be tested. A soft bar holds the top file up so that it makes an angle of about 70°. A hard bar will not hold the top file up until the angle falls to about 15 to 20°. Hardened and tempered bars give readings between 20 and 70°, according to their surface resistance to abrasion. The instrument can also be employed for measuring the coefficient of friction between one material and another, one being attached to, or substituted for, the upper arm, and the other for the lower.

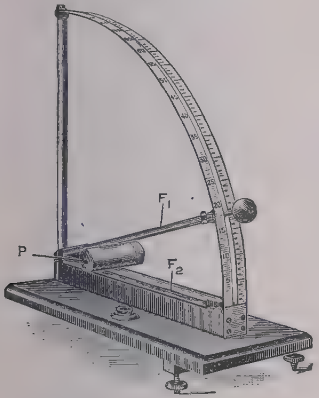

FIG. 122.

§ (95) "DRILLING OR GROOVING" HARDNESS.—S. Bottone[2] measured the resistance to wear as the time required to produce in the material a cut of definite depth with a soft iron disc rotating at constant speed and pressed with constant force.

A. Haussner[3] defined cutting hardness as the resistance, per square mm., to planing, when using a cutting angle of 90°.

Jaggar[4] rotated a diamond point under constant pressure and at a uniform rate, and gave the number of rotations of the point to reach a fixed depth as the hardness. Bauer and Keep[5] both defined cutting hardness as the rate at which a steel drill, running at constant speed and under constant pressure, drills the material.

§ (96) WEAR TESTS. (*a*) Using an abradant or an abrading wheel (pure abrasion).—Felix Robin[6] used cylindrical specimens (50 mm. diameter), which he rubbed under known pressure on papers covered with abrasive powders. Rosiwall[7] defined abrasive hardness as equal to (1/loss of volume), by grinding with an abradant. Behrens[8] used a standard powder and measured hardness by the time required to polish.

Gary[9] determined the resistance to wear by the amount of abrasion caused by a sand-blast, and experimented chiefly with stones, artificial minerals, and timber. W. H. Warren[10] also used the sand-blast on timber.

Jannetaz and Goldberg,[11] and Stoughton and Macgregor[12] measured the comparative loss by grinding. The latter, who also carried out indentation hardness tests, found that the two methods gave different comparative results.

(*b*) Wear by sliding lubricated abrasion.—Derihon[13] constructed a machine in which a specimen was pressed on to the circumference of a polished wheel turning at a speed of 3200 revolutions per minute in an oil bath. The wear was measured by the loss in weight or reduction in diameter in thousandths of a millimetre after 2,000,000 turns of the wheel.

(*c*) Wear by dry rolling abrasion.—Saniter[14] devised a machine for testing the wearing properties of rail steel under dry *rolling* abrasion. In this method the specimen (A), 5 inches long and 0·5 inch diameter, was fixed in a chuck (B, *Fig.* 123) revolving at 4000 r.p.m., and carried near the free end a ball-bearing (C), of inner diameter 1 inch, loaded to produce a pressure of 205 lbs. at the point of contact. The inner ring of the ball-bearing (D, $\frac{11}{16}$ inch wide) was rotated by friction by the test piece, causing the latter to wear. The resistance of the material to rolling abrasion was taken as being inversely proportional to the reduction in diameter in ten-thousandths of an inch after 200,000 revolutions of the test piece.

A similar test was used by Stanton and Batson[1] for a series of experiments on hardness tests. The dimensions of the test piece, etc., were made slightly larger than those employed by Saniter.

It was shown that the resistance to rolling abrasion was approximately proportional to the ball hardness number, but that the comparison was not a safe one, as there were frequently cases in which a considerable departure was found from this ratio, *e.g.* manganese steel which was well known to be susceptible to hardening under pressure. The results confirmed Saniter's conclusions, and showed that what was actually measured was the resistance to disintegration of already deformed material, and that this resistance depended on the amount of deformation produced, and had little relation to the material in the unstrained condition. The method, as a means of predicting the relative resistance to wear under conditions of rolling abrasion with heavy loads, was comparatively rapid and gave the information desired.

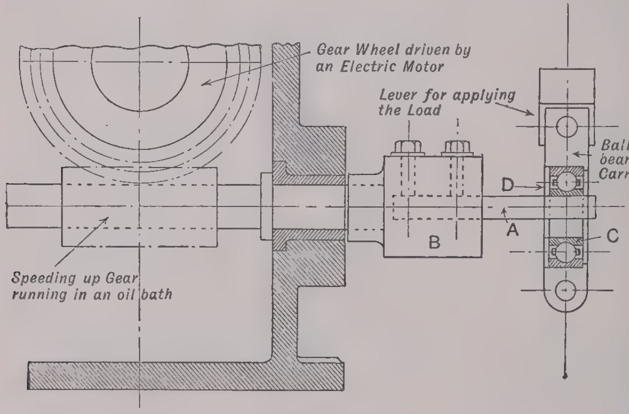

FIG. 123.

(*d*) Wear by dry sliding abrasion.—The Saniter test was carried out with high pressure and *very small* relative motion. Stanton and Batson[1] also carried out a series of tests on dry *sliding* abrasion, in which the amount of relative motion was *large* and therefore corresponding to the wear of pins, collars, etc. This was done by connecting the abrading ring (diameter = D) to the chuck by means of an Oldham coupling, so that both ring and specimen (diameter = d) completed a revolution in the same time, the line of contact remaining fixed relative to the machine. The slip per revolution was then $= \pi(D - d)$ inches. The results indicated that there was very little hardening of the surface of the material under these conditions, and that the Brinell hardness number was not a safe guide in predicting the relative resistances to wear of a miscellaneous selection of steel.

§ (97) IMPACT AND NOTCHED BAR TESTING.—There is no doubt that the tensile test, as usually carried out, does not give all the information about a material it is essential that an engineer should know. A careful examination of a complete load extension diagram, however, reveals differences, such as those due to heat treatment and mechanical treatment, not disclosed by an ordinary tensile test, but the analysis of such diagrams requires considerable experience.

It has, occasionally, been found that a material which has satisfactorily passed the ordinary tensile test fails in practice in a manner which cannot be accounted for by errors in design. Investigation has shown that, in some cases, parts of machinery which have failed in this way have been subjected to shocks. Consequently, various methods of test have been devised to give a definite indication of the shock-resisting properties of materials.

§ (98) NOTCHED BAR TESTS.—Freedom from the tendency to crack at sharp corners, when the variations of stress are considerable, is a property which is very desirable in materials for engineering work. In order to obtain this information about materials "brittleness" tests, in which the test piece is notched so as to limit the plane of fracture and the contraction of area, are employed.

These notched bar tests are made in tension or bending. The test piece is usually broken by a single blow in impact, and the energy of fracture obtained directly from the loss of energy of the striker.

In 1909, Charpy,[2] in a report on impact tests on metals, shows that a static tension test is more efficaciously supplemented by a notched bar bending test than by any other test, and his results seem to indicate that the notched bar bending test gives information regarding the fragility of materials which other tests do not easily furnish. Charpy in the same report shows that materials which give good results with this impact test have stood well in practice, whereas the same class of materials giving low values fail, although the results from the ordinary static tensile test is the same in both cases.

[1] "Hardness Tests Research," *Inst. Mech. Eng. Proc.*, Nov. 1916, p. 693.

[2] "Official Report on Impact Tests of Metals," *Inter. Assoc. Test. Mat. Proc.*, 1909, No. 7, paper iii./1.

The originator of this method of testing appears to have been M. Barba of Le Creusot, who in 1900 described the results of his experiments on the detection of brittleness in steel by tests on flat specimens, notched with a 45° notch on both sides to 0·35 times the thickness, the radius at the bottom of the notch being 0·2 mm. and the total width of the specimen 30 mm. The specimen was fixed in a horizontal position between jaws, with the notch directly over the edges of the jaws and having a piece of the specimen 25 mm. long projecting from the jaws. This piece was struck by a falling weight of 18 kilograms. Each specimen was provided with a number of notches at spaces of 25 mm. along the specimen, and by making a series of tests at different heights of fall it was possible to predict the energy of blow which would just break the specimen.

It was soon realised that this method of testing revealed marked differences in the behaviour of materials which were not detected by the ordinary tensile test, and other investigators (Le Chatelier, Charpy, Frémont, etc.) carried out experiments, the results of which were communicated to the Congress of the International Association of Testing Materials held at Buda Pesth in 1901.

The report of a commission, appointed at this congress to investigate the notched bar test, was discussed at the congress held in Brussels in 1906, but no advance was made in the matter of standardisation except an expression of opinion that the test gave interesting information. The German Association for Methods of Testing Materials thereupon took the matter up and issued a report in 1907, in which they recommended the Charpy method of testing. This consists in the use of a notched specimen, 30 × 30 × 160 mm., supported horizontally at the ends on knife edges of given form and struck in the centre, opposite the notch, by a pendulum. The notch was formed by drilling a hole 4 mm. diameter in the bar and sawing through from one side, leaving a depth of 15 mm. behind the notch, as shown in *Fig.* 124. The span is 120 mm.

The question of notched bar testing was again brought forward at the International Congress held at Copenhagen in 1909, who recommended the 30 × 30 × 160 mm. Charpy test piece, with an alternative specimen, geometrically similar but one-third of the size, where the larger dimensions could not be obtained. The matter was further discussed at New York in 1912, and the recommendations of 1909 were confirmed. No particular machine for carrying out the tests was selected, but further testing research on apparatus and test pieces of different sizes was suggested as being desirable.

The recommendations of the International Association for Testing Materials have never been fully recognised. For most test work the standard 30 × 30 × 160 mm. test piece has been found to be too large, and difficulties have been experienced with the notch of the geometrically smaller test piece.

Frémont suggests a test piece 10 × 8 × 30 mm., placed horizontally on supports 21 mm. span, with a notch 1 mm. deep and 1 mm. wide (square shape, and made on the broad side at the centre of the length), *Fig.* 125.

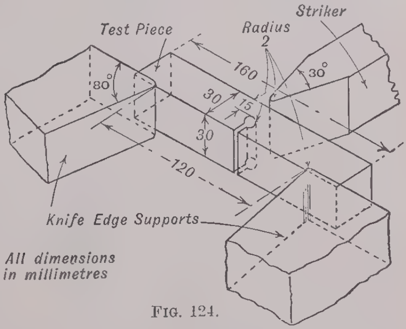

FIG. 124.

In most cases a test piece 10 × 10 mm. in cross-section is used, but the form of notch is varied. Several well-known types of notch are given in *Fig.* 125. The beam test pieces are usually 60 mm. long with a span of 40 mm.

§ (99) NOTCHED BAR TESTING IN BRITAIN.—A considerable amount of work has been carried out, in Britain, on the notched bar test. Yarrows developed a notched bar test in 1902, in which the test bar was broken by more than one blow. Valuable information appears to have been obtained by this test as to the brittleness of steels used for connecting rod bolts.

In 1903, Izod[1] introduced a single-blow notched bar testing machine, in which the specimen is held in a vice at one end and is struck by a falling pendulum at the other. This method is the one which is commonly adopted in this country at the present time.

---

[1] *Engineering*, Sept. 25, 1903.

Seaton and Jude[1] carried out some tests in 1904, in which the test piece was broken by a number of blows, the test bar being reversed between successive blows.

In 1908, Stanton and Bairstow[2] and Harbord[3] communicated results of experiments to the Institution of Mechanical Engineers. The main point brought out by Harbord's paper was the variability in the results of individual tests of specimens of the same material. It was shown that two identical test pieces from the same bar of ordinary commercial steel gave results varying from each other by over 60 per cent. This variability has been attributed to—

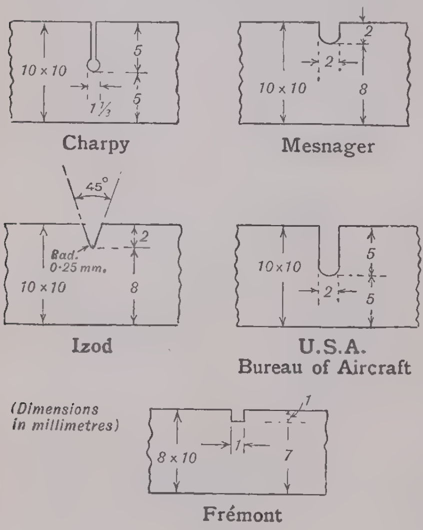

FIG. 125.

(1) The mode of testing.

(2) The heterogeneity of the material under investigation.

Experiments published by Charpy and Cornu Thenard[4] show that by careful selection and heat treatment it is possible to obtain, in the course of experiments in notched bar tests, carried out on bars of steel of different natures or of copper, a degree of uniformity analogous to that obtained by means of tensile or hardness tests. Variability in the results is therefore not due to the mode of testing but to differences in the material under test.

By 1914 there was conclusive evidence that there could be large variations in the resistance of notched specimens of different materials to impact, without any corresponding variation in any of the characteristics brought out by the ordinary tensile test, and there was evidence that this variation was due to correct or incorrect heat treatment.

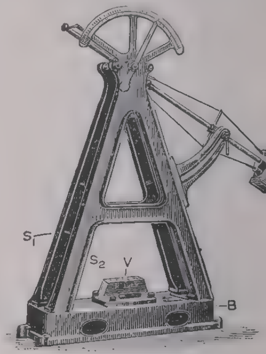

FIG. 126.

§ (100) IMPACT TESTING MACHINES. (i.) *The Izod Test.*—The Izod impact test has of recent years come into great prominence in Government specifications, owing to the great demands made by war conditions.

The original Izod machine had a striking energy of the hammer of 23 ft.-lbs., and the test piece was 2 in. long, $\frac{3}{8}$ths in. wide, and $\frac{3}{16}$ths in. thick, with a vee notch 0·05 in. deep.

The present standard machine made by W. & T. Avery, Ltd., Soho Foundry, Birmingham, has a capacity of 120 ft.-lbs. The cross-section of the test piece is 10 × 10 mm. and it is notched with a 45° vee notch, 2 mm. deep with a root radius of 0·25 mm. The machine is shown in *Fig.* 126, and consists of a heavy base B on to which are bolted two standards S_1, S_2 supporting the pivot of the pendulum. The pendulum P swings on ball bearings and strikes the specimen held in the vice, *cantilever fashion,* its point of contact with the specimen being a hardened steel knife edge. The form and angle of the knife edge is shown in *Fig.* 127. The specimen is gripped in a vice V in such a

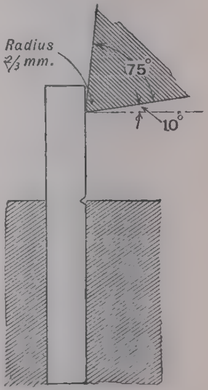

FIG. 127.

position that the bottom of the notch is level with the top of the vice, *Fig.* 128.

The specimen, in being broken, absorbs some of the energy from the pendulum, which is measured by the continued and diminished swing of the pendulum moving an idle pointer over a graduated scale. The pendulum swings less as the resistance of the specimen is greater. The scale is graduated to give the actual energy in foot-pounds absorbed by the blow. The standard three-notch test piece is shown at B in *Fig.* 129.

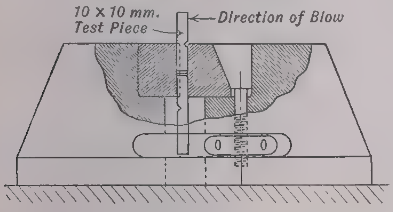

FIG. 128.

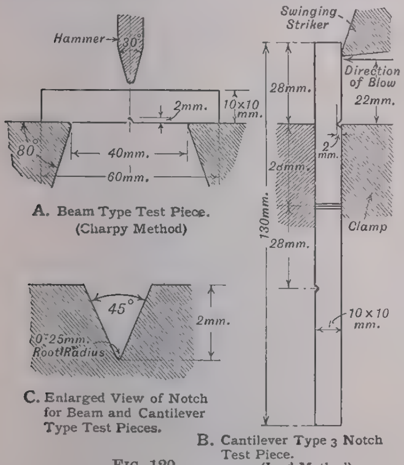
(ii.) *The Charpy Pendulum Machine.*—The small Charpy machine has a power of about 30 kilogrammetres (217 ft.-lbs.) and a maximum striking velocity of 5·28 metres per second (17 ft. 4 in. per sec.). The principal part of the pendulum consists of the hammer M, shaped as shown in *Fig.* 130, and suspended at the end of a light hollow bar. The centre is suspended on ball-bearings, and an index hand is mounted with an easy frictional fit and travels over a graduated semicircular dial with the hammer when this rises up after fracturing the specimen. The latter is held in cast-iron supports in the two uprights which are bolted down to a cast-iron bedplate.



A. Beam Type Test Piece. (Charpy Method)

C. Enlarged View of Notch for Beam and Cantilever Type Test Pieces.

B. Cantilever Type 3 Notch Test Piece. (Izod Method)

FIG. 129.

The hammer is raised up for action by hand, and is held up by a catch operated directly by a small lever D. The drop is constant and 1·420 metres (4 ft. $7\frac{5}{8}$ in.) in height. A hand brake B, worked by the hand lever C, enables the hammer to be stopped rapidly after fracture of the specimen. The weight of the falling parts, position of the centre of gravity, and heights of drop counted from the centre of gravity, are all determined experimentally. The angle of rise after fracture is read off from the graduated semicircle. The difference between the height of fall before fracture and rising back after fracture gives the work absorbed. It is, however, necessary in research work to take into account the friction and energy absorbed by the fragments of the test specimen; the latter may be considered to take the same velocity as the pendulum itself. The weight of the test specimen being very light compared with that of the pendulum hammer, the correction is very slight and can be neglected in ordinary practice.

In order to determine the work absorbed by friction the pendulum is caused to oscillate freely and the decrease in the oscillations due solely to friction is noted down. This gives a table of corrections. The required correction can also be arrived at by noting the angle of rise of the pendulum following that causing the fracture.

A larger machine is made, and this has 200 kilogrammetres energy and a striking velocity of 7·8 metres per second.

(iii.) *Guillery Machine* (*Rotary Tup*).—The latest model of this machine is shown in *Fig.* 131. It consists of a flywheel having a "breaking knife" attached to it. This knife is arranged so that it can assume two positions:

(1) Hidden in the rim of the wheel.

(2) Projecting from the rim of the wheel in which position it is required for breaking the test piece.

The position is controlled by "studs" on the casing of the machine and operated by centrifugal force due to the rotation of the wheel.

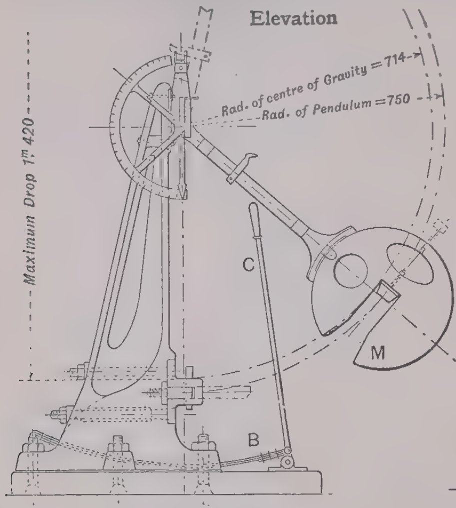
The rotation of the flywheel operates a small centrifugal pump which elevates a coloured liquid in a tube. The machine is designed so that when the liquid is at the top of the tube (and reading zero on the energy scale) there is 60 kilogrammetres of energy in the flywheel. When the flywheel is still, and the liquid is at its lowest level the reading is therefore 60.

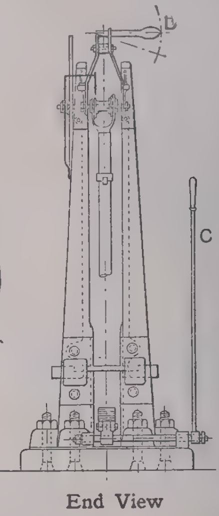
The test bar is placed horizontally on knife edges which have a 40-mm. gap. The front of the machine is covered with a door which is automatically locked when the "knife" is out and the flywheel in motion.

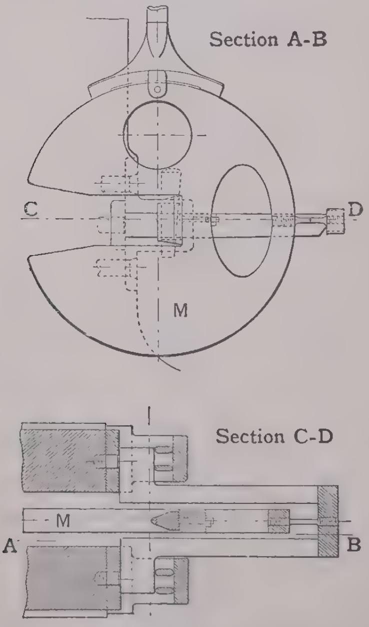
The test is made by rotating the flywheel to a speed slightly in excess of that corresponding to the zero of the energy scale. The gear is then disconnected and the wheel speed allowed to decrease. Immediately the liquid in the tachometer tube reads zero the "out" stud is pressed, the knife springs out and breaks the test piece. The absorption of energy from the flywheel lowers the speed and the tachometer reading gives the energy lost in producing fracture of the test piece. The knife is then set "in" by pressing the "in" stud.

(iv.) *Frémont Machine.* — The Frémont impact machine consists of a hammer of 10 to 15 kilograms, which has on its underside a hardened steel V-shaped striker. The test piece is placed horizontally on knife edges having a gap of 21 mm., so that when the hammer falls from a height of 4 metres the striker hits it midway between the supports and exactly opposite to the notch.

Immediately after the blow of the striker the underside of the hammer, which then only possesses the energy not absorbed by the test piece, strikes against an anvil carrying two housings provided with tempered







Details of Hammer and Knife edges

FIG. 130.

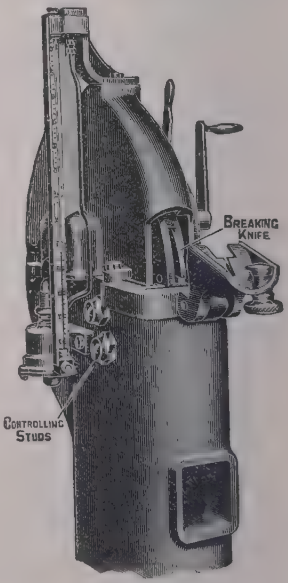


FIG. 131.

steel springs. The springs yield under the blow of the hammer and register by their deflection the energy remaining in the apparatus.

Knowing the initial energy of the hammer, the energy absorbed in fracture of the test piece is found by taking the difference.

(v.) *The Amsler 75-kilogrammetre Pendulum Impact Testing Machine.*—This machine is on the same principle as the Charpy machine, but some of the details are slightly different.

The pendulum is held up by a hook attached to a rope which is wound round a windlass. The tup is released, by detaching the hook by means of a special release, and falling freely swings up on the other side of the machine after having broken the test bar. Instead of swinging back again, as in the Charpy machine, it is held in position by a cord passing round a drum and acting as a brake.

On falling from one side, transverse (bending) tests are made, while tensile tests are made when the pendulum falls from the other side. The energy in the hammer before and after the test is registered on two movable straight scales by the movement of the pendulum. It is so arranged that the second scale raises the pointer on to the first scale and indicates the actual energy absorbed.

	Incorrect	14·2	18·3	26·9	31·6	59·1	0·88
Nickel chrome crank shaft	Correct	27·0	33·0	45·2	21·0	59·2	10·74
	Incorrect	20·0	32·9	44·0	23·5	57·0	2·27

§ (101) FURTHER PARTICULARS OF NOTCHED BAR TESTS.—The leading particulars of the five principal types of notched bar machines are as follows:

Type of Machine.	Striking Energy. Kg.M.	Striking Velocity. Metres/Sec.
Charpy (pendulum) .	30	5·3
Amsler (pendulum) .	75	. .
Izod (pendulum) .	16·6	3·5
Frémont (falling tup) .	20 or 60	8·85
Guillery (rotary tup) .	60	8·85

The notched bar test is principally used as a means of detecting a dangerous condition of microstructure due to faulty heat treatment.

The large variation in the energy absorbed in the Izod test due to alteration of heat treatment is well shown by the figures in Table 32, taken from a paper by Philpot.[1]

Some tests by the author on a piece of boiler plate and nickel chrome crank shaft are given in Table 33, and show the same kind of variability with heat treatment

---

[1] "Some Experiments on Notched Bars," *Inst. of Automobile Eng. Proc.*, April 1918.

Bagnall Wild has shown that the brittleness in steel resulting from a high percentage of sulphur and phosphorus is well marked by the Izod test. He says, "Certain steel for making nuts and bolts was found to contain sulphur and phosphorus in excess of 0·1 per cent; such steel invariably failed to give any higher reading than 2 to 3 ft.-lbs. on the Izod, whereas a steel of exactly similar composition and with similar treatment but with sulphur and phosphorus below 0·06 per cent gave an Izod test figure of over 40 ft.-lbs."

§ (102) DIMENSIONS OF STANDARD TEST PIECES.—Although there are several impact testers in Britain of the Frémont and Guillery type, the majority of the test houses use Izod or Charpy machines. The dimensions of test pieces for these machines have been standardised and are shown in *Fig.* 129. It will be noted that in each case the cross-sectional dimensions are 10 × 10 mm. and that the form of notch is the same (the Guillery machine uses the same size of test pieces as the Charpy machine, while the Frémont test piece is smaller and is described in § (98). The form of notch selected, and sometimes called the Izod notch, is a 45° vee, 2 mm. deep, with a root radius of 0·25 mm.

§ (103) THE ANGLE OF THE NOTCH.—Experiments by Thomas[1] at the Watertown Arsenal show that, with mild steel, the angle of the notch does not appreciably affect the results until it has exceeded 45°. The results that Thomas obtained are given in Table 34.

§ (104) ROOT RADIUS AND DEPTH OF NOTCH.—The 10 × 10-mm. test piece in which the notch is formed by a drilled hole 1⅓ mm. diameter, proposed by the International Association of Testing Materials, cannot be produced economically on the majority of alloy steels.

TABLE 34

EFFECT OF VARIATION OF ANGLE OF NOTCH ON THE ENERGY ABSORBED

Angle of Notch. Degrees.	Charpy Impact Values. Ft.-lbs./Sq. In.			Angle of Bend. Degrees.	Brinell Hardness No.
	Maximum.	Minimum.	Average of 6.		
0	304	266	285	15·8	79
15	346	283	316	15·2	77
30	323	284	298	15·0	81
45	382	304	334	29·5	80
60	571	516	539	54·2	80
75	890	818	854	130	78
90	830	806	814	136	78

The form of notch selected as a standard, viz. 45° vee notch, 2 mm. deep and 0·25 mm. root radius, does not suffer from this objection as it can be easily produced even on the hardest steels.

The shape at the bottom of the notch has an important effect on the work absorbed in fracture, which has its least value when the angle at the bottom of the notch is as nearly zero as possible.

Results by Dix,[2] summarised in Table 35, and by the author (Table 36) show this effect very clearly.

TABLE 35

EFFECT OF RADIUS AT THE BOTTOM OF THE NOTCH ON THE ENERGY ABSORBED IN FRACTURE

Nickel chrome steel rod, ⅝″ in diameter

Form of Notch.	Energy absorbed in Fracture (Charpy Machine).	
	Ft.-lbs.	Kg.M.
2 mm. deep (45° vee) sharp	21·6	2·99
2 mm. deep (45° vee) 0·25 mm. root radius	25·0	3·46
2 mm. deep (parallel sides) 1 mm. root radius	40·3	5·57

TABLE 36

0·65 per cent carbon steel, vee notches, 2 mm. deep

Root Radius of Notch in mm.	Energy absorbed in Fracture (Charpy Machine).	
	Ft.-lbs.	Kg.M.
Sharp	4·05	0·56
0·17	6·86	0·95
0·34	8·31	1·15
0·68	13·7	1·89

It has been found that the sharper the notch is made, the better the test discriminates between brittle and tough materials, that is to say, that as the material tested becomes tougher the effect of alteration of the root radius is less.

It is unsatisfactory, commercially, to standardise a dead sharp notch as it is difficult to be always sure that it is produced. A root radius of 0·25 mm. has been selected as it is found that, with a radius of this size, the test is still effective in the detection of faulty heat treatment.

[1] "Charpy Impact Tests on Heat-Treated Steels," *Amer. Soc. Test. Mat. Proc.*, 1915, xv. 75.

[2] "Single Blow Notched Bar Impact Test as used in the American Industry," *Amer. Soc. Test. Mat. Proc.*, 1919, xix. part ii. 721.

It has also been found that shallow notches increase the energy to fracture of tough materials relatively to that required for brittle materials.

§ (105) SHAPE OF TEST PIECE.—Philpot[1] found that a round test piece can be produced which can be used for acceptance tests on heat-treated steels in place of the standard square specimen. The latter is, however, far the more desirable from the point of view of testing and, by properly rigging up for quantity production, it can be prepared by a pair of straddle mills just as economically as the round test piece.

§ (106) COMPARISON OF TESTS ON DIFFERENT MACHINES.—Philpot[2] has made a comparison of tests in the Charpy (beam) and Izod (cantilever) machines on the standard 10 × 10-mm. test piece with the 45° standard notch, 2 mm. deep and 0·25 mm. root radius. He finds that, where the energy absorbed is less than 70 ft.-lbs., notched bar tests, made in either the Charpy or the Izod machines, give similar values, but where the energy absorbed in fracture is greater than 70 ft.-lbs., there is a tendency for the values from the Charpy machine to be somewhat higher.

Charpy and Cornu Thenard[3] have made a series of experiments, with a steel specially prepared to give consistent results, on "beam" machines of three different types (pendulum, vertical drop, and rotary) and have found that, in regard to energy absorbed in fracture, the results are practically identical when the size of test piece, notch, distance between supports and radii of supports and striker are uniform.

§ (107) EFFECT OF STRIKING VELOCITY ON THE ENERGY TO FRACTURE.—Both Belanger and Frémont have found a variation of the energy absorbed in fracture with striking velocity but in opposite directions. Charpy has found that the influence of the rate of impact is practically negligible within limits which do not exceed those of appliances generally employed in the testing laboratory.

Some tests carried out by the author show that, on a machine of the Charpy type at striking velocities up to 43 ft. per second, increasing striking velocity may either increase, decrease or unalter the energy absorbed in fracture according to the material upon which the tests are made. In any case the effect is not appreciable until after a velocity of 16 ft. per sec. is reached, as is shown by the results in Table 37.

TABLE 37

EFFECT OF STRIKING VELOCITY ON THE ENERGY ABSORBED IN FRACTURE

Material.	Energy absorbed in Fracture.		Striking Velocity.	
	Kg.M.	Ft.-lbs.	Metres/Sec.	Feet/Sec.

	1·05	7·6	6·1	20
	1·05	7·6	13·1	43

§ (108) SLOW BENDING TESTS ON NOTCHED BARS.—It has been shown by Philpot[1] and others that, if a notched bar test piece is broken slowly, the work expended is comparable with that measured by an impact machine (at moderately low striking velocities) and is equally as effective in distinguishing between certain brittle and tough materials.

As an average of a large number of tests Philpot found that the energy absorbed in the slow bending test is about 75 per cent of that given by an impact test (in two or three cases the energies obtained by the two methods are approximately equal), and he attributes this difference to energy dissipated in the pendulum testing machine. The striking velocity in Philpot's impact tests did not exceed 3·5 metres per second, and his conclusions only hold up to that value.

Philpot for his slow bending tests uses an ordinary Brinell machine, and measures the deflections of the specimen for different loads by means of a microscope. The results are plotted and the area of the curve is integrated in order to obtain the total energy absorbed. *The Humphrey Autographic Notched Bar Testing Machine*, made by the Foster Instrument Company of Letchworth, is devised to carry out this class of test rapidly and conveniently and in a manner giving the maximum information as to the material in a minimum time. It is illustrated diagrammatically in *Fig.* 132, and photographically in *Fig.* 133.

[2] *Ibid.*

[3] "New Experiments on Shock Tests," *Iron and Steel Inst. Journ.* No. 2, 1917, p. 61.

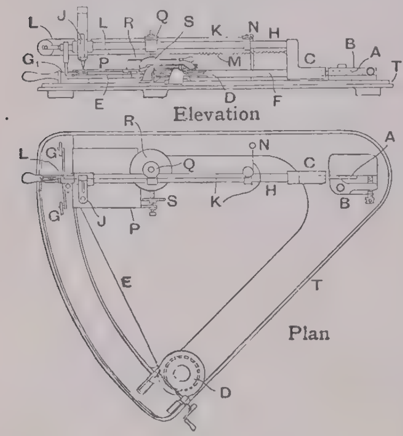

FIG. 132.

The test piece A is gripped in the vice B, so that the jaws of the vice are in line with the notch in the test piece. The socket C is attached on the projecting end of the test piece, and is a reasonably close fit thereon. A bending stress is applied to the test piece by means of the winch D and the wire E, which is attached to the outer end of the spring bar F. The inner end of the spring bar is firmly fixed to the socket C. The outer end of the spring bar is supported by two rollers G and G_1. The socket C carries also a rigid bar H.

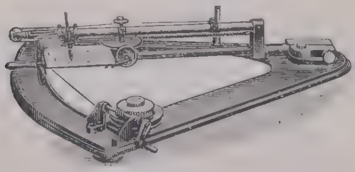

FIG. 133.

The deflection of the spring bar F is a measure of the bending moment applied to the test piece. Since the rigid bar H is not subjected to any bending moment it will move through the same angle as the socket C, and this movement will therefore be a measure of the bending of the test piece. The pen J slides upon the rigid bar H, its position being determined by the thin wires or cords K and L, which are kept taut by a light spring M. One end of the wire K is attached to a post N so that as the rigid bar H moves in consequence of the bending of the test piece, the wire K will draw the pen to the right. The point of the pen marks upon a calibrated chart P carried on the spring bar F, therefore, if the test piece offers no resistance whatever to bending force the pen would draw a horizontal line on the chart, the length of which is proportional to the angle through which the test piece is bent. As, however, the test piece does offer resistance to bending there will be a resulting movement between the spring bar F and the rigid bar H.

The pen, therefore, draws a diagram showing the relation between bending moment applied and angle of bending throughout the duration of the test. The total energy absorbed in the breaking of the test piece can be obtained from the area of this diagram.

The machine can also be fitted with an integrating device so that the energy absorbed can be read directly from the machine. This device is shown in *Figs.* 132-3. The wire K passes round a pulley Q. The pulley Q is attached to a spindle having at its lower end a friction disc R, so that the bending of the test piece which results in the movement of the pen to the right also results in a proportionate rotation of the friction disc R.

The under face of this disc rests upon the edge of the friction wheel, not shown. The spindle of the friction wheel is carried with the chart plate upon the spring bar F. When the bending moment is zero the friction wheel is at the centre of the friction disc, but as bending moment is applied, and there is relative movement between the spring bar F and the rigid bar H, the friction wheel travels towards the circumference of the friction disc, and is consequently rotated. The rotation will be proportional to the product of the bending moment applied and the angle of bending of the test piece, and this device will therefore integrate the total energy absorbed in breaking the test piece. Mounted upon the outer end of the spindle which carries the friction wheel is an index disc S which can be calibrated to read direct in ft.-lbs.

§ (109) TESTS ON SPECIMENS OF DIFFERENT SIZES.—A trustworthy relation has not been found between the energy to fracture in test pieces of different sizes; there is, however, evidence that it is probably different on different materials. This is shown from an examination of the results in Table 38, which gives the results of notched bar impact tests on two different steels with geometrically similar test pieces.

TABLE 38

TESTS ON GEOMETRICALLY SIMILAR SPECIMENS

Dimensions of Specimen in mm.*	Energy to Fracture.					
	Steel A.			Steel B.		
	Kg.M.	Kg.M./Cm.².	Kg.M./Cm.³.	Kg.M.	Kg.M./Cm.².	Kg.M./Cm.³.
10 × 10 × 53·33	4·77	5·96	0·89	1·28	1·60	0·24
30 × 30 × 160	60	8·33	0·42	36·3	5·04	0·25
63 × 63 × 336	296	9·32	0·22	197	6·20	0·15

* The notch for the 10 × 10 test piece was a 45° vee, 0·25 mm. root radius and 2 mm. deep. The notches for the larger test pieces were geometrically similar.

It will be noted that:

(1) The energy absorbed is not proportional to either the square or the cube of the dimensions of the test piece.

(2) With the 10 × 10-mm. test piece, steel A takes 3¾ times the energy that steel B does, but with the 63 × 63-mm. test pieces it is only 1½ times.

There is apparently a scale speed factor in the law of resistance of notched specimens to sudden shock which appears to be of extreme complexity.

§ (110) TESTS ON UNNOTCHED BARS.—With geometrically similar unnotched test bars, either beams or tensile test pieces, the energy absorbed in fracture for the same material is proportional to the volume of the test piece.

Hatt,[1] in 1904, as the result of some experiments in dynamic tension, came to the conclusion that, for steels, there is little difference in the total elongation and the unit work in fracture whether the fracture is brought about in 10 minutes or 0·01 seconds. Stanton and Bairstow [2] in 1908 and Delikhow [3] in 1909 (using a drop hammer type of machine) have also shown that the tensile impact test (*i.e.* dynamic tensile test) gives numerical values which agree with the results of the static tensile test.

Blount, Kirkaldy, and Sankey,[4] in the summary to their paper on steel testing methods, say that "the impact tensile test gives the ductility in the same terms as the static tensile test, namely, elongation and contraction of area, but always with higher numerical values. The breaking stress of the material can be inferred, but must be reduced by a factor in order to obtain the same numerical value as given by the static test; also it only gives the breaking stress. The energy absorbed per cubic inch does not vary greatly with the various types of steel; it is approximately 50 per cent more than that obtained by the static tensile test, and is also no definite criterion of the type of the steel; at any rate, of normal steels containing a small proportion of phosphorus. From the experiments referred to by Breuil [5] it would appear that steels containing an undue proportion of phosphorus give a much smaller energy per cubic inch with impact tensile tests."

§ (111) TESTS UNDER REPEATED BENDING IMPACT.—In 1908 Stanton [6] carried out extensive investigations on the method of testing by repeated impact, and devised a machine to reproduce stress conditions which are met with in certain machine parts in actual use, where the effect of alternating blows is produced on the material at positions where there is a rapid reduction of cross-section. The test bar, 0·500 inch diameter and 6·5 inches long, is supported on knife edges 4½ inches apart. The test piece has a groove turned round the centre of the span 0·05 inch deep, so that the effective diameter at the bottom of the groove is 0·400 inch. The groove is in the form of a vee, whose angle is 55° and root radius 0·01 inch. The test piece is fixed in the machine, where it receives blows at the rate of about 90 per minute from a hammer whose weight is 4·71 lbs., and of which the height of fall is adjustable.

[6] "Resistance of Materials to Impact," *Inst. Mech. Eng. Proc.*, Nov. 20, 1908, and *Revue de métall.*, March 1909.

Between each blow the bar is turned through 180° and the test is continued until failure of the test bar. The number of blows to cause failure is recorded by a counter.

A series of tests is usually made on each material with varying energies of blow, and, by plotting the energies of blow as ordinates and the number of blows to fracture as abscissæ, a curve is obtained from which useful information as to both the impact strength and fatigue strength of the material can be obtained. In Stanton's original paper it is clearly stated that when the number of blows is less than 500 the results approximate to those of the single blow impact test, and that, when the number of blows for fracture exceed 100,000, the results are in the order of the fatigue ranges of the materials as determined in a Wöhler test. During the war it has been a common practice to compare materials by the number of blows required to cause fracture when the height of the fall of the tup is kept constant. As the height of fall selected causes fracture after from 4000 to 6000 blows the results cannot be properly interpreted.

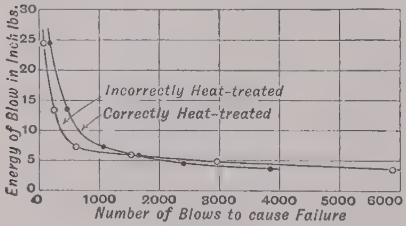

FIG. 134.

The results from tests on steel correctly and incorrectly heat-treated are given in Table 39 and plotted in *Fig.* 134. It will be noted that the incorrectly heat-treated bars are considerably weaker as regards notched bar impact, but slightly stronger under fatigue.

TABLE 39

REPEATED BENDING IMPACT TESTS ON BOILER PLATE CORRECTLY AND INCORRECTLY HEAT-TREATED

Energy of Blow. Inch-lbs.	Number of Blows to cause Failure.	
	Material correctly Heat-treated.	Material incorrectly Heat-treated.
3·53	3886	5871
4·71	2356	2913
5·89	1636	1450
7·35	1043	629
13·32	474	259
24·46	155	61

The test bar previously described is the one adopted by Stanton for his research, and has a notch very similar to the standard Izod notch, which is easily reproduced. A notch 0·05 inch wide and 0·05 inch deep with parallel sides and practically sharp corners has been sometimes used in conjunction with this test.

The Eden-Foster machine, manufactured by the Foster Instrument Company, Letchworth, is a close copy of Stanton's original machine and embodies its principal features.

The illustration (*Fig.* 135) gives a general idea of the external appearance of the machine. The main spindle, not shown in the illustration, projects through the side of the box casting, and is driven by an electric motor with suitable gear or worm reduction. About 0·1 horse-power is required to drive the apparatus.

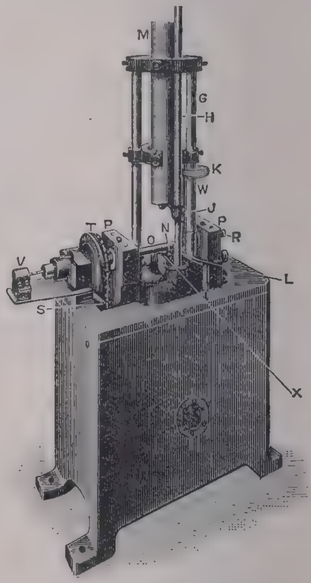

FIG. 135.

The main spindle carries a dog clutch driving a cam, which has a roller bearing on its upper surface and attached to the lower end of the rod H. Fixed on the rod H is an arm J which engages with the lower face of the hammer M; thus, when the rod H rises by rotation of the cam, the hammer M is lifted. The guides for the hammer consist of two sets of three point screws carried by two castings attached to the standard G and its fellow on the opposite side.

Mounted on the standard G is a sleeve W, free to rotate about the standard, but normally held in a fixed position by a spring L. Clamped on the sleeve W is an adjustable catch K. As soon as the arm J has lifted the hammer sufficiently, the spring L causes a partial rotation of the sleeve W, so that, when the arm J again descends, the hammer is held by the catch K. The further descent of the arm J brings its lower inclined face in engagement with the roller N, attached to the sleeve W, in such a manner that the catch K releases the hammer M, allowing it to fall upon the test piece O. The hammer M is furnished with a hardened tool-steel tup. Two hammers are provided to allow for a wide range of tests, the weights being 5 and 2 lbs. respectively. The height of drop, which depends upon the position of the adjustable catch K on the sleeve W, can be varied from 1 to $4\frac{1}{2}$ inches.

The test piece is carried by two hardened steel bushes in the plummer block PP. It is rotated through 180° between successive blows, the rotation being arranged so that it begins and ends entirely between the successive blows.

The revolutions of the test piece are recorded by a counter V, and the number of blows is found by multiplying the counter record by two. When the test piece breaks, it comes in contact with an arm X, and thereby trips the clutch and stops the machine.

The test piece is driven, through a universal joint, by the chain S, free-wheel and clutch T. One end of the chain is attached to the roller, at the lower end of the rod H, which bears on the cam, and the other end carries a suitably guided weight.

All the gear is fixed to the casting which forms the cover of the lower tank casting. The latter is partially filled with oil for lubrication of the surfaces.

§ (112) Effect of Temperature on the Mechanical Properties of Metals.—Many parts of machinery work at temperatures considerably above or below the normal, and it is essential for the purpose of economy and safety in design that the more important effects of temperature on the mechanical properties of materials should be well understood.

§ (113) Testing Apparatus.—The oldest method used for testing at temperatures above that of the air was that of heating the test piece in a furnace, transferring it to the testing machine, and conducting the test very quickly in air. The values obtained by that method were very unreliable, and in recent tests the samples have been immersed in a hot bath for the whole duration of the test.

The medium used in the hot bath can either be a liquid or gas, but it is essential that the heating medium should neither attack nor alloy with the test piece. Suitable materials for liquid baths are given in the following table:

Material.	Temperature used in ° C.
Water	Up to 100
Paraffin	Up to 200
Mineral oil	Up to 350
Nitrate of potassium and nitrate of sodium	350–600
Lead and tin	300–400

Air is nearly always used for the gas bath, but it causes oxidation of the test sample, and for special cases the test may be carried out *in vacuo*,[1] nitrogen,[2] or carbon dioxide.[3] Rudeloff[4] made use of baths of steam (up to 100° C.), naphthalene vapour (200° C.), and naphthylamine vapour (300° C.).

The heating of the bath is carried out in several ways:

(1) By gas jets arranged underneath the test piece, which is held horizontal. This method is adopted by Unwin[5] for a liquid bath, and by Charpy[6] for an air bath.

(2) By gas jets above a horizontal test piece—adopted by Le Chatelier.[7]

(3) By gas jets at the sides. This is used in conjunction with a vertical testing machine by Martens[8] and Bach.[9]

(4) Steam-heating coils are used for tests on 50-feet lengths of copper wire, up to temperatures of 60° C., carried out at the National Physical Laboratory.[10]

(5) Electric heating coils are used by Stribeck,[11] and Hopkinson and Rogers.[12]

For general convenience the last method is to be preferred. Two electric furnaces, successfully used at the National Physical Laboratory, are given in *Figs.* 136 and 137. They are both used in connection with a vertical testing machine.

A platinum furnace for temperatures up to 1200° C. is shown in *Fig.* 136. The heater (a) consists of a platinum strip, 0·75″ × 0·0007″, wound on a fire-clay cylinder (outside diameter 2·25 inches, thickness 0·187 inch, and $13\frac{7}{8}$ inches long), with a pitch of 1 inch. The ends of the strip are clamped in position on the cylinder by metal clips D. A steel case B (about 8 inches diameter and 1/16 inch thick) surrounds the heater, and the space between the two is packed with asbestos and magnesia fluff. The whole is clamped between two end plates C_1 and C_2, on one of which two insulated terminals are fixed; these are connected to the two ends of the platinum heating coil. The furnace, which is slung from the top shackle of the testing machine, takes a current of 15 amperes.

Fig. 136.

Fig. 137 shows the 600° C. furnace. With this furnace the heater is formed with nichrome wire wound on to a brass tube A (2⅜ inches diameter and 15 inches long). The tube is bound with mica, before winding the wire, in order to insulate it, and over the wire a binding of asbestos string is placed so as to keep the former in position when it expands on rise of temperature. The heater is surrounded by a steel case B, 7 inches diameter, and the space between the two is filled with asbestos fluff. Two steel plates C_1 and C_2 are bolted together, clamping the heater and outer case between them, and are arranged to connect the furnace to the frame of the testing machine at E_1 and E_2. The ends of the heating coil are connected to two insulated terminals on the top plate. No. 18 ni-chrome wire, having a carrying capacity of 11 amperes at 500° C., is used for the heater. The wire is coiled closer at the ends, in order to allow for the conduction of heat through the shackles and give uniform heating over the central 3 inches to 4 inches of the furnace.

In another furnace of the same type the conduction of heat through the shackles is equalised by having the main heating coil wound at constant pitch throughout its length, and supplementing this by two further coils, one wound at each end of the furnace. These coils are wound over the main coil, mica insulation being inserted, and are connected to separate circuits.

§ (114) Arrangement of Testing-machine Grips and Rate of Loading.—It is important that the size of test piece, form of grips, and length of furnace should be carefully proportioned to obtain uniform heating of the test piece. It is found that either high chromium low carbon or high tungsten high carbon steels (*i.e.* 13 per cent chromium, 0·35 per cent carbon or 18 per cent tungsten, 0·6 per cent carbon), give the most satisfactory holders for tests at over 600° C., as they combine a fairly high tensile strength with freedom from scaling. Of the two steels the former scales very little, while the latter, although it scales a little more, has a slightly higher tensile strength at high temperatures.

Fig. 137.

Uniformity of speed in loading is an important condition for strictly comparable results. As the speed of loading increases larger strength values are obtained. Le Chatelier found that with hard-drawn copper wire tested at 250° C., the ultimate breaking strength increased from 11·4 to 21·6 tons per square inch as the duration of the test decreased from 1800 seconds to 20 seconds. Both Le Chatelier and Stribeck have shown that the elongation of copper diminishes with reduction in the speed of loading.

§ (115) TEMPERATURE MEASUREMENT FOR STRENGTH TESTS.—With liquid baths sufficient accuracy can usually be obtained by taking the temperature of the liquid, but it is essential that the test should not be carried out until uniformity of temperature is attained.

With an air-bath there is incomplete conduction of the heat between the surrounding air and the test piece, and it is necessary that the temperature of the sample be directly measured. This is most conveniently carried out by means of a thermo-electric pyrometer, which can either be placed in a hole drilled down the test piece, as was done by Bregowsky and Spring,[1] or laid close against the sample and bound to it with asbestos string.

The thermo-electric pyrometer consists of three distinct parts, viz. :

(i.) The thermo-couple[2] which receives the temperature.

(ii.) The indicator from which the temperatures are observed.

(iii.) Leads connecting the thermo-couple to the indicator.

The thermo-couple consists of two wires, A and B, of different composition. The ends of A and B are joined together and form a circuit. One junction is placed in a known temperature, usually zero, while the other is placed against the material whose temperature is to be ascertained. The difference in temperature between these ends sets up an electromotive force which is proportional to the temperature difference. This E.M.F. is measured and, by means of a calibration, gives the temperature. The cold junction is usually placed in ice in order to ensure a constant temperature. A thermos flask is a convenient receptacle for the ice and cold junction.

Various combinations of metals are used for thermo-couples, according to the maximum temperature for which they are to be used:

(*a*) Base metal thermo-couples.

Iron-constantan (wires) thermo-couples for temperatures up to 600° C. Iron-constantan (rods) thermo-couples for temperatures up to 800° C.

(*b*) Rare metal couples.

Platinum—platinum and 10 per cent rhodium for temperatures up to 1400° C.

Platinum—platinum and 10 per cent iridium for temperatures up to 1400° C.

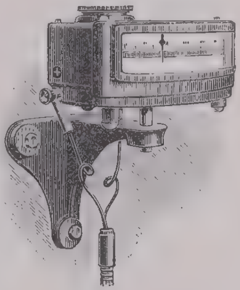

FIG. 138.

It is essential for temperatures above 800° C. that the couple should be protected by quartz or porcelain tubes. A thermo-couple placed in small porcelain tubing is seen at F (*Fig.* 136).

The indicator is usually a sensitive moving coil galvanometer of high internal electrical resistance, having the scale marked in temperature readings which depend upon the type of thermo-couple employed. It is generally an advantage to also have the instrument provided with a scale giving its readings in millivolts.

[2] See "Thermocouples," § (2).

Complete thermo-electric pyrometer outfits are supplied by various firms of instrument-makers. *Fig.* 138 shows the type of indicator which the author has found most suitable for ordinary high temperature test work. It is supplied by the Cambridge & Paul Instrument Company.

§ (116) DETERMINATION OF ELASTIC LIMIT AND YIELD POINT AT HIGH TEMPERATURE.—In the majority of high temperature furnaces the test piece is not visible during the test, so that the yield point, if one exists, cannot be obtained by noting the extension by a pair of dividers, and the attachment of an extensometer is more difficult than with tests at air temperature.

FIG. 140.

In 1890, Martens[1] adapted his mirror extensometer for high temperature work. The test piece *tt* (*Fig.* 139 (A)) was turned down in the centre at *cd*. The extensometer clips were attached at *b* on the lower enlarged end, and were carried out of the furnace for attachment of the measuring rhombs at *a*. The extension was therefore measured on the length *ab*, and correction was made for the extension of the enlarged ends in order to obtain the extension of the gauge length *cd*.

Rudeloff,[2] in 1895, slightly modified Martens' arrangement, and used two pairs of clips, *m* and *n* (*Fig.* 139 (B)), with the mirror rhombs *p* between them. Here again the true elongation has to be obtained by calculation; the length of the thick part, however, is small, and as the whole of the measured length is in the furnace, the observations are uninfluenced by variations of temperature.

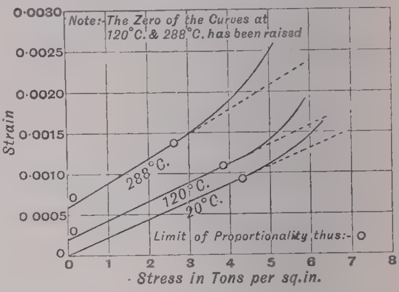

FIG. 141.

Lee and Crowther,[3] in 1914, adapted Rudeloff's arrangement of clips to a horizontal testing machine; they, however, attached them to the reduced part of the test piece.

In *Figs.* 139 (C) and 140 is shown the high temperature extensometer which is proving very useful at the National Physical Laboratory. This is a combination of the best features of both Rudeloff and Lee's extensometers, with the addition of two micrometers for measuring extensions beyond the elastic limit. The clips *aa* and *bb* are attached to the reduced part of the test piece by C springs and protrude from the furnace. The inner clips *aa* are guided on flats on the test piece holders by small rollers *c*. Mirrors and

[3] *Engineering*, 1914, xcviii. 487.

rhombs are placed between the clips, and the whole is clamped together by a special spring attached to notches on the outer clip.

Extension of the test piece causes relative movement between the clips *aa* and *bb*, and therefore rotation of the mirror rhombs *pp*, which is measured in the usual way by a telescope and scale. The relative movement of the clips is also measured by two micrometers *ee* attached to the inner clips and working against the outer ones.

Curves for tests on phosphor bronze with this instrument are shown in *Figs.* 141 and 142. *Fig.* 141 gives the elastic line and limit of proportionality at temperatures of 20, 120, and 288° C., plotted from results with the rhombs and mirrors, and *Fig.* 142 shows the full stress strain curves at temperatures of 20, 120, 205, and 288° C., obtained by using the micrometers.

VII. Results of Tests at Varying Temperatures

§ (117) Results of Tensile Tests. (i.) *Iron and Carbon Steels.*—Strength tests at high temperatures have been carried out since the early part of the nineteenth century.

In 1820 Tremery and Proirier-Saint-Brice[1] showed that, although the tensile strength of hammered wrought iron was 27·6 tons per sq. inch at air temperature, it fell to 5·0 tons per sq. inch at red heat. Fairbairn, in 1856,[2] showed that iron possesses a maximum resistance to fracture at 250° C. and this has frequently been verified for iron and steel. It has also been shown that this maximum resistance is preceded by a minimum, which occurs at about 120° C.

An extensive series of tests were carried out on iron and steel at the Watertown Arsenal[3] in 1888, from which the following conclusions can be drawn:

(1) The change in the ultimate strength is very small up to about 150° C. There is evidence of a slight reduction at from 100 to 120° C., and after 150° C. there is an increase until, at 250° C., a maximum is reached, which is from 10 to 15 per cent higher than the normal. From 250 to 950° C. there is a continuous fall in strength, which at the latter temperature gives a reduction in strength of 80 to 85 per cent of the normal.

(2) The elastic limit decreases with increasing temperature. Up to 350° C. this decrease is directly proportional to increase in temperature, so that at 350° C. the elastic limit is about 70 to 75 per cent of that at normal temperature.

(3) With cast iron the ultimate strength is approximately constant up to 500° C., after which it falls until, at 950° C., it is about 20 per cent of the normal value.

Martens,[4] in 1890, published an elaborate series of tests on the strength of steel at temperatures up to 600° C., and included a determination of the limit of proportionality. He used a paraffin bath for temperatures up to 200° C., a bath of lead and tin for temperatures up to 600° C., and for low temperatures a mixture of three parts by weight of ice and one part of salt. Temperatures up to 400° C. were measured with a mercurial thermometer, and for higher temperatures an air thermometer was employed.

Tests by Lee and Crowther show that the modulus of elasticity of mild steel varies from 29.6×10^6 lbs. per square inch at normal temperature to 12.8×10^6 at 600° C. They also found that the ultimate stress was a maximum at 250° C., but that the stress obtained by dividing the breaking-load by the area at fracture was a minimum at that temperature. The figures given in Table 40 have been taken from the plotted results.

Table 40

Tensile Tests on Mild Steel at Varying Temperatures

Temperature, ° C.	Modulus of Elasticity. Lbs./Sq. In.	Yield Stress. Tons/Sq. In.	Ultimate Stress. Tons/Sq. In.	Reduction of Area. Per cent.
20	29.6×10^6	21·4	28·7	57
110	29.3×10^6	19·4	29·2	..
240	28.3×10^6	16·6	39·0	65
310	27.6×10^6	16·3	37·9	62
445	23.3×10^6	15·4	25·7	32
520	17.7×10^6	12·5	17·3	15
570	14.8×10^6	9·7	12·1	4
600	12.8×10^6	..	..	..

(ii.) *Alloy Steels.*—The behaviour of special alloy steels at high temperature has been studied by Aitchison.[5] A synopsis of results of tensile tests, most of which were made at the National Physical Laboratory, is given in Table 41; these show that the tungsten steels with high percentages of carbon (*i.e.* about 0·6 per cent) have the greatest tensile strength at high temperatures. This strength is nearly equalled by the high chromium steels also containing a high percentage of carbon.

With high chromium and high tungsten steels the percentage of carbon seems to play an important part in their strength at high temperatures. Thus with the 11 per cent chromium steel, reducing the carbon content from 1·0 to 0·4 per cent reduces the tensile strength at 900° C. from 7·5 to 4·8 tons per square inch, while a reduction of the chromium content from 11 per cent to 6·3 per cent, with the carbon content at 1 per cent, has no effect on the tensile strength at that temperature.

When the temperature exceeds 600° C. the strength of alloy steels falls off rapidly; this is particularly noticeable with nickel chrome steels and nickel steels, between which there is very little difference at high temperature.

(iii.) *Alloys.*—The use of fittings under superheated steam involves temperatures up to 400° C., and the study of brasses, bronzes, etc., up to these temperatures has been undertaken by numerous investigators. Unwin,[1] in 1889, communicated a report to the British Association on tensile tests of delta metal, gunmetal, muntz metal, copper, brass, phosphor bronze, and aluminium bronze at temperatures up to 350° C.

Rudeloff,[2] Bregowsky and Spring,[3] Dewrance,[4] and Law [5] have also carried out a great deal of work on this subject.

The tensile strength at high temperatures of aluminium copper, aluminium copper manganese, and aluminium zinc alloys are given in the reports of the Alloy Research Committee.[6]

The variations, with temperature, in the properties of alloys are fairly regular; there is a fall in the tensile strength as the temperature rises, with change of curvature and sometimes humps in the temperature-ultimate stress curve. Rolled monel metal, an alloy of 70 per cent nickel with 30 per cent copper, exhibits high strength and ductility at temperatures up to 550° C.

Tests at the National Physical Laboratory [7] on hard-drawn copper and bronze wire show that between −20° C. and +60° C. a rise of 1° C. corresponds to a decrease of 0·1 per cent of the breaking-load and an increase of 0·3 per cent in the total extension at 15° C. There is also a slight alteration of the modulus of elasticity with temperatures met with under climatic conditions.

§ (118) TENSILE TESTS AT LOW TEMPERATURES.—These tests are usually carried out by surrounding the test piece with a bath containing a cooling substance, such as:

Ice for temperatures down to . . .	0° C.
Ice and freezing salt for temperatures down to	− 20° C.
Frozen mercury for temperatures down to	− 40° C.
Solid carbon dioxide powder for temperatures down to	− 80° C.
Liquid air for temperatures down to .	− 185° C.

It is essential that the bath should be surrounded with a casing containing down packing or asbestos fluff in order to obtain a uniform temperature.

Rudeloff, in 1895, found that iron and steel gave increased yield stress and ultimate stress as the temperature was lowered, while the extension was generally decreased by cooling. Tests made at Watertown Arsenal [8] gave an increase of about 50 per cent in the yield stress and 35 per cent in the ultimate stress over the normal values, when tested at −185° C., but the extension decreased by 63 per cent.

Cast aluminium light alloys show an increase over the normal in ultimate strength of 9 per cent at −80° C., and 27 per cent at −185° C.

§ (119) NOTCHED BAR TESTS AT VARYING TEMPERATURES.—Charpy [9] has shown that, with steel, the work absorbed in the fracture of a notched bar test piece rises as the temperature is increased and reaches a maximum at about 150° C.; it then decreases and passes through a minimum between 400° C. and 500° C., and rises again until red heat is reached.

This work was confirmed by Guillet and Revillon,[1] who gave the temperatures of maximum and minimum resistance to shock as 200° C. and 475° C. They say that there is no particular fragility in a steel broken at blue heat (300 to 325° C.).

Guillet and Revillon carried out their tests on a Guillery 60 Kg.M. machine (see § (100)). The test pieces were heated in an electric furnace to slightly above the temperature required for the test, they were then placed on the anvil and the temperature noted at the time of fracture. The temperature was determined by the use of a thermo-couple inserted in a small hole drilled in the specimen and penetrating up to about 3 mm. from the cross-section to be fractured.

The ends of the test piece were covered with asbestos to prevent the cooling of the extremities when in contact with the anvil. Tests at as close to 100° C. as possible were obtained by heating in boiling water.

Aitchison has shown that with alloy steels the notched bar tests at high temperatures are a reflection of the tensile strength of the steels, being more or less inversely proportional to that property. In all cases the steels gave higher values at elevated temperatures than they did under normal conditions.

§ (120) BALL HARDNESS TESTS AT VARYING TEMPERATURES.—Felix Robin has shown that the curves connecting hardness and temperature are of the same general form as the tensile strength-temperature curves.

Aitchison [2] gives results of hardness tests at high temperatures on tungsten steels of various compositions, ranging from 10 per cent to 18 per cent tungsten, and from 0·2 per cent to 0·7 per cent carbon. Both investigators find a similar regular drop in the hardness as the temperature increases.

In § (88) it is pointed out that a dynamic hardness test is extremely useful for tests at high temperatures. Aitchison notes that his hardness tests were carried out by C. A. Edwards, so that it is probable that the results were obtained by the dynamic method described by Edwards in his paper read before the Institution of Mechanical Engineers.[3]

Hadfield [4] finds that the hardness of steel at the temperature of liquid air ($-185°$ C.) is double that given at normal temperature.

§ (121) ALTERNATING STRESS TESTS AT VARYING TEMPERATURES. — Very little experimental work has been carried out on the effect of high temperatures on the strength of materials under alternating stresses. Unwin [5] conducted some tests at a temperature of 200° C. and found that "the hot bars stood variations of stress rather better than the cold ones."

TABLE 42

NOTCHED BAR TESTS AT LOW TEMPERATURES

Tensile Test of Material at 17½° C.				Charpy Notched Bar Impact Test, on 5 × 5 × 27-mm. Specimens with 45° Vee Notch, 1 mm. deep, and 0·125 mm. Root Radius.		
				Energy absorbed in Fracture in Kg.M.

14	26·1	42·0	61	2·10	0·13	0·10
31	53·1	22·5	44	0·26	0·16	0·19
				Results are the average of five tests.		

Some tests on carbon steels at low temperatures, carried out at the National Physical Laboratory, are given in Table 42.

Tests at the low temperatures on various alloy steels show that, generally, there is an appreciable drop in the energy absorbed in fracture between 17½° C. and −40° C., but that between −40 and −80° C. the drop, if any, is small, and in many cases there is a distinct rise in the value.

Some tests carried out by the author on steel, having a primitive elastic of 21 tons per square inch, ultimate stress of 46 tons per square inch, per cent extension of 26 and per cent reduction of area at fracture of 52, gave the results given in Table 43.

TABLE 43

ALTERNATING STRESS TESTS ON STEEL AT 20° C. AND 250° C.

Range of Stress. Tons/Sq. In.	Alternations before Fracture.	Temperature. ° C.	Remarks.	Limiting Range of Stress. Tons/Sq. In.
+18·2 to −18·2	2,429,400	20	Unbroken	+21 to −21
+19·2 to −19·2	3,299,500	"	"	
+20·9 to −20·9	3,268,400	"	"	
+21·7 to −21·7	1,121,000	"	Broken	
+23·7 to −23·7	3,240,000	"	"	
+24·6 to −24·6	1,996,900	"	"	
+16·5 to −16·5	2,069,000	250	Unbroken	+16·6 to −16·6
+17·0 to −17·0	2,115,600	"	Broken	
+17·2 to −17·2	313,050	"	"	
+18·8 to −18·8	383,750	"	"	

The tests were made in a machine of the Wohler type, the test piece running in an oil-bath heated electrically, and show a reduction of 20 per cent in the limiting range of stress by raising the temperature from 20 to 250° C. They were carried out at a speed of 2000 alternations per minute.

Tests on some rolled aluminium light alloys, by the same method, gave the results in Table 44.

TABLE 44

ALTERNATING STRESS TESTS ON ROLLED ALUMINIUM ALLOYS AT 20° C. AND 150° C.

No.	Ultimate Stress in Static Test. Tons/Sq. In.			Estimated Limiting Range of Alternating Stress in Fatigue. Tons/Sq. In.	
	20° C.	150° C.	200° C.	20° C.	150° C.
A	21·9	. .	. .	+ 6·5 to − 6·5	+5·5 to −5·5
B	26·6	21·1	19·5	+10·5 to −10·5	+7·9 to −7·9
C	28·0	21·5	19·8	+10·2 to −10·2	+5·0 to −5·0
D	24·3	21·4	19·5	+10·2 to −10·2	+8·4 to −8·4
E	22·7	20·3	15·4	+ 9·0 to − 9·0	+6·5 to −6·5

These results show that, whereas the average reduction in static strength by alteration of temperature from 20 to 150° C. is about 17 per cent, the corresponding reduction in the fatigue range is about 30 per cent.

The average limiting elastic range (at 20° C.) for the five alloys (A to E) is about 75 per cent of the static ultimate stress. With steel this value is of the order of 90 per cent.

VIII. TESTS ON MATERIALS OF CONSTRUCTION

§ (122) TESTING OF TIMBER.—Examination of the cross-section of a sawn log of structural timber shows a central pith surrounded by concentric rings which are in turn encircled by the outer bark. Each ring represents the growth of one year in the life of the tree. These annual rings can be roughly divided into two sections, heartwood and sapwood, of which the inner or central portion (heartwood) is usually the stronger in mature trees.

Each annual ring itself consists of two parts, viz. the inner or spring wood and the outer or summer wood, of which the latter is the denser, harder, and stronger. The strength of a piece of timber can therefore be roughly gauged by the proportion of summer wood in the annual rings.

The width of the annual rings indicates the rate of growth of the tree—rapid growth being shown by wide rings—they therefore give useful information as to the uniformity of growth. The rings are usually widest at the centre and become closer near to the bark. Their width and distribution often vary in different trees of the same kind, in various parts of the same tree, and in different parts of the same cross-section.

Timber is usually divided into two classes—hardwood and softwood. The former is derived principally from broad-leaved deciduous trees, while the latter is obtained from evergreen conifers (needle-leaved trees). Exceptions to this classification are yew and long leaf pine, which are hardwoods although coming from conifers, while horse-chestnut, poplar and basswood (broad-leaved trees) are softwoods.

Timber is used by engineers principally for structural purposes, and a knowledge of its behaviour under various conditions of stress is necessary if it is to be used to the best advantage.

(i.) *Density and Specific Gravity.*—The density of timber is largely affected by the percentage of moisture that it contains, by its rate of growth, position in the tree, and percentage of summer wood.

As the density is closely related to the mechanical properties of timber, its determination is of importance. It is usually ascertained by measuring and weighing carefully prepared pieces which, for preference, are made in the form of cubes or prisms. If b, t, and h are the three dimensions of the block in centimetres and W is the weight in grammes,

then the specific gravity $= W/(b \times t \times h)$

and weight per cubic feet $= Wg/(b \times t \times h)$,

where g is the weight of a cubic foot of water in lbs. (62·4).

For comparative results the moisture content must be the same; the density is therefore usually carried out on dried samples. For this purpose they are dried in an oven at 100° C. until of constant weight, and the density calculated from this weight in conjunction with the dimensions (dry).

(ii.) *Percentage of Moisture.*—All the mechanical properties of timber are affected by the moisture content. The strength becomes less as the percentage of moisture increases. A determination of the percentage of moisture is always made from each test piece, and results which do not include this information are valueless.

The determination of the moisture content is made on pieces cut from each sample; in the case of tension, shear, and cleavage tests, these consist of pieces split off adjacent to the failure. From other pieces a disc or cube is taken from as near to the point of fracture as possible.

Discs, etc., are weighed immediately that they are cut; they are then dried in an oven with free circulation, and kept at a constant temperature of 100° C. until they cease to lose weight by further drying. They are then reweighed. The moisture contained is expressed as a percentage of the dry weight of the timber.

If w_w = weight before drying,

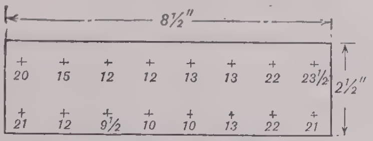
w_d = weight after drying,

percentage of moisture $= 100 \times (w_w - w_d) \div w_d$.

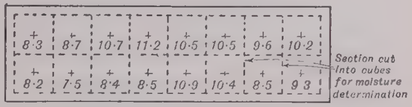
In order to hasten the drying process, the test piece is sometimes cut into small matchsticks or shavings bored from the sample used. If this is done, 12 hours' drying is usually sufficient. Drying at 100° C. will eliminate all except about 2 per cent of the moisture, and this cannot be removed without igniting the sample.

Sections of beams are usually cut into small pieces for a moisture determination of each piece, in order to examine the distribution of moisture throughout the section. The results from such a determination on pieces of spruce and fir are given in *Figs.* 143 and 144.

(iii.) *Rings per inch, per cent of Sapwood, and per cent of Summer Wood.*—These estimations are usually made on the piece cut for percentage of moisture determination. A line, one inch long, is drawn on the cross-section of the disc in a radial direction and passing through a region of average development.

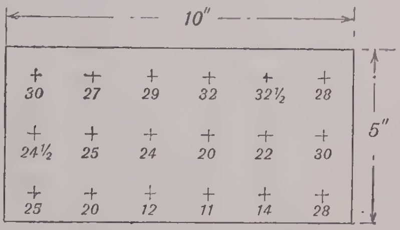


Arrangement and number of annual rings



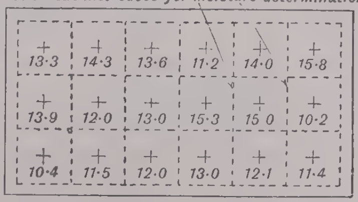
Variation of moisture over the section
Average Moisture = 9·5%

FIG. 143.



Arrangement and number of annual rings.

Section cut into cubes for moisture determination



Variation of moisture over the section
Average Moisture = 12·9%

FIG. 144.

The width of summer wood crossed by this line is obtained by spacing off accumulatively, on a pair of dividers, the width of the summer wood bands for each annual ring in succession. The final distance between the points of the dividers, in hundredths of an inch, is equal to the percentage of summer wood.

The number of rings per inch is obtained by noting the number of annual rings crossed by the measured inch.

The percentage of sapwood is estimated by measuring the amount of the cross-sectional area in which sapwood appears and expressing this as a percentage of the whole area.

§ (123) DRYING TIMBER TEST PIECES.—In order to obtain reliable data from the various tests on timber, the information is usually referred to some standard percentage of moisture. It is considered that timber, if thoroughly dried, will reabsorb 12 to 15 per cent of moisture from the atmosphere. Some experimenters therefore use 12 per cent, but the majority adopt 15 per cent as the standard for comparison. Tests are usually carried out at percentages of moisture above, below, and approximately at the standard, and for this purpose it is necessary to dry samples from the higher to the lower figure.

Two methods of drying are adopted, viz. air drying (or seasoning) and kiln drying, but owing to the long time required for successful air drying, kiln drying is usually resorted to for test work.

An experimental hot-air-drying oven or kiln, which has been successfully used, is shown in *Fig.* 145. The samples are placed on a tray A in a circular vessel B which is heated by a gas burner C, and a current of air is driven through this vessel by a rotary fan D. A complete record of the temperature, which is never allowed to exceed 80° C., is obtained by a recorder which is placed alongside the test samples.

The test pieces are prepared from the samples after drying, and for this purpose the latter are usually left at least ½ in. larger on each of the cross-sectional dimensions and also considerably longer. Before drying in the kiln the percentage moisture is obtained from pieces cut from each end of the sample, and from this information the reduction in weight which is required by the kiln drying in order to reduce the sample to the lower moisture content is calculated. The drying of the test sample is continued until the reduction in weight is obtained.

§ (124) SIZE OF TEST PIECES FOR TESTS ON TIMBER.—Timber tests are divided into two classes :

(1) "Scientific" tests of *small specimens* free from knots or other blemishes and of uniform moisture content.

(2) Tests on *full-size members* of structures—struts, beams, etc., which are not homogeneous and contain serious defects.

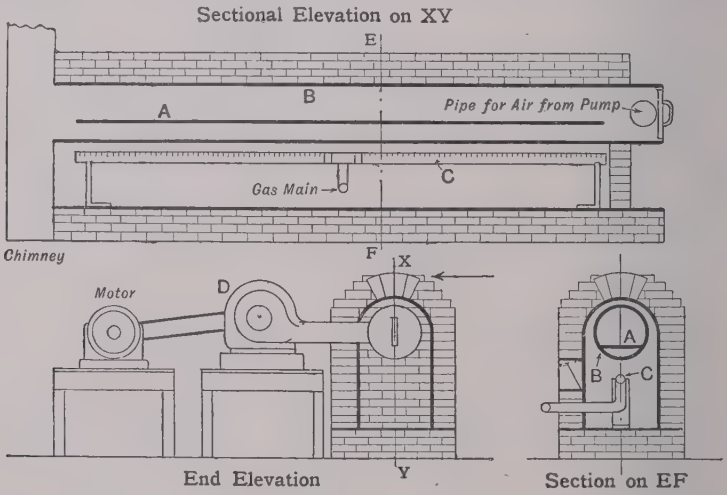


FIG. 145.

Tests are necessary under both conditions. Large sections have the same strength per unit area as small ones when both are of the same proportions and similarly free from defects; but under practical conditions it is found that this law of similarity is not realised, and that tests on small pieces give values for the strength of timber in excess of the strength of large pieces.

§ (125) TENSILE TESTS OF TIMBER.—All comprehensive investigations in regard to the strength of timber include a determination of its tensile strength as it is of scientific importance. The resistance of timber to tensile forces parallel to the grain is greater than under any other kind of loading. In timber structures the tension members are joined at their ends to other parts of the structure, and the weakest point is the joint which is subjected to shear.

It follows that the tensile strength does not govern the strength of the member, and therefore, from a practical point of view, it is of secondary importance.

The heads and shoulders of tensile test pieces have to be very greatly enlarged, otherwise failure takes place either by shearing of the ends along the grain or by crushing of the ends across the grain. The type of test piece adopted is shown in *Fig.* 146. The section to fracture is naturally small in comparison to the ends. Test pieces similar to that shown in the figure, but having the reduced diameter 1·25 inches instead of 0·564 inches, are sometimes used.

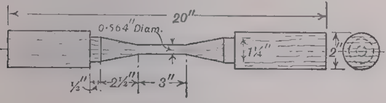

FIG. 146.

§ (126) COMPRESSION TESTS ON TIMBER.—Compression tests along the grain give reliable indications of the quality of samples of timber. Failure usually takes place by shearing along planes inclined about 60 to 75° with the axis, but sometimes by longitudinal splitting. The test pieces (*Fig.* 147) are generally prisms 2 × 2 × 4″ or 3 × 3 × 6″.

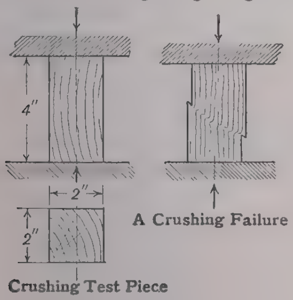

FIG. 147.

For investigatory work it is usual to determine stress-strain diagrams with the aid of a compressometer (§ (34)). These give an initial portion of the curve which is approximately straight, and it is customary from this curve to obtain the modulus of elasticity, and compressive stress at the limit of proportionality. Typical results are given in Table 45.

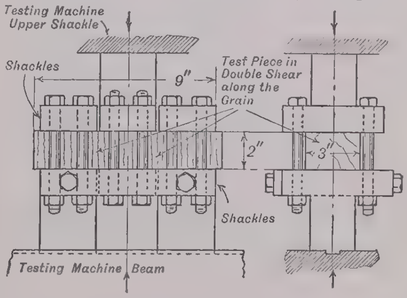
TABLE 45

COMPRESSION (CRUSHING) TESTS ON TIMBER ALONG THE GRAIN

Test Pieces 2 × 2 × 4 inches

Timber.	Rings per Inch.	Moisture. Per cent.	Limit of Proportionality. Lbs./Sq. In.	Crushing Stress. Lbs./Sq. In.	Modulus of Elasticity. Lbs./Sq. In.	Specific Gravity.
Oak (English)	7	24	2770	5300	$0{\cdot}99 \times 10^6$	0·76
	9	11	2530	5410	$0{\cdot}92 \times 10^6$	0·83
Fir (Russian)	18	14	6020	8940	$2{\cdot}60 \times 10^6$	0·74
Spruce (Christiania)	16	12	3200	4600	$1{\cdot}08 \times 10^6$	0·36
Fir (Columbian)	24	12	7200	9990	$3{\cdot}10 \times 10^6$	0·78

§ (127) SHEARING STRENGTH OF TIMBER.—It is generally acknowledged by all authorities that accurate tests of the shearing strength of timber are difficult to make. Two methods have been adopted:



Testing Machine Upper Shackle
Shackles
9″
Test Piece in Double Shear along the Grain
2″
3″
Shackles
Testing Machine Beam

FIG. 148.

(1) With the test piece in double shear as indicated in *Fig.* 148.

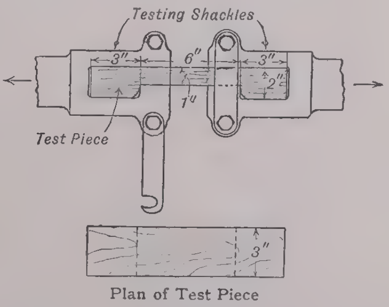


FIG. 149.

(2) With the timber under single shear (*Fig.* 149). This method has been used with success by Warren.[1]

---

[1] *Report of the Department of Forestry N.S.W., Australia*, 1911, on "N.S.W. Hardwood Timbers."

The resistance of various woods to shear across the grain has been determined by Trautwine,[1] whose test pieces were cylindrical pins $\frac{5}{8}$ in. diameter subjected to double shear.

§ (128) Bending Tests.—Bending tests are probably the commonest for timber, because of the great use of wood for rafters, joists, beams, and other parts of structures subjected to bending. Long pieces of fairly large section can be tested without testing machines of big proportions.

Test pieces are usually rectangular, are supported at the ends, and loaded either in the centre or at two points as indicated in *Figs.* 40 and 41 (§ (12)). The latter method (called four-point loading) is now generally preferred, as the maximum bending moment is spread over half of the span and is not limited to the point directly under the application of the load as it is in the central loading method.

A sketch showing the direction of the grain at the ends, and the number of the annual rings, should accompany each test, as well as an indication of the position and mode of fracture. The position and character of any defects such as knots should also be specially noted. Failure may take place by tension, compression, or longitudinal shear along the grain.

For the determination of the limit of proportionality and coefficient of elasticity it is necessary to measure the deflection for known increments of the load. Instruments for doing this are described in § (56).

The strength factor usually measured is the modulus of rupture or coefficient of bending strength. Although a fictitious value, it is, nevertheless, a valuable index of the quality of the timber.

The various values obtained from the test data are calculated in the following way:

If P = Total load at the limit of proportionality,
B = Total load at fracture,
l = Span between the supports,
b = Width of cross-section of the test piece,
h = Depth of the cross-section of the test piece,
d = Measured deflection at the limit of proportionality.

(i.) *For central loading* (deflection measured on length $= l$).

Greatest shearing stress $= 3B/4bh$.
Stress at the proportional limit $= 3Pl/2bh^2$.
Modulus of rupture $= 3Bl/2bh^2$.
Modulus of elasticity $= Pl^3/4bh^3d$.

(ii.) *For four-point loading* (where the distance between the loading points $= L$, and the deflection is measured on length l_1 in the section under uniform bending moment, and l_1 is less than L. B and P are the sum of the two loads at the loading points).

Greatest shearing stress $= 3B/4bh$.
Stress at proportional limit $= 3P(l-L)/2bd^2$.
Modulus of rupture $= 3B(l-L)/2bd^2$.
Modulus of elasticity $= 3P(l-L)l_1^2/8bh^3d$.

Fig. 150 shows typical load deflection diagrams for Christiania spruce and Petersburg fir, while *Fig.* 151 gives the load-extension diagrams in tension and compression for the same materials.

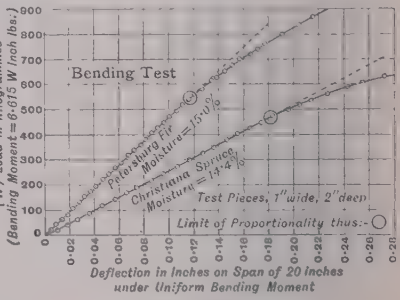

Fig. 150.

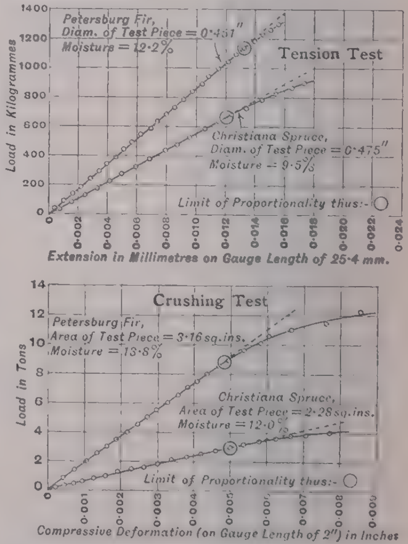

Fig. 151.

§ (129) Toughness Tests.—Toughness is obtained by means of a notched bar impact test in which the energy absorbed by the specimen is measured by the loss of energy in a swinging tup which breaks the material by a single blow. *Fig.* 152 shows the manner in which an Izod testing machine (see § (100)) is utilised to carry out this test, and the form of test piece is given in *Fig.* 153. The test piece is notched with the annular rings as indicated in the sketch, and the top of it, where the tup strikes, is protected by a steel plate.

---

Swinging Tup
2½"
Clamp
Special Vice fixed to Izod Machine

FIG. 152.

Impact Bending Test.—In this test the specimen (2 × 2 × 30″) is supported at the ends on a span of 28 inches. The load is applied by dropping a hammer upon the specimen at mid-span, from an initial height of one inch. For succeeding drops the height is increased by 1-inch increments up to 10 inches, and thereafter drops are made at successive increments of 2 inches, until failure. Hammers of 50, 100, and 250 lbs. are used.

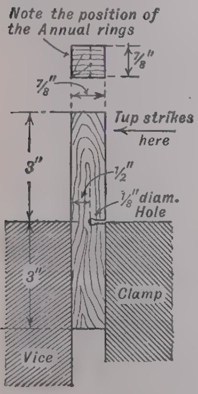

FIG. 153

Deflections of the specimen are measured with each drop, and a curve is drawn connecting height of drop and deflection squared. Deflections are obtained from a drop curve traced on a revolving drum.

If W = weight of the hammer,
H = height of drop at elastic limit,
F = fibre stress at elastic limit,
D = central deflection of specimen at elastic limit,
b = breadth of specimen,
h = height of specimen,
L = span,

then

Fibre stress at elastic limit $= 3\text{WHL}/\text{D}bh^2$.
Modulus of elasticity $= \text{L}^2 \times \text{F}/6\text{D}h$.
Work to elastic limit $= \text{WH}/bh\text{L}$.

§ (130) CLEAVABILITY.—For the resistance to splitting the U.S.A. Department of Agriculture use the test piece indicated in *Fig.* 154, and express the results in pounds per inch of width at fracture. Tests have been carried out to determine the resistance to splitting radially as well as tangentially to the annular rings, and the results (Table 46) show that most hardwoods split more easily along radial planes than along tangential surfaces.

TABLE 46

Kind of Timber.	Cleavage Strength in Pounds per Inch of Width.	
	Radial.	Tangential.
Hardwoods—		
Ash	322	316
Elm	297	357
Oak	370	462
Softwoods—		
Fir	138	149
Hemlock	168	151
Yellow pine	155	173
Spruce	120	139

Splitting is related to tensile strength across the grain. A high value is advantageous for timber which has to be fastened by nails or spikes.

§ (131) HARDNESS TESTS ON TIMBER.—The ball hardness test has been applied to timber in two ways:

(1) The first method, adopted by Warren,[1] follows the Brinell test for metals, viz. a ball of fixed diameter is pressed into the timber under a known load maintained for a stated time. The hardness number is calculated from the formula

$$\text{H} = \frac{\text{P}}{\text{A}},$$

---

[1] *Report of the Department of Forestry, N.S.W., Australia*, 1911, on "N.S.W. Hardwood Timbers."

where H = the hardness number,
P = the load in kilogrammes,
A = the projected area of the indentation ($\pi d^2/4$).

Warren uses a ball of 20 mm., load of 1000 kilos, and time of 2 minutes. He found that the hardness along the fibre is considerably greater than either parallel or perpendicular to the annular rings.

(2) The second method, largely used in the U.S.A., is to press a ball of 0·444 inch diameter into the timber until it has penetrated 0·222 inch. The load required is taken as a measure of the hardness. The test tool is a steel bar with a hemispherical end. This end projects through a hole in the bottom of a cup-shaped washer. When the tool has penetrated the timber to the correct depth there is binding between the steel bar, washer, and specimen. The load at that instant is noted.

With the Ludwik cone test Warren[1] used the standard 90° cone and a pressure of 400 kilogrammes applied for one minute. The depth was measured by an indicator as the test proceeded.

§ (132) RESISTANCE OF TIMBERS TO ABRASION AND WEAR. — Relative wear has been tested by pressing blocks of the material $2 \times 2''$ under a pressure of 26 lbs. against a table covered with fine sandpaper and revolving at 68 revolutions per minute. A better method was used by Warren,[2] who utilised a sand-blast. The test piece, $3 \times 3 \times 1''$, was clamped against a plate having a $2\frac{1}{2}$-inch hole in it, and together with the plate was rotated about its own axis. A jet of superheated steam under a pressure of 43 lbs. per square inch, carrying sand in it, was projected through an expanding nozzle on to the surface of the rotating test piece. The sand-blast wore away the wood on the exposed diameter of $2\frac{1}{2}$ inches, and the loss of weight of the test piece in two minutes' exposure gave a measure of the wearing quality of the wood. Tests were made—

(*a*) Parallel to the direction of the fibre.

(*b*) Perpendicular to the direction of the fibre and perpendicular to the annular rings.

(*c*) Perpendicular to the direction of the fibre and tangential to the annular rings.

The results showed that the wear was least parallel to the direction of fibre, the ratio in the three directions being $a : b : c = 1 : 2\frac{1}{2} : 4$.

§ (133) HOLDING POWER OF NAILS AND SPIKES IN WOOD.—Nails hold in timber by virtue of the friction developed between the surface of the nail and the fibres of the timber. An investigation into the holding power of nails and spikes in Australian timber was carried out by Warren in 1911, who found that Australian timbers were so hard that it was necessary to first bore a hole slightly smaller than the nail in order to prevent either buckling of the nail or splitting of the timber. Six-inch No. 1 S.W.G. smooth steel wire type nails were driven to a depth of $3\frac{1}{2}$ inches in the timber in holes bored to $\frac{9}{32}$-inch diameter. They were withdrawn by pulling in the testing machine, and the loads to pull from various depths were noted. The results showed that the holding power was approximately proportional to the depth, as shown in Table 47.

TABLE 47

HOLDING POWER OF NAILS

Depth driven in Inches.	Mean Load in Pounds.
$1\frac{1}{2}$	1438
2	2201
$2\frac{1}{2}$	2676
3	3158
$3\frac{1}{2}$	3529

For driving spikes, holes slightly smaller than the diameter of the spike must be drilled. Warren found that $\frac{3}{4}$-inch square section twisted spikes required 30 per cent more load to withdraw them than $\frac{3}{4}$-inch square or $\frac{7}{8}$-inch circular black iron straight spikes.

Hatt,[3] experimenting with $\frac{9}{16}$-inch to $\frac{5}{8}$-inch square smooth spikes and screwed spikes pitch $\frac{1}{2}$ inch, root diameter $\frac{11}{16}$ inch, driven in $\frac{11}{16}$-inch holes to a depth of 5 inches, found that the plain spikes had about 55 per cent of the resistance of the screwed ones. Hatt's results agreed with those of Warren in showing that the holding power was proportional to the depth.

§ (134) INFLUENCE OF CONDITIONS OF TESTS UPON RESULTS. (i.) *The Effect of Moisture.*—The effect of moisture on the strength of wood has been thoroughly investigated by Tiemann,[4] and his results, which are fully given by Johnson,[5] show that there is a large increase in crushing strength, modulus of elasticity, and modulus of rupture with a decrease in the moisture content. Table 48 gives the approximate figures for spruce, chestnut, and pine.

(ii.) *Effect of Temperature of Testing.*—The ordinary variations of temperature of the laboratory (15° C. to 25° C.) are not important, but if greater extremes occur it is advisable that the temperature at which the tests are carried out should be controlled. Tests made at Perdue University show an increase in the strength of red oak ties of from 9 per cent to 17 per cent by testing them at 0° C. instead of 20° C.

---

[1] *Report of the Department of Forestry, N.S.W., Australia*, 1911, on "N.S.W. Hardwood Timbers."

[2] *Ibid.*

[3] *Bull.* No. 124, *Am. Ry. Engr. Assn.*

[4] *Bull.* 70, *U.S.A. Forest Service*, 1906, and *Circular* No. 108, 1907.

[5] *Materials of Construction*, 1918 ed., p. 195.

(iii.) *Effect of Speed of Testing.*—Thurston[1] found that 60 per cent of the breaking load given by progressive loading on the ordinary testing machine would break beams if left in place for nine months. Experimenting on the same subject, Johnson[2] determined that it was not safe to assume that the permanent load which timber would carry was greater than 50 per cent of the short time ultimate load as ordinarily found by the testing machine.

TABLE 48

EFFECT ON TEST RESULTS OF VARYING MOISTURE CONTENT

Material.	Per cent Increase in Value by drying from 20 per cent to 10 per cent of Moisture.		
	Crushing Strength.	Modulus of Elasticity.	Modulus of Rupture.
Eastern spruce	62	14	52
Chestnut	59	25	44
Longleaf pine	89	21	47

It is evident, therefore, that the influence of time must be allowed for in testing wood. As a result of work by Tiemann,[3] the U.S.A. Forest Service of Agriculture have standardised fibre strain in testing, *e.g.*:

	Per Minute per Inch.
Bending tests on timber of structural size	0·0007″
Bending tests on small beams . . .	0·0015″
Compression parallel to grain, large test pieces	0·0015″
Compression parallel to grain, small test pieces	0·0030″
Shearing along the grain	0·0150″

The strength of wet or green wood is much more sensitive to changes of speed than is dry wood. A change of the above speeds by 50 per cent may ordinarily be allowed without causing a variation in strength of over 2 per cent.

The modulus of elasticity in bending was found to be practically constant with change of speed.

§ (135) TESTING OF STONE, BRICK, AND CONCRETE.—The important characteristics of stones and bricks from an engineer's standpoint are ease of working, durability, and strength. Durability depends on resistance to

(*a*) Abrasion or attrition.
(*b*) Absorption of water.
(*c*) Alternate freezing and thawing.
(*d*) Fire.
(*e*) Acid.

Stones and bricks are subjected in practice to compression, sometimes to transverse stress and shearing, but not to tension except such as would be caused by wind pressure or other lateral forces. Besides resistance to these forces the specific gravity is an important property. For a given stone the specific gravity and strength increase concurrently, while for some purposes greater stability is given by higher specific gravity.

With concrete, a knowledge of its elastic constants and tensile strength, of its resistance to fatigue and permeability to water, are requisite for the purposes of design.

(i.) *Determination of Specific Gravity.* — In order to determine the specific gravity (including the pores) the sample is dried at 100° C. until it is of constant weight, and, when cool, coated with a thin film of paraffin wax and weighed in air and water.

If W_a = weight in air,
and W_w = weight in water,
the specific gravity $= W_a/(W_a - W_w)$.

A correction for the film of paraffin wax can be made if the results are required to a high degree of accuracy.

The true specific gravity of the stone substance is obtained by grinding the dry stone to a powder and determining the specific gravity of the powder with a standardised Le Chatelier apparatus or similar form of specific gravity apparatus.

The porosity of the material can be obtained by making both the above determinations.

Then if S_s = specific gravity of the stone substance, and the other values are as before:

$(W_a - W_w)$/Weight of a cubic unit of water = Volume of the stone + pores = A.

W_a/(Weight of a cubic unit of water $\times S_s$) = Volume of the stone substance = B.

Then the porosity = (A – B)/A.

(ii.) *Absorption of Water.*—The usual method of obtaining the amount of water which stone, brick, or concrete will absorb is to immerse the specimen in water at approximately 20° C. after it has been dried at 100° C., cooled, and weighed. The immersion is continued for three days, when the surface water is removed and the material is reweighed. The increase in weight divided by the original weight and multiplied by 100 gives the percentage absorption. The process is sometimes hastened by eliminating the long period of soaking and immersing the test piece in water which is slowly raised to boiling-point and kept at that temperature for five hours.

A slight modification is sometimes introduced by weighing the specimen in air (W_a), in water immediately after immersion (W_w), and also in water after three days' immersion

---

[1] *Materials of Construction*, part ii.
[2] *Ibid.*, 1918 ed., p. 208.
[3] *Amer. Soc. Test. Mat. Proc.*, 1918, viii. 541.

(W^1_w). Then the absorption in pounds of water per cubic foot of material

$$=\frac{W^1_w - W_w}{W_a - W_w} \times 62{\cdot}37.$$

(iii.) *Alternate Freezing and Thawing.*—This test is made by subjecting the specimen to a temperature of −10° C. to −20° C. for at least four hours after it has been thoroughly saturated with water. It is usual to apply ten alternate freezings and thawings, and then employ the master test of crushing.

(iv.) *Abrasion and Attrition.*—Bauschinger[1] devised an abrasion test for stone which consisted in pressing a 4-inch cube of the material, under pressure of 4 lbs. per square inch, against an iron plate rotating at 20 revolutions per minute. The test pieces were fixed at a radius of 19½ inches, and the abrasive employed was fine emery (No. 3) fed on to the plate at the rate of 2 grammes per revolution.

This test does not differ greatly from the Dorry test for road stones.

The sand-blast test was used by Gary[2] as an additional abrasion test for stone. He gave comparative results by the two methods, together with the crushing strength; these are given in Table 49.

TABLE 49

RESULTS OF ABRASION TESTS ON BUILDING STONES BY GARY

Area of Specimens used on Grinding Table = 7·75 sq. in.

Granite . . .	21,360	0·041	0·037	0·052
Gneiss . . .	21,230	0·079	0·056	0·045
Porphyry . . .	17,840	0·068	0·046	0·036
Graywacke* . .	15,780	0·085	0·059	0·058
Sandstone . .	6,640	0·144	0·155	0·117
Slate . . .	7,480	0·234	0·111	0·082

* A dense sandstone containing rounded or angular particles of quartz, felspar, or slate.

A "rattler" test is used in the U.S.A. for paving brick, and the conditions of the test have been standardised.[3] It consists in placing ten samples of the material in a cylinder together with an abrasive charge consisting of 20 cast-iron spheres of two sizes. The loss in weight is calculated as a percentage of the initial weight of the samples. This test is somewhat similar to the Deval Attrition Test or Lovegrove Rattler Test for road stones.

(v.) *Crushing Tests.*—The crushing strength is usually accepted as being the criterion of the mechanical qualities of brittle materials such as stone, brick, and concrete.

In carrying out this test the kind of bedding employed has a great influence on the results. Unwin[4] has shown that fluidity of the bedding produces vertical splitting of the test piece and a considerable reduction of the crushing strength. The common practice of putting wood or lead layers in between the test piece and the testing-machine compression blocks, in order to allow for irregularities in the surface of the specimen and to distribute the pressure over that surface, is erroneous. In order to obtain plane parallel faces, Unwin's method of applying thin layers of plaster of Paris has been used by the author for a considerable number of tests without obtaining any unsatisfactory fractures.

The information obtained from the test is the stress at which the first crack appears and the ultimate crushing stress. It is essential that the load should be applied axially, and the compression blocks are usually supplied with spherical seatings (see § (12)).

From the character of the final breakdown and shape of the fragments it can be determined whether the load was applied correctly. Photographs of broken concrete test pieces, showing the shearing angles of 45°, which are obtained with the crushing of brittle materials, are given in *Fig.* 155.

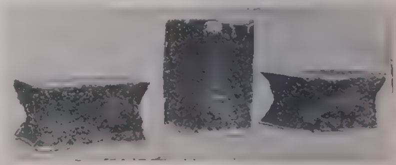

FIG. 155.

[3] Standard Specification for Paving Brick of the American Society for Testing Materials. Serial Designation = C7-15.

[4] *Report of British Association*, 1887, p. 879.

For geometrically similar test pieces the crushing strength is proportional to the cross-sectional area. Within the limits where bending occurs, the crushing strength becomes less as the height of the test pieces increases. For prisms and cylinders of the same height and cross-sectional area the crushing strength squared is inversely proportional to the circumference of the test piece.

The compressive strength of concrete is reduced, by an excess of water during mixing, to a fractional part of that which it would reach under proper conditions (see Table 50).

TABLE 50

EFFECT OF PERCENTAGE OF WATER ON THE CRUSHING STRENGTH OF CONCRETE

(From *U.S. Survey Bull.*, No. 344.)

Percentage of Water.	Concrete 1 : 2 : 4 by Volume ; Strength in Lbs./Sq. In.			
	Crushing.		Modulus of Rupture (Bending).	
	1 Month.	6 Months.	1 Month.	6 Months.
9·8	2299	3814	391	435
9·0	3547	4808	451	520
7·9	4612	4884	426	496

Crushing test pieces of building stone are usually in the form of cubes of 4-inch sides; for concrete, cubes of from 7- to 10-inch sides are employed; while bricks are generally tested on the flat. The dimensions of the test pieces and, with bricks, direction of crushing are always given with the results.

Representative crushing, bending, and absorption results on stone and brick are given in Table 51.

TABLE 51

STRENGTH OF STONE AND BRICK

§ (136) THE ELASTIC PROPERTIES OF STONE, BRICK, AND CONCRETE.—It has been shown that a linear relation is often not obtained between stress and strain for stone, brick, and concrete (§ (64)), and that for the latter empyrical moduli are used for the purposes of design calculation.

Stanton Walker[1] gives the following particulars of the manner in which different variables affect the strength and modulus of elasticity of concrete :

"(*a*) Both the modulus of elasticity and strength increase within certain limits as the aggregate becomes coarser, although the modulus of elasticity increases less rapidly than the strength.

"(*b*) An increase in the quantity of cement in the batch causes an increase in values of modulus of elasticity and strength. The modulus of elasticity is affected somewhat less by change in the cement content than the strength.

"(*c*) The quantity of mixing water exerts a most marked effect on the modulus of elasticity and strength. An addition of 25 per cent of water to a mixture of normal consistency decreases the modulus of elasticity about 15 to 20 per cent, and the strength about 35 to 40 per cent.

"(*d*) Both the modulus of elasticity and strength increase with the age of the concrete so long as the specimens are kept moist during curing. The strength increases in proportion to logarithms of the age. The modulus of elasticity follows approximately the same relation.

"(*e*) There is no marked difference in the modulus of elasticity and strength of concrete made from high-grade pebbles, crushed limestone, crushed granite, or blast furnace slag.

[1] *Amer. Soc. Test. Mat. Proc.*, 1919, p. 584.

"(*f*) A comparison of specimens stored 14 days in damp sand and 77 days in air with specimens stored 91 days in damp sand shows that the modulus of elasticity and strength are higher for the damp sand storage.

"(*g*) Tests for mixing times ranging from ¾ to 10 minutes show both the modulus of elasticity and strength to be greater for the longer mixing times."

§ (137) TENSILE STRENGTH OF CONCRETE.—Considerable difficulty is experienced in designing suitable end attachments for tensile tests on concrete. Many experimenters cast spherically headed bolts in the centre of the ends of the test piece and pull on these heads by the testing-machine grips; others enlarge the ends so as to form the test piece into a flat dumb-bell shape. Particulars of a few dimensions which have been adopted are given in Table 52.

The tensile strength of concrete is about one-eighth to one-tenth of the crushing strength.

TABLE 52

PARTICULARS OF TENSILE AND COMPRESSION TEST PIECES FOR CONCRETE

Authority.	Tensile Test Piece.	Crushing Test Piece.

§ (138) SHEAR STRENGTH OF CONCRETE.—The shear strength of concrete lies between 0·4 and 0·6 of the crushing strength. The shear testing tool is of the same form as that used for metals (§ (12)), but is specially arranged to take a larger test piece. The test pieces are generally cast 5 or 6 inches in diameter and 14 to 18 inches in length, and are tested in either single or double shear.

§ (139) TRANSVERSE STRENGTH OF CONCRETE.—No definite size has been standardised for beams for transverse tests. Withey[1] used beams 6″ × 6″ loaded centrally on a span of 36 inches. The results he obtained on 1 : 2 : 4 concrete, mixed by volume, are given in Table 53.

TABLE 53

	1 : 2 : 4 Concrete—Age 1 Month. Average of 25 to 27 Tests.
Tensile strength—lbs./sq. in. (S_t)	189
Compressive strength—lbs./sq. in. (S_c)	1940
Modulus of rupture—lbs./sq. in. (S_b)	352

$$S_b = 0{\cdot}18S_c = 1{\cdot}86S_t.$$

§ (140) INCREASE OF STRENGTH OF CONCRETE WITH AGE.—The average percentage of strength of concrete at different ages, assuming full strength at one year, is given in Table 54. There is no reliable data for strength of concrete more than two years old.

§ (141) EFFECT OF VIBRATION, JIGGING, AND PRESSURE ON THE STRENGTH OF CONCRETE.—Vibration and jigging methods are useful for getting concrete into place around reinforcing bars and in intricate forms, but do no good, and in some cases are harmful, if applied after the concrete is properly placed in position.

Abrams[2] finds that the vibration of an electric hammer has very little influence on the strength of puddled concrete when applied for periods not exceeding 30 seconds. If a greater time of vibration is employed, there is a steady falling-off in strength. After 45 to 60 seconds the strength is only 90 per cent of that given by the standard method of puddling.

TABLE 54

Age.	Percentage of Full Strength.
7 days	30
1 month	60
2 months	75
3 ,,	85
4 ,,	90
6 ,,	95
9 ,,	98
12 ,,	100

If pressure is applied to concrete after moulding, water is expelled and a drier concrete is produced. This gives increased strength.

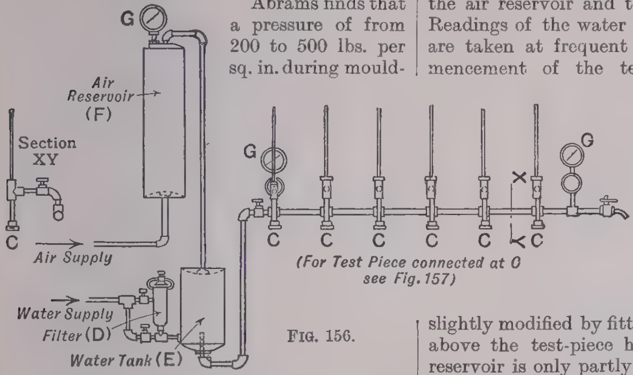
[2] "Effect of Vibration, Jigging, and Pressure on Fresh Concrete," Structural Materials Research Laboratory, Chicago, 1919, *Bulletin* No. 3.

Abrams finds that a pressure of from 200 to 500 lbs. per sq. in. during moulding increases the compressive strength by 20 to 35 per cent.



(For Test Piece connected at C see Fig. 157)

FIG. 156.

§ (142) PERMEABILITY OF CONCRETE AND MORTAR.—Permeability depends upon minute passage ways in the material which are so connected that water can flow right through. Tests under high heads of water have been made, and show that even cement paste is not absolutely impervious. Concrete and mortar can, nevertheless, be made which, under normal pressures, do not show any dampness on the outside.

Two methods of test are employed:

(1) The amount of water passing through the material is collected and weighed.

(2) The weight of water, which has to be supplied in order to keep a constant head, is measured (*i.e.* the water going into the test piece).

The arrangement of a suitable apparatus for Method 1 is given in *Fig.* 156, and a section of the test piece, together with the can for catching the water, in *Fig.* 157.

The test piece (7½ inches diameter) has annular spaces at the outer edges of both the top and bottom surface painted with a rubber waterproofing paint. This leaves an annular piece 5 inches diameter in the original condition. Rubber washers A, A are placed over the waterproofing, and the specimen is securely clamped between the two cast-iron plates P, P.

The water is applied to the top of the test piece through the pipe C, and any water passing through is caught in the can B. The specimen is soaked in water for 48 hours immediately before the test.

The arrangement (*Fig.* 156) permits of six tests being carried out at once. Each test piece with its holder is attached to a union C. The water passes through a filter D and tank E before reaching the specimen. Air pressure is supplied to the tank E by a compressor, an air reservoir F being inserted to equalise the pressure. Three gauges G are provided for reading the pressure—one on the air reservoir and two on the water pipe. Readings of the water collected in the can A are taken at frequent intervals at the commencement of the test; but the rate of percolation of water diminishes as the test proceeds, and the intervals between the readings can be reduced until it becomes constant.

In order to measure the water supplied (Method 2), the arrangement is slightly modified by fitting a water reservoir K above the test-piece holder (*Fig.* 158). This reservoir is only partly full of water, and the pressure is applied to the top of the water by the compressed air. The amount of water added at regular intervals, to keep the level constant in the gauge glass H, is recorded.

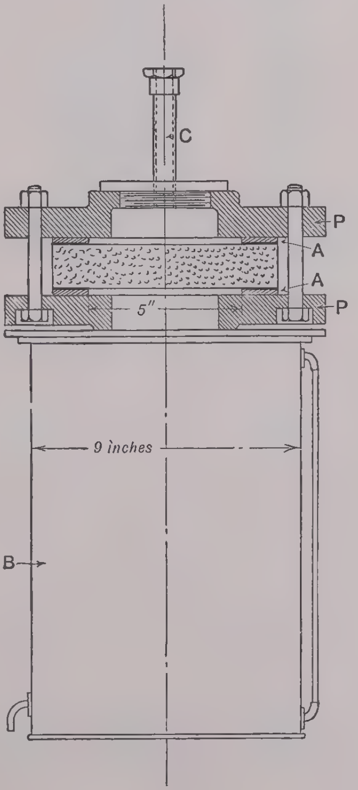


FIG. 157.

With an investigation carried out at the N.P.L. on the permeability of reinforced concrete under a pressure of 8·7 lbs. per square inch, air pressure was replaced by an actual head of water of 20 feet, which was kept constant by adding water to a reservoir as described for the last experiment.

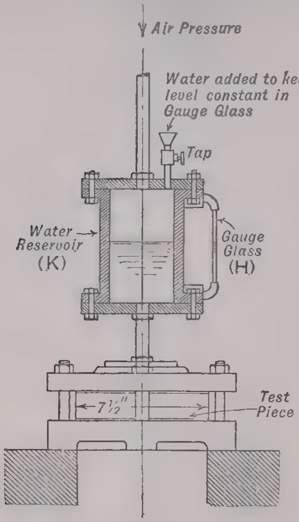

FIG. 158.

§ (143) TESTING ROAD MATERIALS.—There are two methods of estimating the comparative value of materials for road construction. The first is to lay sections of a road with the materials which are to be compared and observe the effect of traffic on them, and the second is to subject the road materials to laboratory tests designed to imitate actual conditions met with on the road. The former method, with great care, will give results, but the process is long and costly. The use of some form of experimental road sections is, however, the only thorough method of testing asphalt carpets. Observations of the behaviour of macadam roads, constructed with rocks whose physical characteristics have been determined by laboratory tests, enables these tests to be used in order to judge the probable adaptability of any rock for use in road construction.

A determination of the relative road-building qualities of different types of rock was first systematically attempted in France. The French School of Bridges and Roads installed a road materials laboratory in 1878, and it was there that the Deval[1] Attrition Machine was designed, and its excellence has led to its general adoption as a standard testing machine.

The testing of road metal was initiated in Germany in 1884 at the first Munich Conference for Establishing Uniform Conditions of Testing. They appointed a committee to draft the methods of testing that were necessary, the work performed by this committee was reported to conferences held in 1886, 1890, and 1893, and definite proposals for testing, including the Deval test, were submitted and approved.

In 1893 Massachusetts Highway Commission[2] founded a laboratory for testing road materials in the Lawrence Scientific School of Harvard University. In 1900 the United States Government, because of the growing importance of road-material investigations, established a laboratory in the Bureau of Chemistry of the Department of Agriculture. This laboratory, transferred in 1905 to the Office of Public Roads, examines, without charge, samples of road material submitted by any citizen of the United States.

The only stone-testing appliance believed to be in existence in England prior to 1911 was the "Rattler" attrition machine, designed and used by E. J. Lovegrove,[3] Borough Engineer and Surveyor of Hornsey.

In 1911 a road laboratory was inaugurated as a division of the Engineering Department of the N.P.L., Teddington, in accordance with a scheme drawn up by the Road Board and approved by the Treasury. The work of the Road Board has now been taken over by the Ministry of Transport (Roads Department).

In order to preserve continuity with the work which has been in progress in other countries, standard types of machines, as used by the United States Office of Public Roads, were adopted.

§ (144) ATTRITION TEST.—The machine used for this test is of the four-cylinder Deval type, which has given satisfactory results in France since 1878. It is shown in *Fig.* 159, and consists essentially of four cylinders, 7½ in. in diameter and 14 in. long, mounted on

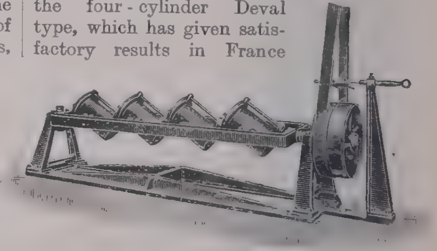

FIG. 159.

[3] Lovegrove, Flett, and Howe, *Road-making Stones, Attrition Tests in the Light of Petrology*.

a frame in such a way that their axes are inclined at 30° to the axis of rotation.

Eleven pounds of rock, numbering as nearly fifty pieces as possible, are placed in one of the cylinders, the cover bolted on, and the machine revolved 10,000 times at a rate of about 30 revolutions per minute. The dimensions of the stones should be such that every stone will pass through a $2\frac{1}{2}$-in. ring but will fail to pass through a 2-in. ring. Only the material worn off which will pass a sieve of $\frac{1}{16}$-in. mesh is considered in determining the amount of wear. This amount is expressed as a percentage of the 11 lbs. used. In addition the French coefficient which is in general use is calculated. This is defined by the relation

$$\text{French coefficient of wear} = \frac{40}{\text{Percentage of wear}}.$$

A wet test is also made, and for this purpose 1·1 gallon of water is placed with the 11 lbs. of stone. With the majority of stones it is found that there is more wear under a wet test than under the dry test, but occasionally the reverse is the case.

An approximate relation has been established between this machine and Lovegrove's Hornsey Rattler.

§ (145) REPEATED BLOW IMPACT (TOUGHNESS TEST). (i.) *Preparation of Specimen.*—The specimen is prepared in the form of a cylinder 1 in. diameter by 1 in. long. A piece of the rock is roughly chiselled to size $1\frac{1}{4}'' \times 1\frac{1}{4}'' \times 3''$. It is ground approximately cylindrical on a large crystolon wheel, and then placed in the chuck of a grinding machine, where it is ground by a small crystolon wheel to exactly 1 in. in diameter. The chuck and stone are then taken to the diamond saw (*Fig.* 160), where the specimen is cut off 1 in. in length.

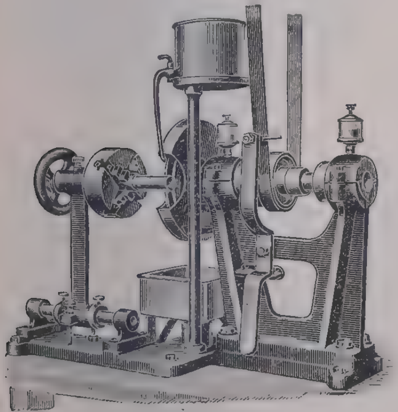

FIG. 160.

(ii.) *The Testing Machine.*—The machine used for this test is known as the Page Impact Machine (*Fig.* 161). The blow is given by a 4·4-lb. hammer H, and acts through a plunger P whose surface of contact with the specimen is spherical, and has a radius of 0·4 in. The blow, as thus delivered, approximates to the blows of traffic, and the spherical end has the further advantage of not requiring great exactness in getting the two bearing surfaces of the test piece parallel; the entire load being applied, at one point, on the upper surface. The test consists of a 0·4 in. fall of the hammer for the first blow, and an increased fall of 0·4 in. for each succeeding blow, until failure of the specimen occurs. The number of blows required to destroy the test piece is used to represent the toughness.

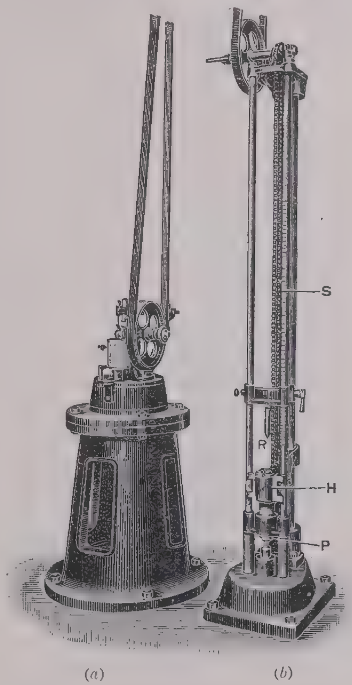

FIG. 161.—(*a*) Repeated Impact Machine for Cementation Tests. (*b*) Page Impact Machine.

A sprocket chain S driven from the shafting is supported on sprocket wheels attached to castings at the top and near to the base of the machine. The chain is provided with small lugs which engage a spring bolt attachment projecting inwards from the top of the hammer. This raises the hammer until it is tripped by a rod R projecting downwards from a crosshead which slides on two rods connecting the upper and lower castings. The crosshead is raised automatically through 0·4 in. after every blow by a lead screw driven by a worm and worm-wheel attached to the same shaft as the upper sprocket wheel. By throwing the lead screw out of gear with the crosshead the latter can be raised or lowered through any desired height or the test can be made with a constant height of fall.

A slightly different method of preparing the test sample is sometimes employed, viz. by the use of a core drill. This consists of a brass core tube having at its lower end a steel ring containing eight small diamonds in its cutting edge, four on the outer edge, and four on the inner edge. The drill arranged to cut a rock core 1 in. diameter runs at 200 to 300 revolutions per minute. Water is supplied to the inside of the drill and the specimen, through a stationary brass ring by a rubber tube connection.

§ (146) Abrasion Test.—The specimen is prepared in the same manner as that for the repeated blow impact test, and in cases where both tests are required the specimens can usually be both cut from the same sample.

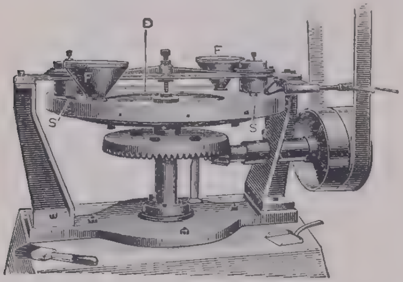

Fig. 162.

The machine used (sometimes called a Hardness Machine) is of the "Dorry" type (*Fig.* 162), and consists of a circular cast steel disc D which revolves in a horizontal plane about a vertical shaft. The specimen S is held with its axis vertical and its lower end pressed with a force of 3·5 lbs. per square inch against the surface of the disc. Standard stand, 30 to 40 mesh, is fed continuously upon the disc through funnels F, and it is important that an even and constant supply of the abrading material should be fed to each sample tested. After 1000 revolutions of the grinding disc, revolving at the rate of about 28 revolutions per minute, the loss of weight of the specimen is found. The test is repeated with the specimen reversed, and the average loss of weight computed from the two runs is used in determining the hardness.

This is given by $H = 20 - \frac{1}{3}W$, where H is the hardness number or coefficient of wear and W is the loss in grammes per 1000 revolutions.

§ (147) Cementation Test.—The cementing value of a rock dust measures the ability of that dust to hold the individual particles together to form a firm impervious road surface.

The processes involved in making a test of the cementation value of a rock are as follows:

(i.) Grinding up a mixture of the rock, coarsely crushed, and water into a stiff paste in a ball mill.

(ii.) Forming briquettes from this paste in a mould under pressure, which are dried after 24 hours.

(iii.) Subjecting each briquette to repeated blows with a small hammer, and measuring automatically the recoil of the hammer after each blow.

(i.) *Ball Mill* (*Fig.* 163).—1·1 lb. of coarsely crushed rock and 0·02 gallon of water are placed in the mill together with two steel shots each 5·1 in. in diameter. The samples are ground in this mill for 2½ hours, the mill revolving at the rate of 2000 revolutions per hour. The resulting paste is then ready to be moulded into briquettes.

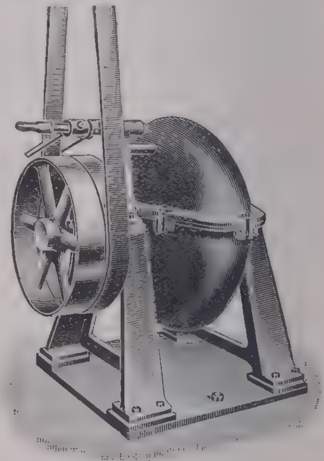

Fig. 163.

(ii.) *Briquette Machine* (*Fig.* 164).—The paste is placed in a mould M and a cylindrical plug P screwed upon it. The mould is in contact with the short arm of a weighted beam W, so that the pressure can be regulated to give a maximum value of 1880 lbs. per square inch. The size of the briquette is 1 in. diameter and 1 in. long.

(iii.) *Repeated Impact Machine* (*Fig.* 165).—After drying for 20 hours in air and 4 hours in a hot-air bath at 200° F., the briquette is allowed to cool for twenty minutes in a desiccator; it is then placed on the anvil of the machine with its axis vertical. A small hammer H is operated by a cam C, so that the effective drop is always 0·4 in., and the force of the blow is transmitted to the specimen S by means of a plunger P working in a vertical guide. This plunger is also connected to the arm of a lever, the other end of which carries a pencil L in contact with paper on a revolving drum, so that any rebound of the plunger after the blow is indicated on the paper. In this way a diagram is obtained which will give the number of blows after which there is no rebound of the plunger, *i.e.* after which the resilience of the specimen is destroyed. Six specimens are made from each sample, and the average result is taken as a measure of the cementing value of the material.

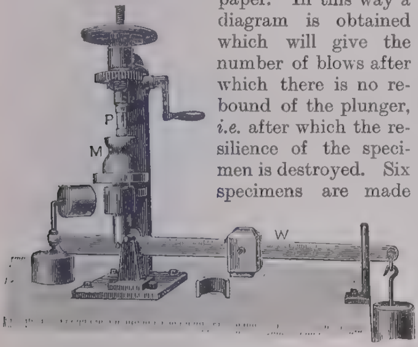

FIG. 164.

Table 55 gives the interpretation of the results from the physical tests on road stones.

§ (148) PETROLOGICAL AND GEOLOGICAL CHARACTERISTICS.—Thin sections are cut from the stone and examined under the microscope to ascertain the nature, quantity, and dimensions of the components which form the stone and determine the correct petrological designation of the material.

TABLE 55

INTERPRETATION OF THE PHYSICAL TESTS ON ROAD STONES

	Attrition Test. Per cent of Wear.		Impact Test. No. of Blows for Failure.	Abrasion Test. Coefficient of Wear.	Cementation Value. No. of Blows for Failure.	Absorption of Water. Lbs./Cubic Ft.	Crushing Strength. Lbs./Sq. In.
	Dry.	Wet.					
Very good . .	2 and under	2 and under	19 and over	19 and over	Over 100	0·10 and under	Over 20000
Good	2·1-2·5	2·1-3·1	16-18	17-18·9	76-100	0·11-0·40	15000-20000
Fairly good .	2·6-3·1	3·2-4·0	13-15	16-16·9	26-75	0·41-1·00	10000-15000
Rather poor .	3·2-4·0	4·1-5·0	8-12	15-15·9	10-25	1·01-3·00	5000-10000
Very poor . .	Over 4·0	Over 5·0	Under 8	Under 15	Under 10	Over 3·00	Under 5000

§ (149) FURTHER TESTS.—Specific gravity, absorption of water, crushing, sand-blast abrasion, and paving-brick rattler tests are carried out in the manner previously described for stones, bricks, and concrete in § (135). It is usual, however, when dealing with road stones, to make the crushing tests on cylinders 1 in. or 2 in. diameter with the length equal to the diameter. The crushing test pieces, when 1 in. diameter, are identical with those for impact and abrasion tests, and can be made with the same apparatus.

§ (150) ENDURANCE TESTS ON MODEL ROADS.—It was recognised that in the case of the various test trial roads laid down in this country, such as those at Sidcup, the best method of road construction would not show measurable wear or deformation until after years of heavy traffic. At the suggestion of Col. Crompton, Consulting Engineer to the Road Board, a model road-testing machine was designed at the National Physical Laboratory in order to provide a more rapid method of comparing the efficiency of methods of construction. This design was approved by the Road Board, and its construction was commenced in 1912, the first run taking place in 1913. The machine (*Fig.* 166) consists of a circular track 30 in. wide, having a mean diameter of 34 feet. The endurance of the centre 24 in. of this track is tested by the rolling on it of eight steel-tyred wheels, 3 in. wide and 39 in. diameter. The wheels are at an angular distance of 45° from each other, and each wheel is rotated by a separate electric motor mounted on a steel arm which

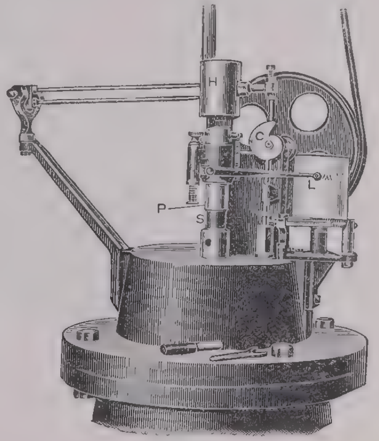

FIG. 165.

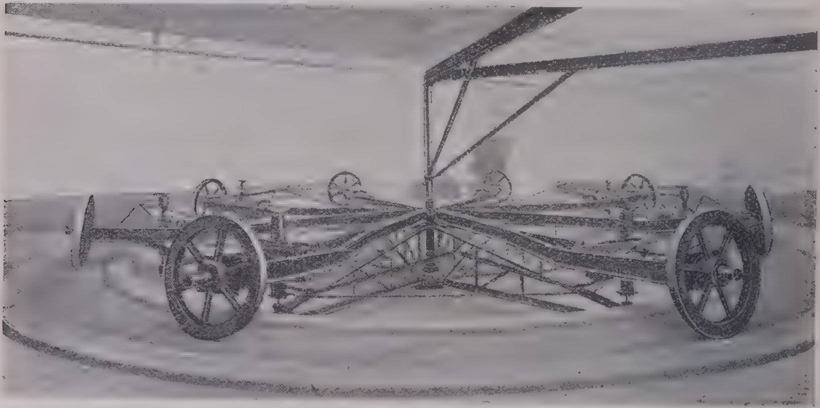

FIG. 166.

revolves round a centre post. The radial distribution of the wheels is such that the whole width of 24 in. is covered in one revolution of the arms, and in order to prevent, as far as possible, the formation of ruts in the tested surface each wheel is moved backwards and forwards radially by a cam mechanism through a distance of 1 in. The eight arms are all hinged to a rotating boss on the centre post, and at their outer ends are connected by spiral springs to eight corresponding cantilevers rigidly fixed to a second rotating boss connected with the former and immediately below it. The pressure of each wheel on the track can be adjusted to any desired value up to one ton.

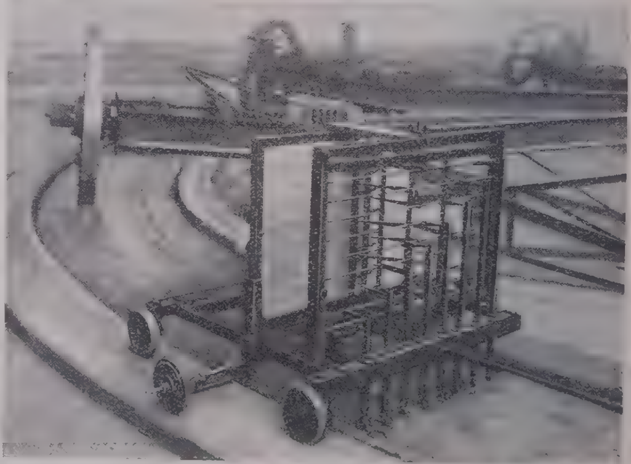

FIG. 167.

In order to investigate the question of the formation of waves a special apparatus (*Fig.* 167) has been constructed for drawing cross-sections of the road at different points round the track and longitudinal sections at the centre of the tracks of the eight rotating test wheels. Plaster casts are also taken to obtain a permanent record of the appearance of the road at various stages during the test.

It has been found that a road becomes too bad for use in three ways:

(i.) By excessive wave formation.

(ii.) By disintegration.

(iii.) By a combination of disintegration and excessive wave formation.

The formation of waves is increased by the road being subjected to heavy traffic after insufficient or unequal consolidation, while disintegration occurs rapidly with change of climatic conditions, if the road consists partly of small or large stones, when these stones are brought to the surface by deformation or wear.

A summary of the more important tests carried out with this apparatus is given in the Sixth Annual Report of the Road Board (1916).

§ (151) BITUMINOUS MATERIALS. — The physical character of bituminous binders and aggregates is determined by microsections, penetrometer and viscosimeter determinations, quantity and quality of the contained bitumen (whether natural or artificial), and the physical and chemical examination of the residue.

§ (152) LIMES AND CEMENTS.—The cementing materials ordinarily used in engineering construction are classified as follows :

(i.) Gypsum plasters.

(ii.) Limes—quicklime, hydrated lime, hydraulic lime.

(iii.) Cements (hydraulic).

§ (153) GYPSUM PLASTERS.—In plaster of Paris, Keene's cement, stucco, etc., the essential constituent is gypsum in a more or less dehydrated state.

Gypsum in its native state is crushed and ground, and then calcined at a temperature of 200° C. The product is then finely ground and screened.

Plaster of Paris is produced when the gypsum is not completely dehydrated. The theoretical composition of gypsum is $CaSO_4 + 2H_2O$ (a hydrous calcium sulphate). Plaster of Paris has the approximate composition of $CaSO_4 + 0{\cdot}5H_2O$. The specific gravity of gypsum is 2·3, of plaster of Paris 2·57, and of completely dehydrated gypsum 2·95.

Keene's cement is practically pure calcium sulphate with a small percentage of calcium carbonate ($CaCO_3$). For the manufacture of this cement the gypsum is procured in as pure a state as possible, and the resulting product is of an exceptionally pure white colour. The small percentage of $CaCO_3$ is introduced by dipping the calcined gypsum into a solution of alum and then burning again. The introduction of this "impurity" produces a slow setting cement which ultimately becomes very hard.

Cement plaster and stucco are calcium sulphates with adulterants which retard setting and increase plasticity.

§ (154) LIMES.—Pure lime (quicklime) is produced by the calcination of nearly pure limestone, at a temperature of about 500° C., in some form of vertical kiln. By this process the carbon dioxide is driven off from the calcium carbonate ($CaO + CO_2 = CaCO_3$). Such limes slake violently on the addition of water, form calcium hydroxide ($Ca(OH)_2$), and increase in volume by about 300 per cent. They harden slowly by absorbing carbon dioxide from the air.

Poor limes have a high percentage of magnesia and slake more slowly.

Owing to the fact that quicklime is insufficiently slaked or mixed in many cases when this is done on the job, this process is sometimes carried out in especially designed and equipped plant, where the operations are conducted more efficiently and with the minimum quantity of water. The resulting product is thoroughly screened and ground and is known as hydrated lime.

Pure hydrated lime should have a specific gravity of 2·08. It is usually tested, by chemical analysis, for fineness and soundness, and sometimes for tensile or compressive strength, in the manner presently to be described for Portland cement.

Hydraulic Lime.—John Smeaton discovered that limestone containing a small percentage of clay, when calcined, produces a lime which hardens by chemical action apart from the absorption of carbon dioxide from the air. This lime slakes in the usual way, and, in addition, hardens under water ; it is therefore called hydraulic lime.

§ (155) HYDRAULIC CEMENTS, of which the best example is Portland cement, are produced by the calcination of chalk and clay or suitable limestone and shales.

In various parts of the world there are deposits in which the mixing of these materials has been carried out by nature. The result of calcination of these natural deposits produces a natural hydraulic cement. The natural rock contains as a rule an excess of carbonate of lime, rendering the resulting cement poor in quality.

Portland cement is an artificially produced cement in which the chalk and clay are accurately proportioned and thoroughly mixed together, before burning to a hard clinker at a temperature of about 750-800° C. The clinker is then ground, and forms the final Portland cement. A finely ground cement makes a stronger mortar than a coarsely ground one, hence the fineness of the cement is a property which it is necessary to specify.

Portland cement is a British invention. It was discovered by Joseph Aspdin in 1824, and owes its name to its resemblance, when set hard, to Portland stone. It sets rapidly, sets under water, and hardens slowly with but little change in volume until it is nearly as strong as stone. The hydraulic property is due to the presence of silicate of alumina.

The British Engineering Standards Association, in their standard specification, define Portland cement as follows : "The cement shall be manufactured by intimately mixing together calcareous and argillaceous materials, burning them at a clinkering temperature and grinding the resulting clinker."

Cementing materials are subject to large variations in the quality. It is necessary therefore to closely control the manufacture by imposing tests to ensure that the properties which it has been found are of first importance should reach a specified standard.

The main properties required in a cement are strength, permanence, and time of setting suitable to the work.

The principal tests which are in general use to determine the suitability of the cement for fulfilling those requirements are:

(*a*) Fineness of grinding.

(*b*) Specific gravity. (This test was deleted from the B.E.S.A. specification in August 1920.)

(*c*) Chemical composition.

(*d*) Strength.

(*e*) Time of set.

(*f*) Soundness or constancy of volume.

In order to obtain uniformity in the testing results, it is necessary that the conditions of test should be exactly the same in each case, and that the personal element should be, as far as possible, eliminated.

This has been provided for in the various specifications for Portland cement, such as those by the British Engineering Standards Association[1] (B.E.S.A.) or the American Society of Testing Materials[2] (A.S.T.M.), in which standard methods for carrying out the tests are described in detail.

(i.) *Sampling.*—It is important that (1) the sample is representative of the whole consignment; (2) a sufficiently large sample is secured to carry out, in duplicate, all the tests required; (3) the storage of the sample is such that the quality of the cement is not affected before the tests are made, and (4) the sample is properly mixed if it is obtained from various parts of the consignment.

Eight pounds of cement are usually sufficient for a sample. The B.E.S.A. specify that each sample shall consist of equal portions selected from twelve different positions in the heaps, bags, or barrels. Samples are usually stored in air-tight tins.

(ii.) *Fineness Tests.*—The fineness of cement for specification purposes is determined by means of the weight of residue (as a percentage of the original weight of the sample) which is left on a sieve after a definite period of sifting. Both the B.E.S.A. and the A.S.T.M. specify that the wire cloth of the sieves shall be woven (not twilled), and that the cloth is to be mounted on frames without distortion. The sizes adopted are slightly different in the two specifications. Particulars are given in Table 56.

TABLE 56

FINENESS TEST

	B.E.S.A. Specification.		A.S.T.M. Specification.
Size of sieve, wires per inch	180 × 180	76 × 76	200 × 200
Diameter of wire, inches	0·0018	0·0044	0·0021
Residue shall not exceed	14 per cent.	1 per cent.	22 per cent.
Weight of sample, grammes	100 grammes.		50 grammes.
Time of continuous sifting	15 minutes on each sieve		Until not more than 0·05 grammes passes through in 1 minute.

Mechanical shakers are sometimes employed in laboratories where a large amount of work has to be carried out. They are not recommended, as very little time is saved as compared with efficient hand sifting, and the results are not so consistent.

It is usually considered that the size of the very fine flour of Portland cement cannot be obtained by the use of sieves. For separating very fine powders, air separators are often used. These are fully described in the Proceedings of the International Association of Testing Materials for 1912.

Abrams,[3] as a result of a series of experiments on the effect of fineness of cement on the strength of concrete, finds that:

(*a*) In general the strength of concrete increases with the fineness of a given lot of cement, but there is no necessary relation between the strength of concrete and the fineness of cement if different cements are used.

(*b*) Fine grinding shortens the setting time, is more effective in increasing the strength of lean mixtures than rich ones, and increases the strength of concrete more at seven days than at times from one to twelve months, *i.e.* fine grinding expedites the hardening of the concrete.

(*c*) If the mixture is "wet," the rate of increase of strength, due to greater fineness, is lowered.

(iii.) *Specific Gravity.*—The weight of cement, or its "apparent" density, decreases with fineness, *i.e.* a cement coarsely ground gives a heavier weight per cubic foot than the same cement ground finely. The "apparent" density of cement is only a comparison of their "real" densities or specific gravities when the cements are of the same degree of fineness.

---

[1] *British Standard Specification for Portland Cement*, Report No. 12.

[2] *Standard Specifications and Tests for Portland Cement*, Specification No. C 9-17.

[3] "Effect of Fineness of Cement," *American Soc. Test. Mat. Proc.*, 1919, xix., part ii. p. 328.

The specific gravity of cement is lowered by adulteration, hydration, or under-burning. The differences in the specific gravity are usually so small that it is necessary to exercise great care in making the determination.

The specific gravity of cement should not be less than 3·10. The method of determination which is recommended is by means of a specific gravity bottle. The standard Le Chatelier apparatus is especially designed for use with cement. It is a volumenometer in which the liquid used is benzine, petroleum, or paraffin which has been freed from water by standing over quicklime (water causes hydration of the cement and therefore an alteration of volume).

(iv.) *Chemical Composition.*—The chemical analysis is not so important as the physical tests on cement. It, however, gives valuable indications in the detection of adulteration with considerable amounts of inert material, such as slag or ground limestone. It is also used to determine whether magnesia and sulphuric anhydride are present in excessive quantities.

(v.) *Strength Tests.*—A finely ground cement will take a certain amount of inert material without reduction of strength, therefore a coarsely ground cement will give as high a strength as a finely ground one when the test pieces are made with neat cement. As cement is seldom used neat, a strength test on the neat material is no criterion of its strength when used in practice; it, however, gives information regarding the time of setting and the soundness. Tests on briquettes made with cement and sand (usually 1 : 3 by weight) are consequently specified, as a rule, in addition to those on neat cement.

Cement is never used in tension, yet tensile tests are generally carried out in order to give an indication of strength. This is chiefly on account of their simplicity, rapidity, and cheapness. There is, however, a tendency in some countries for compression tests to be substituted for the hitherto universally adopted tensile method. It is to be noted that the recent strength tests by Abrams on fineness of cement, already referred to, were made on concrete test pieces in compression.

§ (156) Tensile Strength of Cement and Mortar.—Test pieces used for tensile tests are moulded into the form shown in *Fig.* 168, which represents the briquette standardised by the B.E.S.A. The differences between this and the A.S.T.M. standard are only slight.

The form of briquette has a considerable influence on the results. Coker[1] found that the ratio of the maximum stress to the mean stress with the B.E.S.A. briquette is 1·75 approximately, while the American and Continental forms give a value of 1·70 and 1·95 respectively. The intensity of stress is greatest along the sides of the minimum section and least at the centre.

Either single or gang moulds (see *Fig.* 169) are used for preparing the test pieces. The latter permits a number of briquettes to be moulded at one time and are preferred by many laboratories, since the greater quantity of material that can be mixed tends to produce more uniform results.

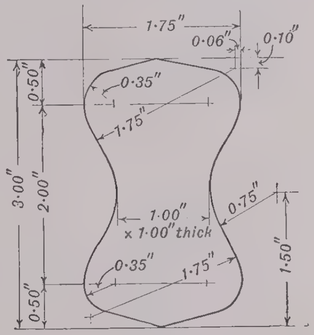

FIG. 168.

(i.) *Neat Cement Tensile Tests.*—The quantity of water used in gauging has a considerable influence on the strength of the briquette, and should be such that the mixture is plastic when filled into the moulds. The amount of water varies with different cements, and it is usual to make trial experiments to find the exact amount of water that is necessary. This varies from 18 to 25 per cent by weight of the cement.

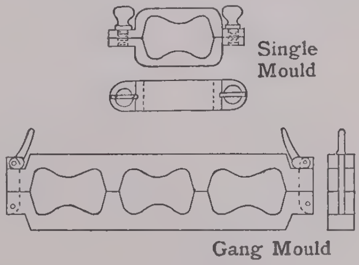

FIG. 169.

The moulds, during filling, rest on slate or some form of non-porous plates. They are filled by using the blade of an ordinary 7½-oz. gauging trowel, and it is usual to specify that no ramming or tamping is permitted.

The temperature of the room and of the mixing water should be as near to 16° C. as it is practicable to maintain it.

The briquettes are kept in their moulds, in a damp atmosphere to prevent them from drying out, for twenty-four hours after gauging. For this purpose a moist chamber is a great convenience and improvement over the method of covering the test pieces with a damp cloth, which is liable to dry out unequally. A moist chamber consists of a slate, concrete or metal lined wooden box covered inside with felt, which is kept wet. The bottom of the box is arranged so as to hold water, and glass shelves for holding the briquettes rest on cleats fixed to the sides of the box.

---

[1] "The Distribution of Stress at the Minimum Section of a Cement Briquette," *International Assoc. Test. Mat. Proc.*, 1910–1913, ii., part ii., paper xxviii$_1$.

After the expiration of twenty-four hours the briquettes are removed from their moulds and immersed in fresh water maintained at a temperature of 16° C. This water is renewed every seven days, and the briquettes are left in water until required for testing.

The strength of cement increases considerably with time from setting, consequently the age at which the test pieces are to be broken is specified. The B.E.S.A. specify that six briquettes are to be broken at seven days and six at twenty-eight days after setting, and that the breaking strength shall not be less than 450 lbs. per square inch at seven days, or $x+40,000/x$ lbs. per square inch at twenty-eight days, where $x =$ the actual strength in pounds per square inch at seven days.

The rate of loading has a marked effect on the strength of the briquettes. The latter increases with the rapidity of loading, which has therefore to be standardised. The B.E.S.A. specify a rate of 500 lbs. per minute, while the A.S.T.M. adopt 600 lbs. per minute. A variation from these rates of 100 lbs. per minute introduces an error of about 2 per cent.

The form of jaws used for gripping the test piece is shown on the testing machine in *Fig.* 170. The load must be applied without shock, and care should be observed to see that projecting edges are removed from the specimens to ensure that the briquettes are properly centred in the clips. A deviation of 0·062 inches from correct alignment will decrease the tensile strength from 15 per cent to 20 per cent.

Tension tests of cement briquettes are generally made in small lever testing machines of various types, in which provision is made for applying the load at a steady and definite rate.

Messrs. Adie, London, supply a machine in which the load is applied by a regulated travelling poise. The poise is pulled along the beam by means of a suspended weight. The speed at which the weight descends, and, therefore, that the poise travels along the beam, is regulated by the cock in the plunger of a dash pot. The plunger is attached, through the poise, to the suspended weight by an arrangement of cords and pulleys.

In the Bailey and Reid patent cement tester a cylindrical cistern is hung at the end of the single lever of the testing machine. A small stream of water is allowed to flow into this cistern, enabling the load to be applied in a gradual and almost imperceptible manner. The height of the water in the cistern is indicated by means of a glass tube similar to the gauge glass of a steam boiler, and the graduations, shown on the outside, indicate the load in pounds. A small trigger automatically closes the water-tap when the material is broken.

A further method of applying the load is indicated in the machine shown in *Fig.* 170. This is a compound lever machine with the load applied by lead shot. The briquette is held between the jaws A, the lower jaw being attached to a straining screw S, by means of which the lever L is raised into position between the stops. The load is applied by running lead shot from the container G through a channel H into the bucket C, which is hung on to the end of the lever.

The rate of loading is regulated by means of the adjustable lever N, and the breaking of the test piece automatically shuts off the supply of shot by operating this lever. With this particular machine the leverage is 50 : 1, so that fifty times the weight of the shot gives the breaking load. The levers are floated before testing by adjusting the balance weight W.

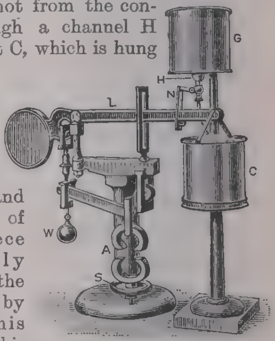

FIG. 170.

(ii.) *Mortar* (*Cement and Sand*) *Tensile Tests.*—Thoroughly washed and dried sand (obtained from Leighton Buzzard in Great Britain), which will pass a 20 × 20 mesh sieve but not a 30 × 30 mesh sieve, is used for tests in which sand is required. The wires for the sieves are 0·0164 inch and 0·0108 inch in diameter respectively.

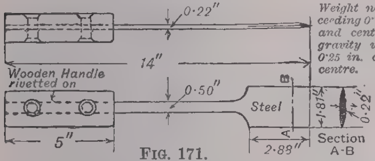
The cement and sand are mixed in the proportion of 1 : 3 by weight for the standard best pieces; about $1\frac{1}{4}$ lb. of cement and $3\frac{3}{4}$ lbs. of sand will make 12 briquettes. The gauging must be made without any excess of water being present. The quantity of water is approximately 10 per cent of the united weights of the sand and cement; the exact quantity required should be determined by a trial mixing.

The gauging is carried out on some form of non-absorbing surface, preferably glass, with a room temperature and water temperature of 16° C.

The method of filling is described by the B.E.S.A. specification as follows:

"The mixture gauged as above shall be evenly distributed in moulds of the form required, each mould resting upon a non-porous plate. After filling a mould a small heap of the mixture shall be placed upon that in the mould and patted down with the standard spatula until the mixture is level with the top of the mould. This last operation shall be repeated a second time and the mixture patted down until water appears on the surface; the flat only of the standard spatula is to be used, and no other instrument or apparatus is to be employed for this operation. The mould after being filled may be shaken to the extent necessary for expelling the air. No ramming or hammering in any form will be permitted during the preparation of the briquettes, which shall then be finished off in the moulds by smoothing the surface with the blade of a trowel." The standard spatula is shown in *Fig.* 171.

Various types of moulding and mixing machines have been devised and are in use in some countries. They are, however, not allowed by the B.E.S.A. specification. Mechanically moulded briquettes give greater strength than hand-moulded ones.



Weight not exceeding 0·75 lb., and centre of gravity within 0·25 in. of the centre.

FIG. 171.

Mortar briquettes are stored in moist air for twenty-four hours and then in water (at 16° C.) until required for testing. They should be broken as soon as possible after being taken out of the water, and should never be allowed to dry. The B.E.S.A. specify that six briquettes are broken after periods of seven and twenty-eight days respectively, at a uniform rate of loading of 500 lbs. per minute (600 lbs. per minute in the U.S.A.). The strength should not be less than 200 lbs. per square inch at seven days after gauging, or $x+10{,}000/x$ lbs. per square inch twenty-eight days after gauging, where x = the actual strength at seven days in pounds per square inch.

§ (157) CHARACTERISTIC EQUATIONS FOR TENSILE TESTS.—Unwin[1] has found that the rate of hardening of cement and cement and sand briquettes follows, very approximately, a simple law.

If y = the strength of the briquette in pounds per square inch at x weeks after gauging, and a, b, and n are empirical constants, Unwin found that $y=a+bx^n$.

n is constant for one cement, and if a be taken as the initial strength after one week,

$$y=a+b(x-1)^n.$$

For tension briquettes the gain of strength is nearly proportional to the cube root of the time of hardening.

Thus for Portland cement in tension $n=\frac{1}{3}$

and $$y=a+b\sqrt[3]{x-1},$$

where a = the initial strength (at 7 days),

b = a constant varying with the rate of increase with time.

These two constants give a clear indication of the character of the cement.

In the B.E.S.A. specification for neat cement briquettes, where the lowest value which is accepted for a is 450 lbs./sq. in., and the minimum value for y is therefore $=450+40{,}000/450=539$,

$$y=a+b\sqrt[3]{x-1},$$

and if $x=4$,

$$539=450+b\sqrt[3]{4-1},$$

therefore $$b=61{\cdot}8,$$

or $$y=450+61{\cdot}8\sqrt[3]{x-1}.$$

§ (158) SETTING TIME.—There is a distinction between setting and hardening. The initial setting is the commencement of the chemical action which occurs when the water combines with the cement; hardening is a much slower process. As a disturbance of the setting process may produce a loss of strength, it is desirable that the initial setting is not interrupted, and that the whole operation of mixing and moulding should be completed before the cement begins to set.

The initial setting time is the time which elapses from the moment water is added until the paste ceases to be fluid and plastic. For the B.E.S.A. specification the time is taken from the moment that the special mould is filled with the gauged cement, and not from the time that water is added to the cement.

The final set is acquired when the material attains a certain degree of hardness.

The B.E.S.A. specification of March 1915 recognised three distinct gradations of time of setting, viz.:

Grade.	Initial Setting Time in Minutes.	Final Setting Time in Minutes.
Quick .	Not less than 2	10 to 30
Medium .	Not less than 10	30 to 180
Slow .	Not less than 30	180 to 420

In the revised specification (August 1920), the medium and slow setting cements are replaced by a grade having a minimum initial setting time of 20 minutes and a maximum final setting time of 10 hours. The quick setting grade is retained, but the minimum final setting time is not now specified—the maximum final setting time is not to be greater than 30 minutes.

---

[1] *Testing of Materials of Construction*, 1910 ed. p. 459.

The test block for setting time is made in a special mould (80 mm. diameter and 40 mm. high) and filled with neat cement, mixed and gauged in the manner described for tensile tests.

The time of initial setting is determined empirically by the time taken, after filling the mould, for a weighted needle to cease to pierce the test block completely. The B.E.S.A. specification has decided on a special apparatus for carrying out this test called the "Vicat" needle. The needle is one millimetre square in section with a flat end, and the total weight of needle and attachments is 300 grammes. The apparatus is fitted with a device for measuring the depth of penetration of the needle.

The final setting time is determined empirically by the same apparatus, but using a slightly different form of needle. A needle of the same section as before projects 0·5 mm. beyond a hollowed-out circular cutting edge (5 mm. in diameter). The final setting time is taken as that when the needle makes an impression but the circular attachment fails to do so.

The setting times are affected by the temperature of the mixing water, the percentage of water used, and the temperature and humidity of the air. It is preferable for the tests to be conducted in moist air.

§ (159) Soundness or Constancy of Volume.—A cement which remains perfectly sound is said to be of constant volume. Failure is shown by cracking, swelling, blowing, or disintegration. To ascertain the soundness of Portland cement a rough test is to make a pat of cement ½ inch thick, gauged with 25 per cent by weight of clean water on non-porous material, preferably glass. This is placed in water at 16° C., after twenty-four hours in moist air, and left there for inspection at intervals; it should show no signs of failure.

This test is sometimes accelerated by exposing a pat of the cement for five hours, in an atmosphere of steam, to a temperature of 98° C. to 100° C.

The test specified by the B.E.S.A. is the Le Chatelier test. This is made in the apparatus shown in *Fig.* 172, which consists of a small split cylinder of brass (0·5 mm. thick) forming a mould 30 mm. internal diameter and 30 mm. high. On either side of the split two indicators with pointed ends are attached. The distance from the ends of the indicators to the centre of the cylinder is 165 mm.

The Le Chatelier test has been accepted unreservedly in England, and the International Association of Testing Materials[1] decided to recommend the method as the standard accelerated test for constancy of volume of cements. The method is to be carried out as follows:

"The cement is gauged and filled into the mould on a plate of glass, the edges of the mould being held together. When the mould has been filled it is covered with a plate of glass held down by a small weight, and the whole is immersed in water at 15° C. for twenty-four hours. Any tie or band which has been used to keep the edges of the mould together during setting time is then removed. The distance between the indicator needles is then measured and the mould is placed in cold water, which is raised to a temperature of 100° C. in the course of half an hour and is kept boiling for six hours. The mould is removed from the water, and after it has cooled the distance between the indicator needles is again measured. The difference between the two measurements represents the expansion of the cement. This must not exceed ten millimetres when the cement has been aerated for twenty-four hours, and five millimetres when the cement has been aerated for seven days."

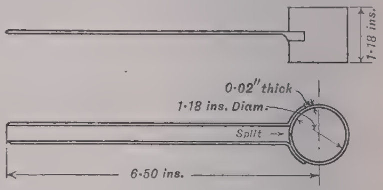


Fig. 172. *Made in Brass*

§ (160) Effect of Storage of Cement on the Strength of Concrete.—Abrams[2] finds that the effect of storage of cement on the strength of concrete or mortar is largely a question of the age at which concrete or mortar is tested. The storage period and the age of the concrete or mortar at test are of greater importance than the exact condition of storage, so long as the cement is protected from direct contact with moisture.

The deterioration of cement in storage appears to be due to absorption of atmospheric moisture, causing a partial hydration, which exhibits itself in reducing the early strength of the concrete and prolonging the time of setting.

Compression tests of concrete and mortar show a deterioration in strength with storage of cement for all samples, for all conditions and periods of storage, and at all test ages.

ELASTICITY, THEORY OF

§ (1) Introductory. — The theory of elasticity is concerned with the small relative displacements of different points in a body which occur under the action of applied forces: the forces may or may not constitute an equilibrating system, but in the great majority of examples which have been treated hitherto they are both in equilibrium and steady, so that ultimately the problem is one of the *statics* of each component particle. Logically considered, the science follows that of rigid dynamics in the process of development by which the scope of mathematical analysis has been extended to embrace more and more of the properties of real bodies. Thus, the theory of the "dynamics of a particle" treats of motion in its simplest form, and can be applied to problems in which it is sufficiently accurate to assume that the displacement of every particle is the same. Rigid dynamics takes account of the additional complexity introduced by rotation, whereby the motion of a constituent particle depends upon its position in the body; but it retains the assumption that the distance between any two particles is unchanging, and is thus equally powerless to deal with such problems relating to the behaviour of real bodies (in which absolute rigidity is never experienced) as the determination of the pressures with which a heavy beam will bear upon three or more supports. It is left for the theory of elasticity to bring problems of this nature, for the first time, within the range of exact calculation.

§ (2) Elasticity defined.—Practically all materials which are employed in construction exhibit in some degree the property of *elasticity*; that is to say, they deform under the action of applied forces, but when the forces are removed they recover their original shape. In the theory of elasticity, as at present developed, this property is regarded as absolute, and the applicability of its results to practice is limited in the main by the extent to which actual materials may be considered to satisfy its fundamental assumption—that their behaviour under applied forces is independent of their previous history. It is doubtful whether perfect elasticity, as thus defined, is exhibited by any actual material.[1] Thus, the behaviour of wood under applied forces is dependent to a considerable extent upon its dryness and temperature, and of rubber upon the forces to which it has recently been subjected: most metals and other crystalline materials possess practically perfect elasticity under small forces, but their behaviour depends in part upon their previous history when the forces exceed certain limits.

§ (3) Stress and Strain.—In the development of the precise mathematical theory, it is found convenient to introduce two new physical concepts, for which we employ the terms "stress" and "strain." To understand these terms, we may consider the motion or equilibrium of that portion of an elastic solid which is contained within the volume of the small parallelopiped indicated in *Fig.* 1. The contained material will in all practical instances be subjected to body forces such as gravity, and to balance these (and also to overcome its inertia, if the material is in accelerated motion), forces must be exerted across the containing faces by the surrounding material. We need not concern ourselves here with the difficult physical problem of explaining the mechanism by which these forces are exerted: it is sufficient for our purpose to remark that the action, whatever it is, must be of a reciprocal nature; that is to say, the force which is exerted upon the contained material, across the face ABDC, by the surrounding material must be equal and opposite to the force which is exerted by the contained material, across the same face, upon the surrounding material. Similar considerations will apply in regard to the other faces.

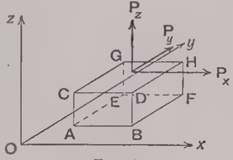

Fig. 1.

Confining our attention to the forces which are exerted *upon* the contained material, let us denote by P the resultant force exerted by the total action across the face ABDC. Whether the elastic solid as a whole be in equilibrium or in motion, the magnitude of P will depend upon the area of this face; but the quantity defined by

$$p=\left[\frac{P}{\text{Area of ABDC}}\right] \quad . \quad . \quad (1)$$

---

[1] See "Elastic Constants, Determination of," §§ (14)-(25): "Structures, Strength of."

will tend to a definite (and in general finite) limit as the area is indefinitely reduced, and to this limit we give the term "stress."

The dimensions of a stress can evidently be represented by $[M][L]^{-1}[T]^{-2}$, and it is clear from the expression (1) that it shares many of the properties of a force. It has magnitude and direction, and the stresses acting on a given surface can be resolved and compounded by the vector law: further, from what has been said above, it is really a quantitative expression for the intensity, not so much of the action on any definite portion of the material, as of the mutual action between the two portions of material which are separated by a specified surface.

Just as the idea of "stress" is an extension, for the special purposes of our subject, of the familiar concepts of mechanics, so "strain" is a development of the purely kinematic concept of relative displacement. Reverting to *Fig.* 1, we assert that the material under consideration will be unstrained, whatever its motion as a whole may be, so long as the volume occupied by any definite part of it remains unchanged both in size and shape; the motion of unstrained bodies is thus the province of rigid dynamics. On the other hand, if we consider the material which in one configuration is contained within the parallelopiped ABDCEFHG, and if in a second configuration the same material is contained within a volume of different size or shape, then we may say that the second configuration can be obtained from the first by a process involving strain.

Confining our attention to the edges of the original parallelopiped, we notice that strain may involve a change in one or more of the lines AB, BD, . . ., etc., or in one or more of the angles CAE, CAB, . . ., etc., or in both. Stretching of the material in the direction of the axis Ox will be accompanied by a change in the length of AB. Let A′ and B′ denote the new positions of the points A and B: then the fractional alteration in the length of AB will be given by

$$e=\left[\frac{A'B'-AB}{AB}\right], \quad . \quad . \quad . \quad (2)$$

and while both the numerator and the denominator of this expression tend to zero in the limit, as the length AB is indefinitely reduced, their ratio will tend to a limit which must be finite (if we exclude the possibility of discontinuous displacements, which would involve rupture of the material), but will not in general be zero. To this limit we attach the definite term "stretch": it is clearly a non-dimensional and scalar quantity.[1]

In much the same way, we may measure the change in the angle CAE by the expression

$$\gamma=CAE-C'A'E'. \quad . \quad . \quad . \quad (3)$$

For strict conformity with (2), we ought, of course, to divide the quantity on the right by the original magnitude of the angle. But owing, probably, to the fact that γ, as defined in (3), is already a non-dimensional scalar quantity, it has become customary to dispense with this operation, and to define γ as *the value of the expression* (3) *when the original angle* CAE *is specified to be a right angle.* We thus obtain the concept of a second type of strain, to which is usually given the term "shear-strain," or "slide."

§ (4) Inter-relation of Stress and Strain. Hooke's Law. Principle of Superposition.—Making use of the terms which we have thus defined, we may say that the theory of elasticity is concerned with the determination of the stresses and strains which occur in a body under the action of applied forces, and the fundamental assumption explained in § (2) may be correspondingly expressed by saying that a perfectly definite stress will accompany any given strain, and *vice versa.* We must now refer to another assumption, totally different both in nature and importance, although in the development of the theory it has become almost as fundamental as the assumption of perfect elasticity. This asserts that *the relation between stress and strain is one of direct proportionality.* That the assumption is representative of actual materials was first discovered, in 1678, by Hooke, and the relation is for this reason commonly known as "Hooke's Law."

To give precision to "Hooke's Law," the constant of proportionality requires to be stated, and we must therefore consider what are the possible types of stress and of strain. We have seen in § (3) that the total stress across any imaginary surface in a body can be resolved into components by the vector law. Let us then resolve in directions normal and tangential to the surface. The first component may be termed a "normal stress," since it constitutes an action between the two portions of material which lie on opposite sides of the surface, tending to prevent their relative motion in a direction normal to the surface: if the action tends to prevent their *separation* it is termed a "tensile stress," and if it tends to resist their *approach,* a "compressive stress." The convenience of these terms is obvious, since they describe the stresses which occur on cross-sections of a straight rod under the action of end tension and compression respectively.

For a component stress of which the direction is parallel to the surface it is usual to employ the terms "tangential" or "shear stress." These terms describe an action between the two portions of material lying on opposite sides of the surface, which tends to prevent them from *sliding* relatively to one another, without separation; it will be realised, therefore, that shear stress is brought into action, by solid friction, at the surfaces of two bodies which are in contact and sliding relatively to one another.

---

[1] The term "extension" is also used to denote this quantity.

Before proceeding further, it will be convenient to introduce a notation for the component stresses which we have just discussed. Let us consider the action at the face CDHG of the elementary parallelopiped of *Fig.* 1, and let the force exerted on the parallelopiped by the material which lies on the z side of this face be resolved into components P_x, P_y and P_z, parallel to the axes Ox, Oy, Oz respectively. Corresponding to the components P_x and P_y we have tangential stresses, which we may denote by Z_x and Z_y respectively; and corresponding to P_z we have a normal stress, which we denote similarly by Z_z. It will be noticed that in this notation the capital letter defines the face on which the stress in question acts, whilst the *suffix denotes the direction of the force exerted.*

Passing through every point in the material we have three mutually perpendicular faces of the kind just considered, and on each there are three independent components of stress which require symbols. Nine stress-components are thus introduced, namely, three normal stresses, X_x, Y_y, Z_z, and six tangential stresses, X_y, X_z, Y_z, Y_x, Z_x, Z_y. But the last six components can be reduced in effect to three, since we may show that

$$X_y=Y_x, \quad Y_z=Z_y, \quad Z_x=X_z. \quad . \quad . \quad (4)$$

These relations may be proved by considering the equilibrium of an elementary parallelopiped, such as is shown in *Fig.* 2, which requires, *inter alia*, that there shall be no tendency to rotate. A little reflection shows that body forces such as are exerted by gravity, if of finite intensity, have a negligible turning effect, and that the only components of stress which have a tendency to turn the parallelopiped about the axis YY (if the dimensions of the faces are so small that the resultant force corresponding to any stress can be assumed to act at the centre of the face affected) are the components X_z, on the two faces which are normal to the x-axis, and the components Z_x, on the two faces which are normal to the z-axis. The total forces contributed are, for the former stresses, of magnitude (X_z . AC . AD) (we have to multiply the stresses by the areas of the faces upon which they act), and for the latter, of magnitude (Z_x . AB . AC), as shown. Now the first two forces act in opposite directions along lines which are a distance AB apart, and the second in opposite directions along lines which are a distance AD apart: thus the first pair produces a couple of magnitude (X_z . AB . AC . AD), and the second a couple of magnitude (Z_x . AB . AC . AD), and (as is evident from the diagram) of opposite sign. The condition of equilibrium therefore requires that

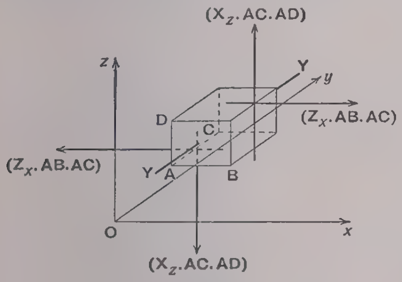

FIG. 2.

$$Z_x . AB . AC . AD = X_z . AB . AC . AD,$$

whence the third of the relations (4) follows directly, and the other two relations by similar reasoning.

It can be shown that the stress-components defined as above, and reduced in number, by the relations (4), to six, are sufficient for representing the most general system of stress which can obtain at any point in a body. By means of certain "formulae of transformation," the stress-components on any other plane through the point can be written down, and it may be shown that in any possible system of stress there will be three planes through any point, mutually perpendicular, on which the stresses are purely normal. Hence, in proceeding to derive the exact stress-strain relations required to give precision to Hooke's Law, we may confine our attention to a system of three mutually perpendicular normal stresses.

Notation is similarly required for the different components of *strain.* In § (3) we considered two distinct types, to which we gave the names "stretch" and "slide." We now introduce the notation e_{xx} for the stretch in the direction of the axis Ox—the double suffix indicating that the strain in question is a relative displacement of two planes, each of which is perpendicular to the axis of x; and in conformity with this notation we employ the symbol e_{yz} for the angle γ defined in (3)—the double suffix here indicating that the strain in question is a relative displacement of planes which are perpendicular to the axes y and z respectively. It is obvious that

$$e_{xy}=e_{yx}, \quad e_{yz}=e_{zy}, \quad e_{zx}=e_{xz}, \quad . \quad . \quad (5)$$

so that corresponding to our six distinct components of stress we have six distinct components of strain, and these may be shown to be sufficient for defining the most general type of strain which can obtain at any point. By means of "formulae of transformation" similar to those which we have noticed as holding for stresses, we can express in terms of e_{xx}, . . ., e_{yz}, . . ., etc., the strain-components corresponding to any other system of axes, and we may prove that in any possible system of stress there will exist three directions through any point which are mutually perpendicular, both before and after strain: the strains in these directions are termed "principal strains" at the point considered, and the directions themselves are termed "principal directions of strain."

Considerations of symmetry show that the principal directions of strain will always coincide, in materials which are *isotropic,—i.e.* which exhibit similar properties in all directions,—with the directions of the three purely normal stresses to which we have referred above; we shall therefore define our stress-strain relations completely if we can write down relations between the three "principal stresses," as they are generally called, and the corresponding "principal strains." We begin by considering the strain system which is involved by a simple tensile stress, of amount

T_1. This stress will evidently be one of the three principal stresses at the point considered, and the other two will be zero; it might be expected, therefore, that two of the three corresponding principal strains will vanish. Experiment shows, however, that the facts are different: the tension T_1 is accompanied by a proportionate stretch in its own direction, together with proportionate *contractions* (*i.e.* stretches of negative sign) in directions perpendicular to this. That is to say, if we choose our axis of x to coincide with the direction of T_1, then corresponding to the stress-system

$$X_x = T_1,\ Y_y = Z_z = 0,$$

we have the strain-system

$$\left.\begin{aligned} e_{xx} = \frac{T_1}{E},\ e_{yy} = e_{zz} = -\sigma e_{xx} = -\sigma\frac{T_1}{E}, \end{aligned}\right\} \quad (6)$$

where E and σ, by Hooke's Law, are constants of the material.

The quantity E is known as *Young's Modulus*. It evidently has the dimensions of a stress, and may in fact be defined as the stress which, acting alone, would involve a stretch of magnitude 1—*i.e.* a doubling of the distance between any two points in the material—measured in its own direction.[1] On the other hand, the quantity denoted by σ is non-dimensional, being the ratio of the lateral contraction $(-e_{yy})$ to the longitudinal extension (e_{xx}): it is known as *Poisson's Ratio*, and the fact that it has finite values in actual materials introduces very considerable complexity into the calculations of elastic theory.

Similar expressions will give the strain-systems which correspond to tensile stresses acting in the directions of Oy or Oz; thus, corresponding to the stress-system

$$X_x = 0,\ Y_y = T_2,\ Z_z = 0,$$

we have the strain-system

$$\left.\begin{aligned} e_{xx} = -\sigma\frac{T_2}{E},\ e_{yy} = \frac{T_2}{E},\ e_{zz} = -\sigma\frac{T_2}{E}, \end{aligned}\right\} \quad (7)$$

and corresponding to the stress-system

$$X_x = Y_y = 0,\ Z_z = T_3,$$

we have the strain-system

$$\left.\begin{aligned} e_{xx} = e_{yy} = -\sigma\frac{T_3}{E},\ e_{zz} = \frac{T_3}{E}. \end{aligned}\right\} \quad . \quad (8)$$

The most general system of stress, as we have seen, will involve three principal stresses at every point, and by a suitable choice of axes it can be written in the form

$$\left.\begin{aligned} &X_x = T_1,\ Y_y = T_2,\ Z_z = T_3, \\ &X_y = Y_z = Z_x = 0. \end{aligned}\right\} \quad . \quad (9)$$

We can at once write down the corresponding strain-system, by means of the relations (6)-(8) above, *if we may assume that each component stress is accompanied by the same strains, whether it acts alone or in conjunction with others.* This assumption cannot be completely justified on *a priori* grounds, but all experimental evidence supports it, and it has become one of the foundations upon which elastic theory has been built up. It is known as the *Principle of Superposition.*

We adopt, therefore, for the strain-system corresponding to (9) the following expressions:

$$\left.\begin{aligned} e_{xx} &= \frac{1}{E}\{X_x - \sigma(Y_y + Z_z)\}, \\ e_{yy} &= \frac{1}{E}\{Y_y - \sigma(Z_z + X_x)\}, \\ e_{zz} &= \frac{1}{E}\{Z_z - \sigma(X_x + Y_y)\}, \\ e_{xy} &= e_{yz} = e_{zx} = 0, \end{aligned}\right\} \quad . \quad (10)$$

and from what has been said above it will be evident that in these equations we have a complete and definite statement of the stress-strain relations, in an isotropic material, of which Hooke's Law is the qualitative expression. It is easy to deduce from them the following alternative forms of the stress-strain relations:

$$\left.\begin{aligned} X_x &= \frac{(1-\sigma)E}{(1+\sigma)(1-2\sigma)}\left\{e_{xx} + \frac{\sigma}{1-\sigma}(e_{yy} + e_{zz})\right\}, \\ Y_y &= \frac{(1-\sigma)E}{(1+\sigma)(1-2\sigma)}\left\{e_{yy} + \frac{\sigma}{1-\sigma}(e_{zz} + e_{xx})\right\}, \\ Z_z &= \frac{(1-\sigma)E}{(1+\sigma)(1-2\sigma)}\left\{e_{zz} + \frac{\sigma}{1-\sigma}(e_{xx} + e_{yy})\right\}, \\ X_y &= Y_z = Z_x = 0. \end{aligned}\right\} \quad (11)$$

§ (5) STRESS-STRAIN RELATIONS IN THE GENERAL CASE.—Equations (11) give the principal stresses in terms of the principal strains. They are frequently written in the simpler form

$$\left.\begin{aligned} X_x &= \lambda\Delta + 2\mu e_{xx}, \\ Y_y &= \lambda\Delta + 2\mu e_{yy}, \\ Z_z &= \lambda\Delta + 2\mu e_{zz}, \\ \text{where}\quad \lambda &= \frac{\sigma E}{(1+\sigma)(1-2\sigma)},\quad 2\mu = \frac{E}{(1+\sigma)}, \\ &\text{and } \Delta \text{ denotes the quantity} \\ &e_{xx} + e_{yy} + e_{zz}, \end{aligned}\right\} \quad (12)$$

which is known as the *dilatation*. Obviously, Δ represents the fractional change of volume which will be produced in an elementary parallelopiped of the material, as the result of the three strains e_{xx}, e_{yy}, and e_{zz} occurring simultaneously, if we may regard these strains as small; for this fractional change is given by

$$\begin{aligned} \frac{\delta V}{V} &= (1 + e_{xx})(1 + e_{yy})(1 + e_{zz}) - 1, \\ &= e_{xx} + e_{yy} + e_{zz}, \end{aligned}$$

if we neglect small quantities of order higher than the first.

By addition of the three equations (12) we have

$$X_x + Y_y + Z_z = (3\lambda + 2\mu)\Delta,$$

---

[1] This is on the assumption that the elastic properties of the material are not impaired by the action of a stress of the magnitude considered; in actual materials, as is stated later (§ (7)), failure of elasticity would occur at a very much smaller stretch.

and if the three stresses X_x, Y_y, and Z_z are equal, and of magnitude T, this equation may be written in the form

$$\Delta = \frac{3T}{3\lambda + 2\mu}, \quad . \quad . \quad . \quad (13)$$

which gives the fractional increase of volume caused by a stress of uniform intensity T in all directions. A stress of this nature, but negative in sign, is produced by the action of hydrostatic pressure; the fractional change of volume is also negative, *i.e.* a contraction; and the quantity $\frac{1}{3}(3\lambda + 2\mu)$, which evidently corresponds in equation (13) to the quantity E in the expression (6) for e_{xx}, is by analogy termed the *Modulus of Compression*, or *Bulk Modulus*, of the material. It is often convenient to have a special symbol for the quantity, although it is not an independent constant of the material, and the symbol usually employed is K: we have, from (12) and (13),

$$K = \frac{1}{3}(3\lambda + 2\mu) = \frac{E}{3(1 - 2\sigma)}. \quad . \quad (14)$$

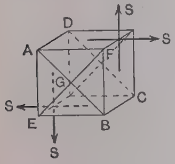

FIG. 3.

Another constant of frequent occurrence, also expressible in terms of E and σ, is the "modulus of rigidity," often denoted by C or N. We may conceive a stress-system such that a small cube of the material is completely free from stress on two opposite faces, and subjected to simple shear, of intensity S, on the other four: the relations (4) show that the shears on one pair of opposite faces must be equal to the shears on the other pair, and we may therefore take *Fig.* 3 as representing the stress-system. If we consider the corresponding stress across the diagonal surface ABCD, it is easy to show, from the condition for equilibrium of either of the two parts into which this surface divides the cube, that it will be purely normal, tensile, and of intensity S; similarly, the stress on the other diagonal plane will be purely normal, compressive, and of intensity S. If, therefore, we take our axes of x, y, and z parallel to EF, BA, AD respectively, we see that the stress-system will be given by

$$\left.\begin{array}{l} X_x = S, \quad Y_y = -S, \quad Z_z = 0, \\ X_y = Y_z = Z_x = 0, \end{array}\right\} \quad . \quad (15)$$

and the corresponding strain-system, by (10), will be given by

$$\left.\begin{array}{l} e_{xx} = \dfrac{1+\sigma}{E} \, . \, S = -e_{yy}, \\ e_{zz} = 0. \end{array}\right\} . \quad . \quad (16)$$

Thus we see that the diagonal EF will lengthen by a fractional amount $(1 + \sigma)(S/E)$, and that the diagonal AB will contract by a like amount. The two diagonals will remain perpendicular, and if dashes indicate positions after strain, we have

$$\tan A'E'G' = \frac{A'G'}{E'G'} = \frac{(1 + e_{yy})AG}{(1 + e_{xx})EG} = \frac{1 + e_{yy}}{1 + e_{xx}}.$$

Now the change produced by strain in the right angle AEB is obviously equal to

$$\frac{\pi}{2} - 2(A'E'G'),$$

and this change is the angle γ of shear strain, or "slide," as defined in equation (3) of § (3). Thus we have

$$\frac{\gamma}{2} = \frac{\pi}{4} - \tan^{-1}\left(\frac{1 + e_{yy}}{1 + e_{xx}}\right),$$

whence
$$\tan\frac{\gamma}{2} = \frac{e_{xx} - e_{yy}}{2 + e_{xx} + e_{yy}}, \\ = \tfrac{1}{2}(e_{xx} - e_{yy}),$$

if we regard the strains as small, and neglect small quantities of the second order. To the same approximation, we may write $\gamma/2$ for $\tan\gamma/2$; we thus obtain, finally,

$$\begin{aligned} \gamma &= e_{xx} - e_{yy}, \\ &= 2(1 + \sigma)\frac{S}{E}. \quad . \quad . \quad . \quad (17) \end{aligned}$$

The "modulus of rigidity," by analogy with the definition of E which has been given above, is defined as the intensity of shear stress required to produce a slide of amount 1. Hence the slide γ which corresponds to a shear stress S is given by

$$\gamma = \frac{S}{C}, \quad . \quad . \quad . \quad . \quad (18)$$

and by comparing (17) with (18) we see that

$$C = \frac{E}{2(1 + \sigma)}: \quad . \quad . \quad . \quad (19)$$

that is to say, the modulus of rigidity C (or N) is identical with the constant μ of equation (12).

The results expressed by (14) and (19) enable us to impose certain limits upon the values which are possible for σ. It is clear that the three moduli denoted above by E, C, and K must all be positive: otherwise, it would be possible to obtain an indefinite supply of energy from elastic material by putting it through an appropriate cycle of stress, and the principle of Conservation of Energy would be violated. It follows that the two ratios K/E and C/E, and hence the quantities $1 - 2\sigma$ and $1 + \sigma$, are necessarily positive: that is to say, σ must lie within the range given by

$$-1 < \sigma < 0{\cdot}5.$$

So far as is known, no material exhibits a negative value of σ; but it is of interest to note that such values are not *a priori* impossible.

If our axes of x and y had been taken parallel to the sides, EB, EA, instead of to the diagonals, EF, BA, of the cube, the stress-system of *Fig.* 3 could have been expressed in the form

$$\left.\begin{array}{l} X_y = S, \quad Y_z = Z_x = 0, \\ X_x = Y_y = Z_z = 0, \end{array}\right\} . \quad . \quad (20)$$

and the corresponding strain system, from what has just been said, would have been given by

$$\left.\begin{aligned} e_{xy}=\frac{S}{\mu},\ e_{yz}=e_{zx}=0, \\ e_{xx}=e_{yy}=e_{zz}=0. \end{aligned}\right\} \quad . \quad . \quad (21)$$

The strains corresponding to shear stress-components Y_z or Z_x could be similarly written down, and by the Principle of Superposition these may be combined with one another, and also with the expressions (11) or (12), which in § (4) were derived on the assumption that X_x, Y_y and Z_z were principal stresses—*i.e.* that X_y, Y_z and Z_x were zero; for the principle asserts that any one stress-component has a definite expression in terms of the strain-components, which will not be affected by the coexistence of any other. Thus, in the general case, where the axes of *x*, *y* and *z* do *not* coincide with the directions of the principal stresses, we have the following relations between stress and strain:

$$\left.\begin{aligned} X_x=\lambda\Delta+2\mu e_{xx},\quad X_y=\mu e_{xy}, \\ Y_y=\lambda\Delta+2\mu e_{yy},\quad Y_z=\mu e_{yz}, \\ Z_z=\lambda\Delta+2\mu e_{zz},\quad Z_x=\mu e_{zx}. \end{aligned}\right\} \quad . \quad (22)$$

The most general expression of Hooke's Law, in isotropic material, is thus seen to involve only two elastic constants.

FIG. 4.

§ (6) DYNAMICAL EQUATIONS IN TERMS OF STRESS.—We have now expressed the purely empirical law of Hooke in a form which is mathematically convenient, and we may proceed to apply our results to the analysis of stress and strain in elastic solids. The motion of any portion must be governed by the ordinary laws of dynamics; that is to say, its acceleration will be determined by the resultant unbalanced force which acts upon it, and by its inertia. If we consider the portion contained within the boundaries of a small parallelopiped, as shown in *Fig.* 4, it is clear that we can express the unbalanced force exerted by the surrounding material in terms of the stress-components defined above. Consider, in the first place, the component of this force which acts in the direction of the axis O*x*. The stress-components which contribute to it are X_x, Y_x and Z_x, acting on the faces shown. The components X_x act on faces whose area is $\delta y \times \delta z$, and which are a distance δx apart, so that the magnitudes of the stresses on the two faces (which clearly tend to pull the parallelopiped in opposite directions) differ by the amount $(\partial X_x/\partial x)\delta x$; hence, their combined contribution to this force is

$$\frac{\partial X_x}{\partial x}\,.\,\delta x\,.\,\delta y\,.\,\delta z.$$

The contributions of the other stresses are given, similarly, by

$$\frac{\partial Y_x}{\partial y}\,.\,\delta x\,.\,\delta y\,.\,\delta z$$

and

$$\frac{\partial Z_x}{\partial z}\,.\,\delta x\,.\,\delta y\,.\,\delta z,$$

and hence we see that the total unbalanced force on the parallelopiped, in the direction O*x*, is given by

$$\left(\rho X+\frac{\partial X_x}{\partial x}+\frac{\partial X_y}{\partial y}+\frac{\partial X_z}{\partial z}\right)\delta x\,.\,\delta y\,.\,\delta z,$$

where ρX is the body-force, per unit volume, acting at the point considered: the substitution of X_y for Y_x is justified by the relations (4) above.

But the mass of the material contained within the parallelopiped is $\rho\,.\,\delta x\,.\,\delta y\,.\,\delta z$, where ρ is the density; hence, if f_x is its acceleration in the direction O*x*, we have as the equation of motion in this direction

$$\rho X+\frac{\partial X_x}{\partial x}+\frac{\partial X_y}{\partial y}+\frac{\partial X_z}{\partial z}=\rho\,.\,f_x,$$

and the equations

$$\rho Y+\frac{\partial X_y}{\partial x}+\frac{\partial Y_y}{\partial y}+\frac{\partial Y_z}{\partial z}=\rho\,.\,f_y$$

and

$$\rho Z+\frac{\partial Z_x}{\partial x}+\frac{\partial Y_z}{\partial y}+\frac{\partial Z_z}{\partial z}=\rho\,.\,f_z \quad . \quad (23)$$

can be obtained similarly.

Equations (23) must obviously be satisfied at every point in a body, independently of any assumption regarding its elasticity. No additional equations are required to define the rotational motion of the parallelopiped, which may ultimately be regarded as infinitesimal, and so treated as a particle. The absence of any resultant turning tendency has been ensured already, by the relations (4).

§ (7) STRAINS EXPRESSED IN TERMS OF DISPLACEMENT.—When the stress-strain relations are known for the material considered, we can express the quantities (other than X, Y and Z) on the left of equations (23) in terms of strain-components; but the equations will still be intractable mathematically, unless we can find a common system of variables in terms of which they may be completely expressed; and the fact that the acceleration components f_x, f_y, f_z may be expressed in terms of the component displacements of the point considered indicates that we should endeavour also to relate the six strain-components to these quantities.

Let *u*, *v*, *w* denote the component displacements of any point (x, y, z) in the directions Ox, Oy, Oz respectively; then

$$f_x = \frac{\partial^2 u}{\partial t^2}, \quad f_y = \frac{\partial^2 v}{\partial t^2}, \quad f_z = \frac{\partial^2 w}{\partial t^2}. \quad . \quad (24)$$

The strain-component e_{xx} denotes the stretch in the direction Ox, and this term was defined in § (3) as the limiting value of the expression (2) when AB is parallel to Ox and indefinitely reduced. We may now write δx for the length AB in the denominator; the numerator is the total increase in the length of AB which results from strain, and this will clearly be equal to the amount by which the displacement of the point B exceeds the corresponding displacement of the point A—*i.e.* to the quantity $(\partial u/\partial x) . \delta x$. Thus, in the limit, when δx is indefinitely reduced, we have

$$e_{xx} = \frac{\partial u}{\partial x},$$

and similarly

$$\left.\begin{aligned} e_{yy} = \frac{\partial v}{\partial y}, \quad e_{zz} = \frac{\partial w}{\partial z}. \end{aligned}\right\} \quad . \quad . \quad (25)$$

The strain-component e_{yz} denotes the slide in the (y, z) plane, *i.e.* the value of γ in equation (3), when AE is initially parallel to the axis of y, and AC to the axis of z. It is the angle by which AC and AE approach one another, and this obviously is the sum of (i.) the angle at which A′E′ is inclined, after strain, to the y-axis, and (ii.) the angle at which A′C′ is inclined, after strain, to the z-axis. By reasoning similar to what has been given above, we may show that the first angle is of magnitude $\partial w/\partial y$ (we shall always be concerned with strains which are very small, and hence it is unnecessary to distinguish between the angle and its tangent) and the second of magnitude $\partial v/\partial z$; hence we have

$$e_{yz} = \frac{\partial w}{\partial y} + \frac{\partial v}{\partial z},$$

and similarly

$$e_{zx} = \frac{\partial u}{\partial z} + \frac{\partial w}{\partial x}, \quad . \quad . \quad (26)$$

and

$$e_{xy} = \frac{\partial v}{\partial x} + \frac{\partial u}{\partial y}.$$

Making use of the results expressed in equations (22) and (24)-(26), we can write the equations of motion (23) in terms of the three variables u, v, w, and of constants which are known for the material considered. We thus obtain the result given in equations (28).

The fact that all six of the strain-components can be expressed in terms of the three component displacements u, v, w, indicates that these six quantities are to some extent interconnected; that is to say, if we assign an arbitrary expression to each strain-component, we shall not in general obtain a possible distribution of strain. It is not difficult to see that the reason why such arbitrary expressions are not permissible is that they violate the conditions for continuity of the material after strain.

The necessary and sufficient relations which must be satisfied by the strain-components, in order that the corresponding system of displacement may be a possible one, can be written as follows:

$$\left.\begin{aligned}
&\frac{\partial^2 e_{yy}}{\partial z^2} + \frac{\partial^2 e_{zz}}{\partial y^2} = \frac{\partial^2 e_{yz}}{\partial y \partial z}, \quad 2\frac{\partial^2 e_{xx}}{\partial y \partial z} = \frac{\partial}{\partial x}\left(-\frac{\partial e_{yz}}{\partial x} + \frac{\partial e_{zx}}{\partial y} + \frac{\partial e_{xy}}{\partial z}\right), \\
&\frac{\partial^2 e_{zz}}{\partial x^2} + \frac{\partial^2 e_{xx}}{\partial z^2} = \frac{\partial^2 e_{xz}}{\partial z \partial x}, \quad 2\frac{\partial^2 e_{yy}}{\partial z \partial x} = \frac{\partial}{\partial y}\left(\frac{\partial e_{yz}}{\partial x} - \frac{\partial e_{zz}}{\partial y} + \frac{\partial e_{xy}}{\partial z}\right), \\
&\frac{\partial^2 e_{xx}}{\partial y^2} + \frac{\partial^2 e_{yy}}{\partial x^2} = \frac{\partial^2 e_{xy}}{\partial x \partial y}, \quad 2\frac{\partial^2 e_{zz}}{\partial x \partial y} = \frac{\partial}{\partial z}\left(\frac{\partial e_{yz}}{\partial x} + \frac{\partial e_{zx}}{\partial y} - \frac{\partial e_{xy}}{\partial z}\right).
\end{aligned}\right\} \quad (27)$$

These equations are generally known as the "Conditions of Compatibility for Strain-Components." They can be verified by substitution from (25) and (26), and are obviously independent of any assumption in regard to the properties (other than continuity) of the material.

§ (8) Equations of Motion.—Reviewing the position reached in the preceding paragraphs, we notice that—

(*a*) The equations which express the equilibrium or motion of the material contained within any elementary parallelopiped may be written down from considerations of statics or of dynamics, in terms of its density and of the stresses which act upon its faces;

(*b*) The component velocities and accelerations of the contained material can be expressed in terms of the component displacements u, v, and w;

(*c*) The strains (or changes in the sides and angles of the parallelopiped) may be expressed in terms of the same three quantities, from geometrical considerations alone;

(*d*) An innovation is introduced in the theory of elasticity, by the assumption of relations between stress and strain which enable us to substitute strains for stresses in the equations of equilibrium or of motion, and thereby to express these equations solely in terms of the relative displacements of different points in the body.

The resulting equations of motion, when the body-forces are zero or negligible, may be written in the form

$$\left.\begin{aligned}
(\lambda + \mu)\frac{\partial \Delta}{\partial x} + \mu \nabla^2 u &= \rho \frac{\partial^2 u}{\partial t^2}, \\
(\lambda + \mu)\frac{\partial \Delta}{\partial y} + \mu \nabla^2 v &= \rho \frac{\partial^2 v}{\partial t^2}, \\
(\lambda + \mu)\frac{\partial \Delta}{\partial z} + \mu \nabla^2 w &= \rho \frac{\partial^2 w}{\partial t^2},
\end{aligned}\right.$$

where ∇^2 denotes the operator

$$\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}, \quad . \quad (28)$$

and the "dilatation"

$$\Delta = \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z}.$$

When the displacements u, v, w, are steady, the terms on the right of these equations vanish; we are then left with "equations of equilibrium."

For some purposes it is convenient to replace the rectangular (or Cartesian) system of coordinates which we have employed above by other systems, such as polar coordinates. For particulars of such systems, reference must be made to the authors cited at the foot of this article: it is sufficient here to state that the motion can always be defined by three variables, between which three independent relations may be found from the equations of motion for the material contained within an elementary volume.

The equations (28) will be satisfied at every point in an elastic body, on the assumption that the relation between stress and strain may be expressed as in § (5) above (*i.e.* that it is linear, and independent of the previous stress-history of the material), *and that the strains occurring in the body are everywhere small.* The latter assumption is necessary both to justify the equations of equilibrium as expressed in terms of stresses, and to give precision to the relationship between stress and strain: fortunately, it imposes no serious restriction upon the extent to which our results may be applied in practice, since it is found that the strains produced in actual materials, by any stress which they are able to sustain elastically, are always extremely small. Remembering this restriction upon the validity of the equations, we may draw a deduction of great practical importance from their form; for it is evident that when any two solutions are combined in any proportion, the resulting expressions for the displacements will also be solutions of the equations. This is, of course, a restatement, in a general and mathematical form, of the "Principle of Superposition" which we have noticed, as an experimentally established law, in §§ (4) and (5) above.

We have said that the general problem in the theory of elasticity is to determine the relative displacements of different points in a given body, produced by forces which are specified as acting either on its surfaces or throughout its volume: forces of the first type are termed *surface tractions*, and of the second type *body forces.* A second form of the problem may now be mentioned, in which the *displacements* of the surface are specified: body forces may also be assumed to act, and in general the specified conditions may include specified tractions at some points of the boundary, and specified displacements at others. The surface displacements or tractions may be specified by their components perpendicular and parallel to the surface, but the displacements can obviously be resolved along any specified direction (and hence expressed in terms of u, v, and w), and the formulae for transformation of stress-components (referred to in § (4) above) enable us to express boundary conditions which consist of specified surface-tractions in terms of the stress components, $X_x, \ldots, X_y, \ldots$ etc., and hence in terms of u, v, and w. Mathematically, therefore, our general problem is to determine the forms of three functions, u, v, w, which must satisfy the equations (28) of motion or equilibrium at every point in the body, and which are subject to certain boundary conditions at the surfaces. If such functions can be found, we are in a position immediately to deduce the strains and stresses which occur at every point in the elastic solid considered, and its behaviour is then completely defined; for Kirchhoff has shown that any solution of the equations of equilibrium, which also satisfies the specified boundary conditions, is unique, and Neumann has extended his theorem to the equations of motion, by showing that a solution of these equations which satisfies specified initial conditions in regard to displacement and velocity is also unique.

For practical purposes, we are often concerned almost entirely with the distribution of *stress* in the interior of an elastic body, and the displacements and strains which accompany the stresses are of little interest. When the surface tractions are specified, it is, therefore, evident that a considerable gain in point of convenience might be expected from methods which would enable us to calculate the stresses directly, without introducing the quantities u, v, w. Much attention has been devoted in recent years to this problem, and methods for the "direct determination of stress" are coming into more and more frequent use. Their principle consists in expressing the different components of stress in terms of one or more common functions, which are determined by characteristic differential equations obtaining at every point, and by appropriate boundary conditions: for details, reference must be made to the authors cited.

§ (9) APPLICATION OF THEORY TO ENGINEERING DESIGN.—The theory, of course, possesses an interest, from the purely mathematical standpoint, which is independent of its practical applications; but for the purpose of the present article it is necessary here to inquire what is its value to the physicist and to the engineer. The immediate answer, from the point of view of the engineer, is that the calculation of stresses is an essential preliminary to the design of structural members of adequate strength. Actual materials, as has been stated above, are elastic only so long as the stresses to which they are subjected lie within certain definite limits: if these limits are exceeded, permanent distortion occurs, by processes of great complexity, about which it is unnecessary to say more here than that they are invariably accompanied by more or less serious deterioration of the materials' capacity for resisting stress. The problem of deciding whether the calculated stress-system will or will not produce this "failure of elasticity" in a given material is one with which the theory of elasticity, in its strict sense, has nothing to do: it is fully discussed in the article on "Theory of Structures," and it is sufficient here to remark that the theory of elasticity supplies the mathematical basis for the calculation of stresses; that the science of Testing of Materials (see article under this heading) supplies experimental data in regard to the strength of the materials of construction; and that the Theory of Structures employs the information thus provided in the practical science of "Design."

§ (10) SOME GENERAL THEOREMS. — Apart from questions of strength, the practical utility of the theory of elasticity will be most easily judged from an account of the problems which have been solved up to the present time by its means. We may notice, in the first place, certain general theorems which have been established. First, it has been shown that the stresses set up by a load which is suddenly applied may be as much as twice as great as those which would be produced by a gradual application of the same load, and that if a load be suddenly *reversed* the stresses may be trebled; this result has, of course, a very great importance for engineering design. Again, the effects of small flaws in materials have been investigated, and it has been shown, for example, that if a member which is subjected to simple tension or compression in one direction contain a small spherical flaw at some point in its interior, the tension or compression in the material will be approximately doubled at certain points on the surface of the flaw; if the flaw have the form of a circular cylinder, with its axis perpendicular to the direction of the tension, the stresses will be trebled.

Again, the effect of an impulsive pressure at the surface of a body has been investigated in general terms, and it has been shown that waves of stress can be propagated in an elastic solid which, if the solid is isotropic, may be of two types, propagated with different velocities. The first is a wave of dilatation, involving an alteration in the volume, but not in the shape, of each element of the material as the wave passes it; such waves are propagated with a velocity $\sqrt{(\lambda+2\mu)/\rho}$. The second is a wave of distortion, involving change of shape, but no change of volume in each element affected; such waves travel with velocity $\sqrt{\mu/\rho}$. Further, it has been shown that a certain type of wave exists which is propagated over the surface of a solid body, and involves practically no disturbance in the interior; its velocity is a little less than that of the waves of distortion just referred to. These results have, of course, an important bearing upon the phenomena which occur in the collision of elastic solids, and in earthquakes.

Light has also been thrown upon the nature of the stresses produced by concentration of load at some point in a body, by means of exact solutions for certain particular examples; and a knowledge of the velocity with which a wave of stress is propagated along a thin cylindrical rod has been used by Hopkinson in devising apparatus for the measurement of the large impulsive pressures which are set up in the detonation of explosives.

§ (11) SPECIAL SOLUTIONS. PRINCIPLE OF ST. VENANT.—Turning now to the consideration of special solutions of the equations of equilibrium and of motion, we may notice that exact solutions have been found for several types of periodic vibration in spheres and circular cylinders, and that the equations of equilibrium have been solved in a form which provides exact knowledge of the stresses produced in a prismatic body of any cross-section, under certain particular systems of loading, of which the general effect is to produce extension, flexure, or twisting; these results, as will be seen later, have been extended to give an *approximate* theory of such actions, *without restriction upon the exact distribution of the loads which produce them*. We also possess exact solutions for the stresses set up in thick tubes, or in spherical shells, by uniform tractions applied to their surfaces, and for the stresses which are produced by the rotation about their axes of certain solids of revolution such as cylinders and thin discs.

In these exact solutions, it is sometimes necessary to assume that a small "auxiliary stress-system" acts at certain parts of the boundary, and the results thus fail to apply exactly to practical problems, in which such systems cannot be assumed to exist: but St. Venant has shown that the discrepancy which thus arises may be, for practical purposes, regarded as involving a slight and unimportant decrease of accuracy, rather than a loss of generality. The principle upon which he bases this conclusion, and which is usually designated by his name, states that any locally applied system of surface tractions, which is itself a completely equilibrating system, has a negligible influence upon the stresses, except at points of the body lying quite close to the region within which the system is applied.

§ (12) PROBLEMS OF THE SPHERE AND OF THE PLANE.—General solutions have also been obtained for the stresses produced by symmetrical distributions of surface traction acting upon circular cylinders or spheres, and the solutions found in the latter case have been applied to problems relating to the form of the earth, such as the dependence of its ellipticity of figure upon the diurnal rotation, and the relative displacements produced by the disturbing attractions of the sun and moon. The latter are analogous to the tidal motion of the sea relative to the land, and for this reason have been called "tides." Lord Kelvin has calculated what he has termed the "tidal effective rigidity of the earth,"—*i.e.* the rigidity which must be attributed to a homogeneous, incompressible solid sphere, of the same size and mass as the earth, in order that tides in a replica of the actual ocean resting upon it may be of the same height as the observed oceanic tides. His calculations led him to interesting speculations as to the constitution of the earth, which do not, however, appear to be entirely supported by evidence obtained from tidal phenomena.

Finally, we may notice that solutions have been obtained for the effects of certain particular distributions of surface traction upon a body of infinite extent, having one plane boundary; it does not appear, however, that these results are of much practical importance.

§ (13) APPROXIMATE RESULTS.—The practical value of the theory of elasticity has been extended less by discovery of exact solutions, such as have been referred to above, than by investigations which have shown that increased generality can be obtained at the cost of some slight loss in accuracy. For the practical purposes of physics or engineering, it will be recognised that generality is of much greater value than absolute accuracy, since a margin of safety has in any case to be provided, to meet such contingencies as faulty workmanship, corrosion, or local damage. We have already referred to the value of St. Venant's principle in this connection: one of its most important applications has been to the theory of such problems as the stresses in beams and thin plates. The exact solutions for the stresses produced by flexure in a uniform beam, to which reference has been made in § (11), show that the resultant action of the stresses occurring on any section of the beam may be expressed in terms of the extension and curvature, at that section, of its strained centre-line (*i.e.* the line through the centroids of cross-sections). It may be shown that St. Venant's principle justifies us in assuming that these expressions will obtain, with reasonable accuracy, even when the external forces are not applied in the manner postulated by the exact solutions, or when the shape and size of the cross-section change at different parts of the beam. Hence, instead of having to consider the motion of each infinitesimal element of the beam, we may write down equations for the motion as a whole of the material contained between two adjacent cross-sections, and we may express these in terms of the relative displacements of the corresponding points of the centre-line. The number of independent variables is thus reduced from three (the co-ordinates of any point in space) to one (the distance of any section, measured along the centre-line, from a fixed point), and a great increase of simplicity in the calculations is thus obtainable.

For an account of the ways in which these principles are applied by engineers, in calculating the deflections which occur in girders under the action of lateral loads, reference may be made to the article on "Theory of Structures." Similar methods enable us to calculate the frequency with which a beam of given dimensions will vibrate, and the results thus obtained are of importance, both in engineering design (where it is necessary to take precaution in advance against the dangers associated with "resonance"), and in the theory of sound. Corresponding simplification has been introduced into the calculations relating to thin plates or shells, and although such problems are necessarily of somewhat greater complexity, it is true to say that many problems can be solved by these approximate methods—with an accuracy which is quite adequate for practical purposes—which would be almost intractable by rigorous analysis. For the physical theory of sound, the late Lord Rayleigh's generalised treatment by approximate methods of problems relating to the vibration of elastic solids has proved particularly fruitful in results.

§ (14) ELASTIC STABILITY.—One class of problem still requires notice. We have referred in § (8) to a theorem of Kirchhoff, that any solution of the equations of equilibrium which also satisfies the specified boundary conditions is unique. If we combine with this the assumption of Hooke's Law, that the strain varies proportionately with the stress, we may conclude that any strained configuration which we can determine will be *stable*, since departure from that configuration must of necessity be accompanied by an increase in the total potential energy of the system. But the theorem of Kirchhoff, being based upon the general equations (28) of motion or equilibrium, depends with them upon the implied assumption, that the strain which occurs in an elastic body, as the result of applied forces, does not affect appreciably the stress which those forces bring into existence at any point. This assumption is in general legitimate: but it fails in some instances when applied to elastic solids, such as thin rods or plates, of which the dimensions are widely different in different directions. For example, if we imagine a straight shaft, which initially rotates about its axis, to deflect into a curved form, then additional stresses will be called into existence as a result of that deflection, since the centrifugal effect of rotation will tend to deflect the shaft still further.

At some definite speed of revolution this distorting effect will exactly neutralise the capacity which the shaft possesses, in virtue of its elasticity, of reverting to the straight form, and hence the deflection, if it occurs, will be maintained. The equilibrium of the straight configuration has in fact become neutral, and the shaft is said to "whirl."

A similar tendency towards "elastic instability" is exhibited by a long straight rod, or "strut," which is subjected to axial compression. At a certain definite value of this end load, the equilibrium of the straight configuration becomes neutral, and the load can hold the strut bent into a curved form. Both of the examples here cited are of the first importance in engineering design, and the reader who desires to have further information about them should refer to the article on the "Theory of Structures."

Elastic instability can also occur in thin circular tubes, when these are subjected either to uniform end compression or to hydrostatic pressure on their external surfaces (as occurs in practice in the flues of steam-boilers), or to torsion. It is then accompanied by the formation of waves, or corrugations, of very regular geometrical types, and the analysis, though difficult and lengthy as compared with that of the problems just described, is tractable and interesting, more particularly as regards the indications which it affords of precautions to be observed in practical work when structural members have to be built up from thin sheets of metal. The development of metal construction for aircraft has, in fact, given to this subject, which was formerly regarded as mainly of theoretical interest, a practical importance comparable with that of the more familiar problems of elastic theory.

§ (15) PHOTO-ELASTICITY AND SOAP-BUBBLE METHODS.—Compared with other branches of mathematical physics, the subject of elasticity is remarkable for the extent to which theory has developed in advance of its experimental verification. Indeed, a little reflection shows that such verification is a matter of the greatest difficulty. No means have been devised for measuring the strains in the interior of an opaque body, and a comparison of the breaking loads given by theory and by experiment fails to supply the required verification of theory, for the reason that fracture in actual materials is preceded by a more or less lengthy period of transition from the elastic to the plastic state, during which the relations between stress and strain fail to obey Hooke's Law (cf. § (9)).

The nearest approach to precise experimental verification which has yet been made employs the property of *photo-elasticity*. It is an experimental fact that an isotropic transparent body—such as glass (which has the merit that it obeys Hooke's Law with considerable precision)—becomes doubly-refracting when stressed, its optical principal axes at any point being coincident with the directions of the principal axes of stress at the point; hence, by the aid of polarised light, it has been found possible to study many two-dimensional systems of stress which are not amenable to mathematical analysis.

In such systems, the stress-components are expressible in terms of a function χ, determined by appropriate boundary conditions, and by the equation

$$\left[\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}\right]^2\chi=0, \quad . \quad . \quad (29)$$

which must be satisfied at every point of the (x, y) plane lying within the elastic solid considered. In the solutions obtained by St. Venant for the stresses produced in a prismatic solid by torsion or flexure (see § (11)), the stress-components are found to be expressible in terms of a function ψ which satisfies the simpler equation

$$\left[\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}\right]\psi=0. \quad . \quad . \quad (30)$$

Now equation (30) is satisfied by the normal displacements (when these are small) of an initially flat membrane which is subjected to equal tensions in all directions, and advantage has been taken of this fact by Taylor and Griffith, who have shown how to determine the function ψ, for prisms of any given cross-section, by measurements made on a soap film stretched across a closed boundary of appropriate form. Such experiments are not, of course, to be regarded as a verification of elastic theory, but as a means of extending its results: they are typical of the present trend of its development, which tends more and more in the direction of practically useful extension, even at the cost of some slight decrease in accuracy. R. V. S.

References.—The standard work on the subject is Professor A. E. H. Love's *Mathematical Theory of Elasticity*, which in its third edition (Cambridge, 1920) includes references to practically every paper of importance in the subject which has so far been published. Most of the problems which have been applied successfully to practice are described (in general, with diagrams which serve to show the order of magnitude of the stresses considered) in Dr. A. Morley's *Strength of Materials*, Sir J. A. Ewing's work of the same name, and other engineering treatises of similar scope. The following table of references, for individual paragraphs of the present paper, will serve as an acknowledgment of the use which has been made, in their preparation, of the works of Love and Morley:

ENGINES AND PRIME MOVERS, THE BALANCING OF

§ (1) Preliminary.—An engine is said to be balanced when it runs without vibration.

Masses are added to the moving parts to secure this immunity from vibration, and these masses are called *Balance Weights.*

The importance of keeping the engine still by balancing the moving parts lies in the fact that if it vibrates it communicates its vibration to the foundation on which it is secured, and thus starts a wave which may spread to the surrounding buildings and cause trouble.

The trouble is very much increased if the foundation has a natural period of vibration equal to the periodic time of the vibration of the engine. Then the disturbance produced in the buildings is out of all proportion to the disturbance of the engine itself.

Synchronism of the engine vibration, or a harmonic of it, with the natural period of vibration of the foundation, or a harmonic of it, may thus cause troublesome or even dangerous disturbances in the buildings surrounding the station in which the engine is at work.

The balancing of marine engines when their speed was low and the period of vibration of the ship's hull high was not a pressing problem. But ships grew in size and engines increased in speed so that the natural period of vibration of the hull and the time of revolution of the engine approached synchronism and in some ships found it. Such ships were uncomfortable to travel in. Again the vibration produced by unbalanced engines in destroyers and cruisers was so noticeable that the designed speed in some ships had to be reduced because of the dangerous vibration produced.

The problem of balancing the engines so that they could work at any reasonable speed without producing vibration thus forced itself on the attention of engineers, and solutions exact, approximate, or roughly approximate, had to be found.

The necessity for balancing the moving parts of an engine arises from the manner in which these parts are compelled to move.

Change of speed or change of direction of a moving mass requires the action of an external accelerating force.

The moving parts of a machine are compelled by their mechanical connections to change continuously the speed and direction of their motion, and therefore accelerating forces are in continuous action on them.

These forces have equal and opposite reactions and these reactions ultimately appear as a system of forces acting on the frame of the engine.

The system is complex and changes from instant to instant, but the changes are periodic.

Balance weights are disposed on the moving parts so that, considered as a separate system, they have a resultant action on the frame as nearly as practicable equal and opposite to the resultant of the reactions produced by the motion of the parts.

A part may be balanced in such a way that the reaction supplied by the balance weight is applied directly to the part, and thus no force appears on the frame at all so far as that part is concerned.

A more detailed consideration of the main principles will make the matter clear.

§ (2) Frame Forces and the Balancing of them.—The moving parts of a machine are jointed together and with the frame in such a way that every point in every piece is constrained to move in a definite path. The constrained path is closed and the motion of the point in it is in general periodic.

The first part of the general problem is to find the forces which constrain a mass to move in a path defined for it by its mechanical connections.

The second part of the problem is to find how these forces may be directly or indirectly neutralised and so prevent their reactions acting on the frame.

Let us consider the example of constrained motion furnished by the crank and connecting rod mechanism, because the problems involved in the balancing of its moving parts illustrate the general principles involved in the balancing of any mechanism.

The crank OA (*Fig.* 1) is jointed with the frame at O. The frame being at rest, every point in the crank is compelled to move in a circle about O.

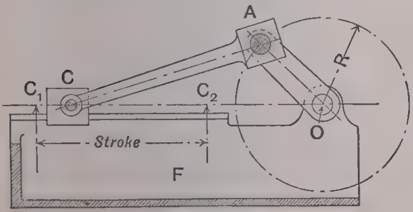

Fig. 1.

The reciprocating mass C is guided in a slide on the frame F and can move therefore only in a straight line.

The crank pin A is connected with the mass C by a rod AC, technically called the connecting rod.

However the mechanism is set in motion the path of every point in every link is defined.

The distance OA is the crank radius. The distance C_1C_2 is the stroke of the reciprocating mass and is equal to 2OA. The end points C_1 and C_2 are called the outer and inner dead points respectively.

The mechanism furnishes three separate problems for consideration.

(1) The motion of a mass in a circular path at uniform speed.

(2) The motion of a mass in a straight path at varying speed.

(3) The motion of a link as defined by the motion of two of its points.

(i.) *Motion of a Mass in a Circle at Uniform Speed.*—Let M (*Fig.* 2) be the mass; R the radius of the circle in which the mass centre moves, and ω the angular velocity of the mass about the centre of the circular path.

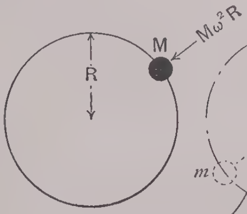

Fig. 2.

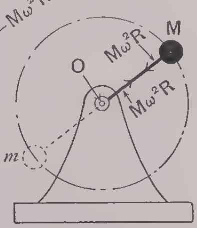

Fig. 3.

Then it is demonstrated in dynamics that the force necessary to cause the motion acts at the mass centre in a direction towards the centre of the circular path and that its magnitude is equal to $M\omega^2R$.

If M is reckoned in pounds the force is expressed in absolute units. If M is reckoned in gravitation units so that $M = W/g$, the force is expressed in lbs.-weight, W being the weight in pounds.

The force acts at right angles to the direction of motion and has therefore no effect on the speed in the path.

This force can be automatically called into existence by connecting the mass to the centre of the path by a radial connector, OM (*Fig.* 3).

When the shaft is turned the mass must move in a circle prescribed by the length of the connecting arm. The necessary constraining force is applied to the mass by the arm. An equal and opposite force is applied by the arm to the frame.

The force acting on the frame is constant in amount but varies in direction. At one instant it tends to lift the frame up, and next it acts to push it down. Placed on the platform of a suitable weighing-machine the weight of the whole apparatus seen in *Fig.* 3 would appear to vary above and below its proper value by the amount $M\omega^2R$.

For example, suppose the weight of the apparatus to be 100 pounds, of which the mass at the end of the arm, 1·5 foot radius, weighs 10 pounds. Then if the shaft were driven by a motor mounted on the apparatus at, say, 1 revolution per second, equal to 2π radians per second, the force in pounds acting on the frame would be 18·35 lbs.-weight.

The scale would therefore show a weight varying between 118·35 pounds and 81·65 pounds.

Increase the speed above that found from the relation $M\omega^2R=100$, and the upward force would be sufficient to lift the whole apparatus momentarily off the platform. For example, at 5 revolutions per second the force is 457 lbs.-weight, and under the action of this force the whole apparatus would jump up and down on the platform of the scale and produce quite a hammer blow.

This is in fact what may actually happen to the driving wheels of a locomotive if the revolving masses put in the wheel to balance forces in the line of stroke are massive enough and are driven at a high speed. This point is specifically considered in § (12) below.

The frame force (*Fig.* 3) may be entirely eliminated by the simple device of extending the radial connector as illustrated by dotted lines and securing to it a mass equal to M at the radius R. Then each mass provides the reaction to the other and the frame is not called upon for any reaction. The arm with its equal pair of masses may be driven at any speed without any tendency to produce vibration of the frame.

On the platform of a weighing-machine the mass could be driven at any speed and no change of weight would be observed.

The tension in the connector rises and falls as the speed rises and falls.

The mass M is said to be balanced by the mass m. It is not necessary that the balance weight m should be equal to M. The added mass has only to require a constraining force equal to the constraining force required by M. If a mass m is added at radius r to balance a mass M at radius R, then equality between the constraining forces is secured when

$$M\omega^2R=m\omega^2r,$$

that is when

$$MR=mr \quad . \quad . \quad . \quad (1)$$

This is the condition for the balancing of two masses on an arm and in the same plane.

It is customary to consider all masses as though they acted at a common radius. The radius usually selected is the Crank Radius. Reduction to crank radius is effected by equation (1).

(ii.) *Motion of a Mass in a Straight Line at Varying Speed.*—Consider the reciprocating mass C (*Fig.* 4). It is compelled to move in the straight path defined by the slide bars. Assume that the crank turns with constant angular velocity. Then the problem is to find what forces are required to produce the motion of the mass C which is defined by the uniform turning of the crank.

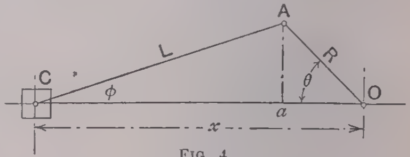

Fig. 4.

The general method of finding the acceleration of C is to form an expression giving the position of the mass in its path in terms of one independent variable. Then differentiate this variable twice with respect to the time. The result of the first differentiation gives the velocity of the mass in its path. The result of the second differentiation gives the acceleration of the mass in its path. The mass multiplied by the acceleration is then the force we are seeking.

The position of the mass C (*Fig.* 4) is defined by the distance x. When the crank angle is θ the value of x is

$$x=Oa+aC=R\cos\theta+L\cos\phi. \quad . \quad (2)$$

Eliminating ϕ by means of the relation $R\sin\theta=L\sin\phi$ and differentiating twice with regard to the time, remembering that $d^2\theta/dt^2$, the acceleration of the crank, is assumed to be zero, the acceleration is found to be

$$A=-\omega^2R\left\{\cos\theta+\frac{RL^2\cos 2\theta+R^3\sin^4\theta}{(L^2-R^2\sin^2\theta)^{\frac{3}{2}}}\right\}. \quad . \quad (3)$$

The instantaneous value of the force is then MA and the reaction on the frame is $-MA$.

The force is seen from this expression to vary in a complex manner. A way of producing an exactly equal and opposite reaction on the frame to balance this is sketched in *Fig.* 5. A mass C_1, equal to the mass C, is made to slide by a connecting rod A_1C_1, equal in length to AC. For this arrangement to work there would be three cranks on the shaft: the centre one OA, and two outer ones

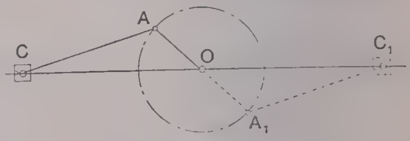

Fig. 5.

in the direction OA_1. The mass C_1 would then be driven by two connecting rods, together equal in mass to the rod AC. The reciprocating masses of an engine constructed in this way would be in perfect balance.

In an actual engine the accelerating force is derived from the fluid pressure in the cylinder. The pressure on the piston has to produce the acceleration of the piston and rod and to transmit force to the crank pin through the connecting rod. The force therefore transmitted to the crank pin is the difference between the total force on the piston due to the steam pressure and that part of the force which has been employed in giving motion to the piston. After about the middle of the stroke, however, where the acceleration changes sign, the pressure on the crank pin is greater than that due to the total fluid pressure by the retarding force, which must be applied to the reciprocating masses by the crank pin.

The acceleration[1] can be found graphically. Bennett's construction, given to the author by G. T. Bennett, D.Sc., of Emmanuel College, Cambridge, in 1902, is convenient for this purpose, and is as follows:

First (*Fig.* 6) find a point B on the connecting rod so that $AB \times BC = AO^2$. This point is found by drawing a perpendicular from O to the rod when the crank is at right angles with the line of stroke.

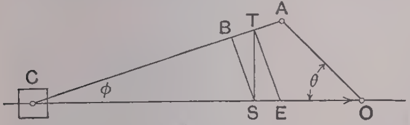

FIG. 6.

Then set out the mechanism with the crank at an assigned angle θ. From B draw BS perpendicular to the rod. From S draw ST perpendicular to the line of stroke. From T draw TE perpendicular to the rod. Then EO represents the acceleration of the mass C to the scale on which AO represents the radial acceleration of the crank pin. The acceleration of C is therefore $M\omega^2R(EO/AO)$ ft. per second per second.

The construction is exact and gives the same value for the acceleration as that which is calculated from expression (3). The proof of the construction is found from equation (1) by eliminating ϕ instead of θ. It is given in Dalby's *Balancing of Engines.*[2]

The expression found in (3) is intractable. An approximation of great utility in practice is found by putting $\cos\phi = 1 - (R^2 2/L^2)\sin^2\theta$ in the process of eliminating ϕ from equation (2). The resulting expression for x differentiated twice then gives for the acceleration

$$A = -\omega^2R\left(\cos\theta + \frac{R}{L}\cos 2\theta\right). \quad . \quad . \quad (4)$$

As close an approximation to the true expression (3) as may be desired can be made by expressing A as a Fourier series.

The general expression then becomes

$$A = -\omega^2R\,(\cos\theta + A_1\cos 2\theta - B\cos 4\theta$$
$$+ C\cos 6\theta \;.\;.\;.)$$

in which A_1, B, and C have the following values, c being the ratio R/L,

$$A_1 = c + \frac{c^3}{4} + \frac{15\,c^5}{128} \quad . \quad .$$

$$B = \frac{c^3}{4} + \frac{3c^5}{16} \quad . \quad . \quad .$$

$$C = \frac{9c^5}{128} \quad . \quad . \quad .$$

See for details a paper by Mr. J. H. Macalpine in *Engineering*, Oct. 22, 1897.

(iii.) *The Motion of the Connecting Rod* (*Fig.* 7).—The end A, called the big end, is compelled to move in a circle. The end C, called the small end, is compelled to move in a straight line.

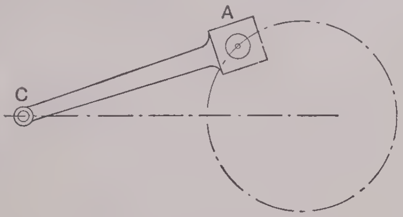

FIG. 7.

The dynamical problem is, assuming the rod to be freed from its connections, what is the instantaneous force which must be applied to the rod to cause it to move the one end in a circle with uniform velocity, the other end in a line passing through the centre of this circle (*Fig.* 7).

The answer to this problem depends upon the mass of the rod and the way the mass is distributed, and on the speed.

There are two important mass points which must be located before the solution can be found. These are the mass centre and the centre of percussion relative to the small end of the rod.

The mass centre is found by balancing the rod on a knife edge.

The centre of percussion H (*Fig.* 8) relative to the small end is found by suspending the rod so that it can oscillate about the small end, and then adjusting a plumb bob to oscillate in time with it. The length of the simple pendulum formed by the bob and its string is the distance from the small end to the centre of percussion required.

The following construction then gives the force corresponding to a given crank angle.

[2] *The Balancing of Engines*, W. E. Dalby. Edward Arnold, London, 1906.

Draw the mechanism in the configuration corresponding to the given crank angle (*Fig.* 9).

Apply Bennett's geometrical construction to find EO, the acceleration of the end C. Join EA.

EA is called the acceleration image of the rod. It has this property. Regarded as the connecting rod on a smaller scale, A being the big end and E the small end, the line joining any point on it to O represents in magnitude and direction the acceleration of the corresponding point on the actual rod. Let V be the mass centre, and H the centre of percussion of the rod about C.

Draw Vv parallel to the line of stroke and join v to O; then vO is the magnitude and direction of the acceleration of the mass centre to the scale on which AO is the acceleration of the crank pin A.

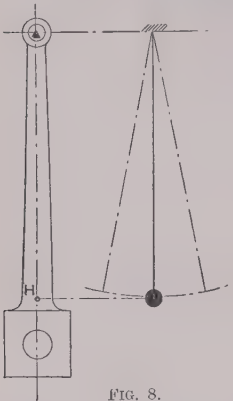

FIG. 8.

The magnitude of the accelerating force is then

$$M\omega^2R\frac{vO}{AO}=R.$$

It remains to find its position.

Draw Hh (*Fig.* 9) parallel to the line of stroke and join h to O. Through H draw a line parallel to hO cutting the line of stroke in J. J is then a point in the line of action of the force. But its direction is given by vO.

Therefore through J draw a line parallel to vO. This is the line of action of the force R, which is competent to produce the motion of the connecting rod at the instant the crank is passing through the angle θ.

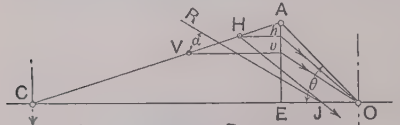

Fig. 9. To find force R competent to produce the motion of the Connecting Rod.

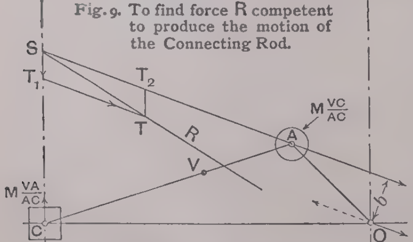

Fig. 10. Frame Reactions.

This force varies in magnitude and direction as the crank angle varies.

The force R is equivalent to an equal and parallel force R acting at the mass centre V, and a couple Ra. The force R at the mass centre produces the linear motion of the rod, and the couple Ra produces the angular motion of the rod about its mass centre V. The combination of this linear and angular motion produces the actual motion.

The proofs of these propositions and constructions are given in detail in Dalby's *Balancing of Engines.*

The next step is to find the frame reactions. Force can only be brought on to the rod at its ends. There is the pull from the crank pin and the reaction at the slide bars.

Neglecting friction the reaction at the slide bars can only be at right angles to the line of stroke.

Therefore at C (*Fig.* 10) set up a perpendicular to the line of stroke to meet R produced in S. Join S to A.

Then if ST represents the force R, the component ST_1 represents the force which must be brought upon the small end of the rod by the slide bars, and the component ST_2 the force which must be brought on to the big end by the crank pin. These two components together produce the actual motion of the rod.

The crank-pin component transferred to the crank shaft gives the couple $ST_2 \times b$, and the equal and parallel force ST_2 acting from the frame to the shaft.

The couple modifies the turning moment on the crank.

The frame reactions are shown by dotted lines in the figure.

The final result is then that the motion of the connecting rod involves forces on the frame like those shown, changing in magnitude from instant to instant, but passing periodically through the same values. These forces tend to cause vibration of the frame.

The connecting rod could be balanced exactly by the method already illustrated in *Fig.* 5. With this arrangement providing that the rods on the right are equal in weight to the rod on the left and similar in form, the resultant of the forces on the frame consequent upon the motion of the rods on the right is exactly equal and opposite to the resultant of the forces on the frame consequent upon the acceleration of the rod on the left.

The forces wax and wane and change their directions in exact unison, so that they neutralise one another from instant to instant, and the frame itself, although under the stress produced by these forces, is never under the action of an unbalanced force and therefore has no tendency to vibrate.

In practice it is usual to eliminate the effect of the rod by treating the problem as though its mass were divided between the crank pin and the reciprocating masses inversely as the mass centre divides the rod.

The share assigned to the crank pin is then balanced as part of the revolving masses; that assigned to the reciprocating masses is balanced with the reciprocating masses.

Considered as a system of two masses the frame forces produced are not exactly the same as the frame forces produced by the actual connecting rod, but while it is impossible to balance the rod except by another rod in the way shown, it is possible to balance these divided masses with ordinary balance weights with sufficient accuracy for most practical purposes.

§ (3) THE CENTRIFUGAL COUPLE.—Referring to *Fig.* 3 it will be seen that the mass M is balanced by the mass *m* placed diametrically opposite to it.

Let *Fig.* 11 be the side view of a shaft carrying a mass M at radius R, and for the moment suppose it to be supported on a pair of parallel knife edges at B_1 and B_2. If the balance weight *m* is placed opposite M at radius *r* such that $MR=mr$, but at a distance A along the shaft as shown in *Fig.* 11, and this is usually necessary in practice, it will still be found to balance M when the shaft is at rest. The shaft will stand in any angular position on the knife edges. It will be in perfect static balance. If now the shaft is put in bearings, say, at B_1 and B_2, its revolution will set up vibrations.

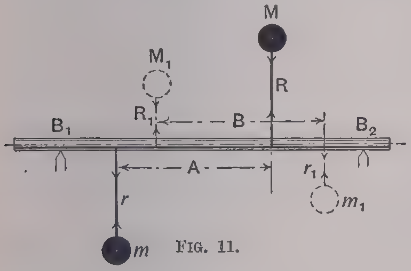

FIG. 11.

Although it is in static balance it is not in running balance. The disturbance is now produced by the couple formed by the reaction of M on the shaft, giving a force Mw^2R, and by the equal and opposite reaction mw^2r on the shaft, these two reactions being separated by the distance *a*. This couple tends to turn the system about an axis perpendicular to the plane containing the forces.

The distance A between the forces is called the ARM of the couple, and the product of one force into the arm is called the MOMENT of the couple.

The couple is called the centrifugal couple, because its forces are the centrifugal forces caused by the rotation of masses.

A couple can only be balanced by an equal and opposite couple acting in its plane. That is, the four forces of the pair of couples lie in one plane, and this plane contains the axis of the shaft.

The moment of the centrifugal couple caused by the mass M and its balancing mass *m* is $M\omega^2RA$.

It may be balanced by a couple $M_1\omega^2R_1B$, the quantities being taken so that

$$M_1R_1B=MRA. \quad . \quad . \quad (1)$$

These couples must act so that they tend to produce rotation in opposite directions.

The dotted lines in *Fig.* 11 show a balancing couple. If masses, radii, and the arm B satisfy the equation above, and if in addition $M_1R_1=m_1r_1$ and $MR=mr$, then it will be found that the shaft may be driven at any speed and there will be no vibration.

At the same time the shaft will stand in any angular position on the knife edges. The masses disposed round it satisfy in fact two separate conditions.

They are in static balance, and they are also in running balance. Static balance implies that the mass centre of all the masses lies on the axis of revolution of the shaft.

Running balance implies that the centrifugal couples of all the masses form a system in equilibrium.

§ (4) THE PRACTICAL PROBLEM.—The problem of balancing an engine presents itself in practice in this way. An engine is designed to fulfil conditions of power, speed, and arrangement, and the result is a crank shaft driven from a number of cylinders. Usually the lines of stroke of the cylinders are contained in one plane, and this plane contains the axis of the crank shaft. If there are *n* cylinders, then there are *n* piston masses, *n* cranks, and therefore *n* revolving masses, and also *n* connecting rods. The accelerations of each of these systems of *n* masses cause frame reactions.

As mentioned above, the connecting rod is eliminated from the problem by distributing its mass between the revolving and the piston masses.

There are now two balancing problems:

(1) To balance the revolving crank shaft masses.

(2) To balance the reciprocating piston masses.

Both fall under one method of solution.

§ (5) SOLUTION OF THE BALANCING PROBLEM.[1]—The initial problem to be solved may be stated in this way. Given a revolving shaft with a number of masses attached to it, find the balance weights which must be added to secure static and running balance.

---

[1] This solution by Professor Dalby was first published in 1899. It is contained in a paper entitled "The Balancing of Engines with special reference to Marine Work," printed in the *Transactions of the Institution of Naval Architects*, 1899, xli. In this paper will be found applications of the method to the balancing of torpedo-boat engines, including with the pistons the reciprocating slide valves as well. The development of the method to include primary and secondary balancing, the balancing of locomotives, and the treatment of many problems arising out of the dynamical conditions involved will be found in *The Balancing of Engines*, by W. E. Dalby, mentioned above.

Solution.—Select a plane at right angles to the shaft in which it is intended to attach one of the balance weights. This plane is called specifically the REFERENCE PLANE. The reference plane may be regarded as a definite plane like a drawing-board, keyed to and revolving with the shaft.

Transfer each centrifugal force $M\omega^2R$ in turn to this plane. Each force transferred gives rise to

(1) an equal and parallel force, $M\omega^2R = F$, acting in the plane;

(2) a couple Fa, where a is the distance through which the force is transferred.

The transference of one force to the reference plane is illustrated in *Fig.* 12. Here the rotation of the mass M produces the centrifugal force $M\omega^2R = F$ on the shaft, and this transferred to the reference plane gives the equal and parallel force F and the couple Fa.

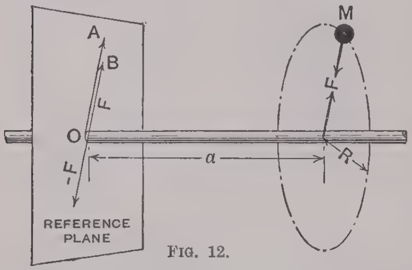

FIG. 12.

For, introduce two equal and opposite forces F at the point O in the reference plane. Then these forces being in equilibrium themselves do not affect the equilibrium of the system. The three forces, F from the mass M, and F and $-F$ introduced at O, may then be analysed into the equal and parallel force F acting at O in the reference plane and the couple Fa.

Draw a line OA parallel to the radius to M to represent the couple Fa. Its length OA is chosen so that $OA = Fa$ and its sense is marked off according to the direction in which the couple tends to turn the shaft about O.

That is, its sense will be from O outwards in the radial direction of the mass for all masses on the right of the reference plane, and from O in the direction opposite to the radial direction of the mass for all masses to the left of the reference plane.

Also draw OB to represent the force.

Then every mass M revolving with the shaft will give rise to two vectors in the reference plane, a force vector like OB pointing always in the radial direction of the mass, and a couple vector OA pointing in the radial direction settled as above.

The next step is to find the resultant of the couples. For this purpose set the couple vectors out in any order to form a polygon. If the polygon closes, then there is no unbalanced couple. If it does not close, the vector required to close it gives in magnitude sense and direction the couple required to balance the couples about O.

The couple closure, as this line is called, is the product of four quantities, namely, ω^2, an unknown mass M acting at a convenient radius R from the shaft and in a plane at a convenient distance d from the reference plane, and is equal to $MR\omega^2 d$.

Select a plane at a distance d from the reference plane where a balance weight may be conveniently introduced.

Select a radius R at which it is convenient to place the balance weight in this plane.

Finally calculate the magnitude of the balance weight from the equation

$$M = \frac{\text{Couple closure}}{dR\omega^2}.$$

The angle at which the radius stands in relation to the other radii on the shaft is given by the direction of the closure line in the polygon.

Then add this balance weight to the system, and transfer it to the reference plane as before, thus adding one more force to the system already there. The couples now balance.

Then set out the force vectors in any order to form a polygon. If this force polygon closes, then there is no unbalanced force. If it does not close, the vector required to close it gives in magnitude sense and direction the force required to balance the forces acting at O.

The force closure is the product of three quantities, namely, a mass, a radius, and ω^2.

Select a radius at which it is convenient to place the balance weight in the reference plane, and then calculate its magnitude from the equation

$$\text{Mass} = \frac{\text{Force closure}}{R\omega^2}.$$

The angle of the radius to the balance weight is given by the direction of the closure in the polygon.

ω^2, being constant for all masses, may have any value in working out the solution. Therefore call it unity.

The addition of the balance weight in the reference plane to balance the forces there has no effect on the balance already produced between the couples. Because a force acting at O has no moment about O, and can therefore be added or removed without introducing a couple into the system.

This is the essence of the solution. The couples are balanced first, and then the forces are balanced without disturbing the balance between the couples.

It is easily shown that if the forces and the couples are separately balanced about any one point along the shaft they are separately balanced about every point along the shaft. Therefore, after the balance weights have been found by the method explained, and have been added to the system, it will be found that both the couple and the force polygons will close for any position of the reference plane along the shaft.

The balance weights found are independent of the position chosen for a reference plane.

This property enables the work to be checked. Having found the balance weights as described, include them in the system, and then select a reference plane at a new place along the shaft.

Ignoring the knowledge that the system is balanced, proceed to find balance weights. It should be found that both force and couple polygon close, showing that no balance weights are required. If the polygons do not close, there has been some error in the original determination of the balance weights. This check on the accuracy of the work is a valuable element of the Dalby Solution.

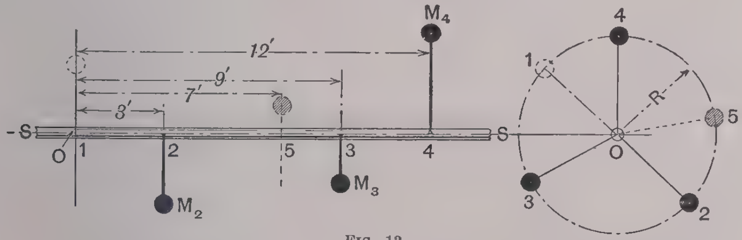

FIG. 13.

End View of Shaft

§ (6) EXAMPLE.—Let there be three masses—$M_2=17$ pounds, $M_3=15$ pounds, and $M_4=7$ pounds—attached at common radius R to the shaft SS (*Fig.* 13) spaced along the shaft as shown, and spaced angularly around the shaft as defined in the end view of the shaft (*Fig.* 13).

The mass centre of each mass revolves in a plane to which the shaft is perpendicular.

Let the problem be to balance these three masses by two balance weights, the one being placed in the plane No. 1 and the other in the plane No. 5.

Choose the reference plane to coincide with the plane of revolution of one of the balance weights. We may therefore choose either plane No. 1 or plane No. 5. Let us choose plane No. 1. Then write on the drawing the distance of each plane in which a mass revolves from the reference plane in the manner indicated in the figure.

Arrange the data in the way shown in SCHEDULE No. 1.

Column 1. Write in the numbers of the planes of revolution.

Column 2. Write in the distances of these planes from the reference plane.

Column 3. Write in the values of M, the mass at common radius R. This mass is equivalent to the centrifugal force when $\omega^2R=1$. The column is therefore headed FORCE.

Column 4. Write in the products Ma calculated from the figures in columns 2 and 3. This product is equivalent to a centrifugal couple when $\omega^2R=1$. The column is therefore headed COUPLE.

SCHEDULE 1

No. of Plane or No. of Crank.	Distance of Plane from Reference Plane.	FORCE. Equivalent Mass at Common Radius, or Centrifugal Force when $\omega^2R=1$.	Couple when $\omega^2R=1$.
	a.	M.	Ma.
No. 1	0	Unknown bal. wt. (14·4 pounds)	0
No. 2	3′	17 ,,	51 lbs.-ft.
No. 3	9′	15 ,,	135 ,,
No. 4	12′	7 ,,	84 ,,
No. 5	7′	Unknown bal. wt. (11·9 pounds)	83 = closure.

Next set out the couple vectors of column 4 in the way shown in *Fig.* 14. Choosing any convenient scale, draw

AB = 51 and parallel to radius 2 (end view, *Fig.* 13).
BC = 135 and parallel to radius 3.
CD = 84 and parallel to radius 4.

DA the closure, measuring 83, is the couple required to produce balance amongst the couples.

The balance weight in plane 5 is calculated from $(R\omega^2=1)$,

$$M=\frac{\text{Couple closure}}{aR\omega^2}=\frac{83}{7}=11{\cdot}9 \text{ pounds.}$$

The angular position of the radius of this balance weight is defined in relation to the others by drawing radius 5 in the end view parallel to the closure of the couple polygon.

This mass is now entered in the schedule as indicated.

There are now four forces acting at O in the reference plane. Starting from any origin, set out (*Fig.* 15)

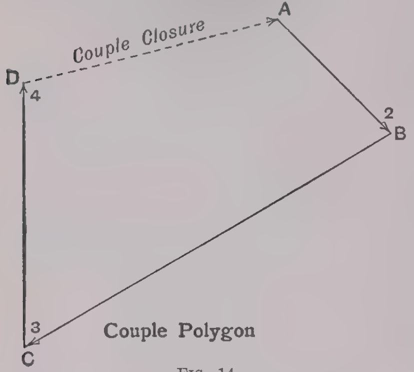

FIG. 14.

$ab=17$ parallel to radius 2 (end view, *Fig.* 13) ;
$bc=15$ parallel to radius 3 ;
$cd=\ 7$ parallel to radius 4 ;
$de=11{\cdot}9$ parallel to radius 5.

ea, the closure measuring 14·4, is the balance weight at common radius required to balance the forces at O. The angular position of the radius of this balance weight is defined in relation to the others by drawing radius 1 in the end view parallel to the closure of the force polygon.

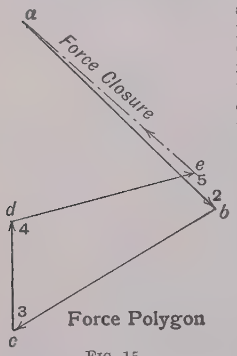

FIG. 15.

These two balance weights added to the system in the planes specified, and in the angular positions defined in the end view, produce a system of five masses in both static and in running balance. The shaft can be driven at any speed when held in a pair of bearings placed anywhere along the shaft without producing vibration of the supports.

Whatever value be given to ω^2R it will be the same for each mass, and therefore will not make any difference in the balance weights found.

§ (7) DEDUCTIONS FROM THE FORCE AND COUPLE POLYGONS.—The balance of a system of *n* revolving masses may be tested by selecting a reference plane at any point along the shaft and then following the method above. Unless the plane has been selected to coincide with one of the planes in which a mass revolves there will be in the reference plane, after the transference of the forces to it, *n* couple vectors, and *n* force vectors. If the masses are in balance the couple vectors set out in any order will form a closed polygon of *n* sides; and the force vectors set out in any order will form a closed polygon of *n* sides. Corresponding sides of these two polygons are parallel, but the ratio of the lengths of a pair of parallel sides is different for each pair. The ratio of a pair is in fact the distance *a* from the reference plane of the mass whose force and couple are respectively represented by the pair of parallel sides.

The balancing of *n* masses amongst themselves is thus conditioned by these geometrical properties of the force polygon and the couple polygon.

If, when the vectors are set out, it should be found that the force polygon closes, but the couple polygon does not close, then the masses are in static balance, but are not in running balance. There is no unbalanced force, but there is an unbalanced couple causing reactions on the frame.

A few important practical limitations can at once be deduced from these polygons.

(*a*) Three masses carried on three arms spaced along a shaft can only mutually balance if the arms are in one plane, a plane containing the axis of the shaft. Seen in end view the arms would all lie in a diameter.

For it is only possible to draw two polygons of three sides each, with corresponding sides parallel, and the ratio of the lengths of each parallel pair different, if the polygons close into a line. It follows that the arms carrying the masses must be in a line so that the middle arm is at 180° with the two outer arms.

Therefore a crank shaft with three cranks at 120° cannot be designed so that the masses mutually balance. If the masses are equal, the force polygon closes and static balance is obtained. But in these conditions the couple polygon cannot be closed.

To balance three masses set at angles with one another a fourth mass must be added to the system equivalent to a fourth crank. The system is then equivalent to four masses on four cranks.

(*b*) Four masses on four arms spaced along a shaft can in general be balanced amongst themselves, because a pair of polygons can be found in which corresponding sides are parallel, and in which the ratio of the lengths of each parallel pair is different.

(*c*) But four masses spaced along a shaft on four arms set at 90° with each other cannot be designed to balance. If the four masses are equal the force polygon closes and there is static balance. But with the angles all right angles the couple polygon cannot be made to close.

Therefore a crank shaft with four cranks set at 90° with each other cannot be designed so that the masses balance. Balance can only be obtained by adding a fifth mass to the system equivalent to a fifth crank. The system is then equivalent to five masses on five cranks, but with the condition that four of the cranks are mutually at right angles.

Many other useful conditions can be deduced from the geometric properties of the force and couple polygons.

§ (8) THE BALANCING OF A ROTOR.—The rotor of a steam turbine is truly turned, and the blading is symmetrical. At first sight it would appear that there is here no balancing problem, because so far as constructional skill can go the mass centre of each elementary disc, of which the length may be imagined to be made up, lies in the axis of rotation.

But owing to slight variations in density, and in the symmetry of the blading, the mass centre of each elementary disc is in general slightly displaced from the axis of rotation. Although these displacements are slight the speed at which the rotor is driven involves accelerating forces which are large enough to cause vibration. So that, after all, there is a rotor balancing problem, and a difficult one, because the displacements of the mass centres of the elementary discs cannot be identified by any method of weighing or measurement.

The problem is in fact similar to that which would be presented to a designer asked to work out the balance weights for a totally enclosed reciprocating engine, with access to the parts denied. All he would see of the moving parts would be the ends of the crank shaft projecting through the bearing at each end, and all he would know of them would be that their motion produced vibration.

Similarly, all he can see in a rotor is an apparently truly turned mass, symmetrically bladed, and all he knows of it is that when driven it produces vibration.

He might by imagination conceive the rotor to be made up of a series of elementary discs, but the position of the mass centre of each disc would be hidden from him without possibility of discovery.

Mr. King Salter, in a paper to the Institution of Naval Architects read at the spring meeting of 1920, has described an ingenious method of solving the problem.

The rotor to be balanced is placed in bearings and is driven by a motor. Being unbalanced it produces a reaction on each bearing. These reactions are separately measured in the horizontal direction. Let R_1 and R_2 be the respective maximum reactions measured in the apparatus when the rotor is driven at ω revolutions per second. Then each reaction may be regarded as produced by a mass M attached to the rotor at radius r. So that the maximum horizontal reaction at each bearing is expressed by

$$R_1 = M_1\omega^2 r_1, \qquad (1)$$

$$R_2 = M_2\omega^2 r_2, \qquad (2)$$

from which

$$M_1 = \frac{R_1}{\omega^2 r_1}, \qquad (3)$$

$$M_2 = \frac{R_2}{\omega^2 r_2}. \qquad (4)$$

M_1 and M_2 can be calculated from (3) and (4) because ω^2 is observed, and r may be put equal to unity or to any convenient constant length.

The next part of the problem is to find the angular position of the radii r_1 and r_2. This is done by the apparatus described in the paper.

The rotor, with its hidden system of unbalanced masses, may now be replaced by a shaft with two known masses attached to it at known angular spacing as illustrated in *Fig.* 17. *Fig.* 16 shows the rotor and the centre line of the bearings at which the reactions are measured. *Fig.* 17 shows the equivalent unbalanced system of two masses as determined in Mr. King Salter's apparatus.

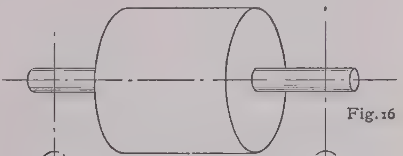

Fig. 16

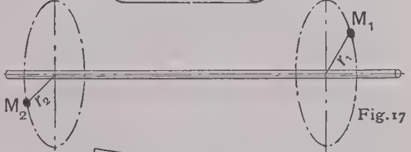

Fig. 17

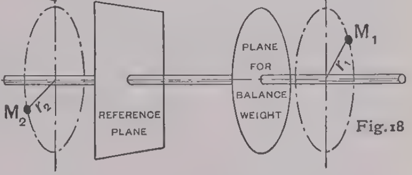

Fig. 18

The two planes in which balancing masses are to be placed are now fixed upon. One is chosen as a reference plane, and then the solution of § (5) is applied to find the actual magnitude and position of the balancing masses to be placed in the two respective planes. The arrangement is shown in *Fig.* 18.

The usual shop method of balancing a rotor is to place it on a pair of level and parallel knife edges and then add balance weights until it will stand in any angular position on these knife edges. This process ensures static balance but not running balance. The unknown unbalanced couple cannot be estimated from experiments on parallel knife edges, and in practice the proper distribution of balancing masses to secure running balance is done by trial and error. After static balance is secured the rotor is driven up to speed, and if the couple is sufficient to produce disturbance the weights added to secure static balance are distributed so that the running balance is improved without interfering with the static balance. Considerable experience is required to get this done satisfactorily. It is advisable to test the balance of a turbine rotor in steam so that the rotor and its blades have expanded to the positions they occupy at the normal running temperature.

A full description of Mr. King Salter's apparatus will be found in the paper cited above. Briefly it consists of a substantial bed with a bearing at each end. Each bearing can slide horizontally through a limited distance, but is prevented from doing so by a spring screwed up against it. When a trial of a rotor is being made the spring is compressed against the bearing so that it just prevents it moving. The strength of the spring is known, so that the maximum force acting horizontally on the bearing in the direction of motion can be observed.

On each end of the rotor is placed a spider or flange, carrying on its periphery a number of radial spokes like the spokes on a steering wheel, but with this difference, that they are free to slide inwards radially, but once pushed in they cannot come back, being held by a spring. When these spiders have been keyed on the end of the rotor, all spokes out to the limit allowed, the rotor is driven at the testing speed by an independent motor, and this motor is then disconnected. The bearings are then slightly relieved so that the rotor can move horizontally under the unbalanced forces. A kind of brake shoe is then gradually approached to the spokes and pushed on to them until the ends are running in a circle. The rotor is then brought to rest, and an examination of the spokes shows the particular radius corresponding to the maximum horizontal displacement, and therefore to the maximum value of the force on the corresponding bearing.

The displacement of the mass centre of a rotor and the angular position of the plane containing the mass centre and the axis of the rotor can be found by direct weighing in the Martin rotor balancing apparatus. The method and the apparatus are described in *Engineering*, December 31, 1920. By the aid of this apparatus a static balance of great accuracy can be obtained. For many rotors static balance may be sufficient, as for the thin disc-like rotors of gyrostats. If the static balancing of a rotor is found to be insufficient, its dynamical balance can be tested and secured by the aid of Mr. King Salter's apparatus.

§ (9) FOUR MASSES. SPECIAL CONSTRUCTION. —Four masses may be set together in mutual balance in an infinite variety of ways. For an infinite number of pairs of four-sided force and couple polygons can be drawn at random to satisfy the geometrical conditions mentioned above.

There is a simple construction, due to Dr. Schubert, and published by the Hamburg Mathematical Society, 1898, which gives the spacing along the shaft, the angular positions, and the masses for mutual balance amongst four masses.

Let the spacing of the cranks along the shaft SS be given as indicated in *Fig.* 19. Choose any pole O. Join points 1, 2, 3, 4, with this pole.

Take any point A on O1, and through it draw a line AB parallel to the shaft SS, and a line AC parallel to the line O3.

Through B draw a line BC parallel to the line O2.

Then OACB is the force polygon corresponding to the position of the pole O and the crank spacing given.

This force polygon defines by the lengths of its sides the relative magnitudes of the masses, and by the directions of its sides the positions of the cranks.

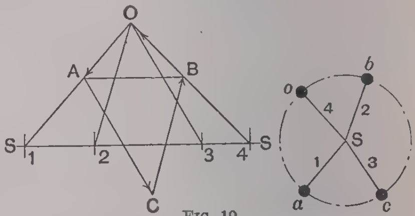

FIG. 19.

Thus in the end view draw crank S*a* parallel to the side OA; S*c* parallel to the side AC; S*b* parallel to the side CB, and S*o* parallel to the side BO.

If now the system be tested it will be found that the couple polygon is closed. The proof of this will be found in Dalby's *Balancing of Engines*, 2nd edition, 1906, p. 50.

The construction may be varied in many ways. For example, the angular position of the cranks in end view may be drawn at random. Then select any pole O and draw lines radiating from it parallel to the crank directions. Then draw across the rays a line SS, and the intersections define the spacing along the shaft.

Then draw a line as AB parallel to the line SS and finish the force polygon. The sides then define the magnitude of the masses.

§ (10) THE BALANCING OF RECIPROCATING MASSES.—We have now to consider the balancing of the reciprocating masses of a multi-cylinder engine of the type where the centre lines of the cylinders lie in a plane containing the axis of the crank shaft.

In the marine type the plane is vertical. In the ordinary land type the plane is usually horizontal, though often vertical. In the V engine the plane is inclined, and there are two systems of parts to be separately balanced, one set in each inclined plane.

The frame reaction caused by the reciprocation of a mass M by a crank turning with uniform velocity is given by equation (3), § (2).

A way of producing an exact equal and opposite reaction on the frame is described and illustrated in *Fig.* 5.

This construction is, however, excluded from the problem before us.

An expression giving values close to the values from (3), and derived from equation (4), § (2), is

$$F = M^2R \cos \theta + M(2\omega)^2 \frac{R^2}{4L} \cos 2\theta. \quad . \qquad (1)$$

The first term of this expression is the projection on the line of stroke of the centrifugal force due to the rotation of the mass M at radius R and at speed ω.

The second term is the projection on the line of stroke of the centrifugal force due to the rotation of a mass M at radius $R^2/4L$ and at speed 2ω.

The greater the length of the connecting rod in relation to the crank radius the smaller the second term.

In the limit, when the rod is infinitely long, the second term vanishes. The crank and slotted bar mechanism partly realises this condition. The ratio of rod to crank is often large enough to make this second term negligibly small. In locomotives the ratio of rod to crank may be 7 to 1, and even more. But in some kinds of marine engines it may be only 3½ to 1. The second term then becomes important.

When the second term is ignored in the balancing the engine is said to be balanced for PRIMARY FORCES and PRIMARY COUPLES only.

If, however, the second term is included in the problem, the engine is said to be balanced for PRIMARY AND SECONDARY FORCES AND COUPLES.

(i.) *Primary Balancing.*—Since the term $M\omega^2R \cos \theta$ is the projection on the line of stroke of the centrifugal force produced by the rotation of a mass M, the conditions of primary balance amongst n reciprocating masses are the same as those for n revolving masses, and may be investigated by assuming that each mass is attached to its own crank pin, so that the n reciprocating masses are replaced by n revolving masses. For if a polygon is closed, then the projections of the sides on any line are algebraically equal to zero. In other words, if the conditions of balance for the revolving masses are satisfied, so too are the conditions for the equivalent reciprocating masses. The Dalby Solution of § (5) may then be applied without change to find the balance weights of the substituted revolving system, and the balance weights found reciprocated in the cylinder plane will balance the reciprocating masses.

The example of § (6) may be restated thus. The reciprocating masses of a three-cylinder vertical engine weigh respectively $M_2=17$ pounds, $M_3=15$ pounds, $M_4=7$ pounds. These masses are reciprocated by cranks spaced along and around the crank shaft, as defined by *Fig.* 13. Find the reciprocating balance weights. The answer is (see Schedule 1), 14·4 pounds reciprocated by crank No. 1; 11·9 pounds reciprocated by crank No. 5; the lines of reciprocation lying in the plane containing the centre lines of the cylinders.

The masses may be designed as lumps of metal reciprocated in properly lubricated guides on the engine frame. They would then be called BOB WEIGHTS.[1] The engine would be described as a three-cylinder engine in which the reciprocating masses, that is the piston masses, were balanced by a pair of bob weights.

Each balance weight may, however, be designed into a set of piston masses and added complete with cylinder and valve gear to the engine. Then the engine would be described as a five-cylinder engine with the piston masses in balance amongst themselves.

The problem of balancing an engine, as stated in § (4), involves the separate solution of two problems. First find the reciprocating balance weights, and add them to the engine either as bob weights or as pistons. Secondly, find the balance weights for the revolving system of the crank shaft and add them to the crank shaft.

Each of these problems is separately solved by the application of the method given in § (5).

The deductions of § (7) apply equally to systems of reciprocating masses. It follows that the fewest number of cylinders in which the pistons may be set in mutual balance is four.

Much has been written about the balancing of four-cylinder engines. In practice, however, even for primary balancing, the valve gear must often be included to get the best results. In particular a four-cylinder torpedo-boat engine becomes with its valve gear a problem in balancing twelve lines of parts. There are some subsidiary problems involved in the complete solution, for which see the worked-out example in Dalby's *Balancing of Engines.*

(ii.) *Secondary Balancing.*—Since the second term of equation (1) above gives a force which is the projection on the line of stroke of a mass M revolving at twice the speed of the main crank at radius $R^2/4L$, the condition that the secondary forces shall balance is that the corresponding force and couple polygons shall close. A schedule is made, as illustrated in Schedule 1, and the work is carried out as in § (5), but with this difference: the end view of the shaft must now show all the crank angles doubled.

Balancing to satisfy the conditions of equation (1) is therefore conditioned by the closing of four polygons, namely, a primary force polygon, a primary couple polygon, a secondary force polygon, and a secondary couple polygon.

---

[1] "On the Balancing of Marine Engines," Sir Alfred Yarrow, *Trans. Inst. Naval Architects*, 1892.

Given an engine, there is no difficulty in applying § (5) to test the primary and secondary balance, but it is more convenient to deduce the related conditions analytically.

The following method affords a solution.[1]

The direction of a crank measured from a fixed line is defined by the expression x_1+iy_1, where $i=\sqrt{-1}$. x_1 is measured along the fixed direction. y_1 is measured at right angles to it. Also $x_1^2+y_1^2=1$.

The direction of a crank corresponding to this, starting in coincidence along the fixed direction and revolving twice as fast, is given by

$$x_1^2-y_1^2+i2y_1x_1.$$

If M_1 is the mass at radius R_1 the corresponding force and couple vectors are

Primary force—

$$M_1\omega^2R_1(x_1+iy_1), \quad . \quad . \quad . \quad . \quad (2)$$

Primary couple—

$$M_1\omega^2R_1(x_1+iy_1)a_1, \quad . \quad . \quad . \quad . \quad (3)$$

Secondary force—

$$\frac{M_1\omega^2R_1^2}{L}(x_1^2-y_1^2+i2x_1y_1), \quad . \quad . \quad (4)$$

Secondary couple—

$$\frac{M_1\omega^2R_1^2}{L}(x_1^2-y_1^2+i2x_1y_1)a_1. \quad . \quad . \quad (5)$$

Fig. 20 shows the relations of these quantities for one mass M_1.

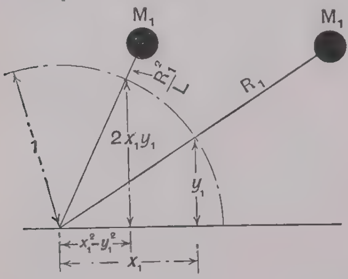

FIG. 20.

For every reciprocating mass there is a set of terms corresponding to these four expressions. The condition that the masses may balance is expressed by the eight simultaneous equations:

Primary forces vanish—

$$(M_1x_1+M_2x_2\ +\ +)=0.$$
$$(M_1y_1+M_2y_2\ +\ +)=0.$$

Primary couples vanish—

$$(M_1x_1a_1+M_2x_2a_2\ +\ +)=0.$$
$$(M_1y_1a_1+M_2y_2a_2\ +\ +)=0.$$

Secondary forces vanish—

$$(M_1(x_1^2-y_1^2)+M_2(x_2^2-y_2^2)+\ +)=0.$$
$$(M_1\,x_1y_1\qquad +M_2\,x_2y_2\qquad +\ +)=0.$$

Secondary couples vanish—

$$(M_1(x_1^2-y_1^2)a_1+M_2(x_2^2-y_2^2)a_2\ +\ +)=0.$$
$$(M_1\,x_1y_1a_1\qquad +M_2\,x_2y_2a_2\qquad +\ +)=0.$$

With the general relation $x^2+y^2=1$ for all x's and y's with the same subscript.

Each of these eight equations has one term for each reciprocating mass.

It is not possible to find a solution of any practical value with fewer than 5 lines of parts, that is, with 5 terms in each line. The engine could be built either as a five-cylinder engine or a three-cylinder engine with a pair of bob weights.

The exploration of the possibilities of balance with engines of different numbers of cranks will be found in the book cited above.

§ (11) THE YARROW SCHLICK TWEEDY MARINE ENGINE.—This is a four-cylinder engine with reciprocating parts balanced amongst themselves for primary forces and primary couples.

Later a four-cylinder symmetrically arranged engine with the reciprocating parts balanced amongst themselves for primary and secondary forces and for primary couples was used, and the method of getting this balance was described in a paper at the Naval Architects in 1900 by Schlick.

Although the eight fundamental equations of the preceding section cannot be simultaneously satisfied for an engine giving only four terms in each equation, yet it is possible to satisfy the first six of them with four terms per equation. Thus a four-crank engine can be set to satisfy the first six equations, and thus it can be designed for primary and secondary balance of the reciprocating forces and primary balance of the couples, but the secondary couples must remain unbalanced.

The symmetrical engine is indicated in *Fig.* 21. A reference plane is taken at the centre of the shaft

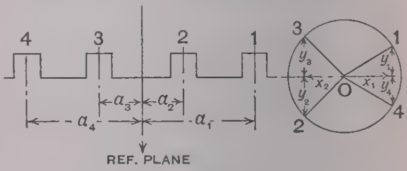

FIG. 21.

and the cranks are spaced so that $a_1=-a_4$. The angle 103 is made equal to the angle 204, and the mass M_1 is taken equal to the mass M_4. With these assumptions, the first six equations give

$$M_2=M_3 \text{ and } a_2=-a_3,$$

and further

$$x_1x_2=-\tfrac{1}{2}, \quad . \quad . \quad . \quad (1)$$

$$x_1^2=-P\pm\sqrt{P^2+Q^2}, \quad . \quad . \quad (2)$$

where

$$P=\frac{a_1^2-a_2^2}{8a_2^2} \text{ and } Q^2=\frac{a_1^2}{4a_2^2}$$

and

$$\frac{M_2}{2M_1}=x_1^2. \quad . \quad . \quad . \quad (3)$$

When the spacings a_1 and a_2 are given, x_1 is calculated from (2), and then x_2 from (1), and the ratio of the reciprocating masses from (3).

---

[1] Dalby, "On the Balancing of the Reciprocating Parts of Engines, including the Effect of the Connecting Rod," *Transactions of the Institution of Naval Architects*, 1901.

The solution of the first six equations with four terms per equation is not limited to the symmetrical engine.

The expressions for unsymmetrical engines are complicated. The general solution is given by Lorenz in *Dynamik der Kurbelgetriebe* (Leipzig, 1901), and Professor Ingles, in a paper printed in the *Transactions of the Institution of Naval Architects*, gives curves from which the graphical solution can be found for the proper given conditions.

It will be remembered that in the special construction given in § (9) for the four-crank engine the pole O can be chosen at random. The quantities then satisfy the first four of the eight equations. There is one position of the pole and one only which yields results which satisfy the first six equations. Schlick, in the paper mentioned above, gives a geometrical construction for finding this position for the symmetrical engine. See also study of the problem by G. T. Bennett in a paper entitled "The Balancing of the Four-Crank Engine," read before the International Congress of Mathematicians at Cambridge, August 1912; also a paper by Professor Inglis, *Trans. Inst. Naval Arch.*, 1911, Part 1.

The setting of the four main cranks derived from these six equations and the resulting four reciprocating masses produce balance only amongst themselves. The valve gear with its heavy reciprocating valves has received no consideration. In practice the valve gear must be brought into the problem to secure the best results. A compromise can be made which results in perfect primary balance for forces and couples of all the reciprocating parts, including the pistons and the valves, whilst the condition for secondary balance of the forces is nearly satisfied.

§ (12) THE BALANCING OF LOCOMOTIVES.[1]—Each coupling rod is imagined to be replaced by masses concentrated at the crank pins. The pins share the mass of a rod in the proportion in which they share its weight. Then by § (5) may be found the angular positions and the masses at crank radius to balance the revolving masses of each axle. A balance weight is usually cast with the wheel and is often shaped in the form of a crescent. Let m be the mass of the crescent-shaped balance weight, excluding the mass of the spokes passing through it, and let r be the radius of the mass centre, then by trial and error values of m and r must be found such that $mr = MR$, where M is the balancing mass at crank radius R.

The reciprocating masses are usually balanced by revolving masses placed in the driving wheels. These are combined with the masses required to balance the revolving parts, so that the balance weight seen in a driving wheel is the resultant of two balance weights, namely, one to balance the revolving masses, the other to balance the reciprocating masses. The balance weights added to balance the reciprocating masses are themselves unbalanced in the vertical direction and so produce a varying pressure on the rails. Let W be the static load on a driving wheel, that is, the load measured on a weigh bridge, and let m be the revolving mass at radius r added to balance the reciprocating masses, then the static load is alternately increased and diminished per revolution by the amount $m\omega^2 r/g$ pounds. Omega is here the angular velocity of the wheel in radians per second. It is more convenient to express the angular velocity in terms of the speed of the engine. Let V be the speed of the engine in miles per hour, and D the diameter of the wheel in feet, then the maximum and minimum load on the rail can be calculated from

$$W \pm \frac{0{\cdot}00012 mrV^2}{D^2} \text{ tons.}$$

An average type of coupled engine would have $W = 7\frac{1}{2}$ tons on the driving wheel, and if the reciprocating parts were fully balanced the second term may reach the value of 4 tons at 60 miles per hour even on a wheel as large as 7 feet diameter.

The rail load would then vary between 12½ tons and 3½ tons per revolution. This would be destructive to the permanent way, especially to the cross girders of bridges, but the tractive pull would be even. It is better from the permanent way point of view to leave the reciprocating masses unbalanced. But if this is done the 4 tons variation appears in the tractive pull. In practice a compromise is made and it is usual to balance only ⅔ of the reciprocating masses, leaving ⅓ to vary the tractive pull and throwing the effect of ⅔ on the permanent way.

Having decided what proportion of the reciprocating masses is to be balanced, proportionate masses are supposed concentrated on their respective crank pins. And since the balance weights are going to be added, not as reciprocating masses but as revolving masses, these masses can be included in the schedule of the revolving masses, and § (5) applied to find straight away the resultant balance weights for the driving axle.

When the driving wheel is small there may be difficulty in designing a suitable balance weight for it. The revolving balance weight added to balance the reciprocating masses may then be distributed between the coupled wheels equally or in any proportion thought suitable. The balance weight then seen in any one of the coupled wheels is the resultant of the balance weight required to balance its revolving masses, and the balance weight required to balance the proportion of the reciprocating mass transferred to it.

This distribution of the balance weight required to balance the reciprocating masses also distributes the hammer blow, as the variation of rail load is called. For example, the hammer blow of 4 tons under the driving wheel may be distributed to give 1·3 ton under each of three coupled wheels.

---

[1] "Steam Engine, Reciprocating," § (8).

The reciprocating masses of a four-cylinder locomotive may be balanced amongst themselves, as explained in § (10). The possibility is not, however, taken advantage of because the cranks are generally arranged in two 180° pairs at right angles.

It has been pointed out in § (7) (*c*) that this is the one angular spacing at which mutual balance is impossible. If the reciprocating masses are equal there is balance for the forces but the couple is unbalanced. This means that the reciprocating masses produced no variation of the tractive pull, neither is there any variation of rail pressure, so that there is no hammer blow. But the unbalanced couple acts on the engine to make it sway laterally. This swaying can be corrected by the addition of revolving masses in the driving wheel, but these masses, although without effect on the tractive pull, introduce a hammer blow.

If the angles and masses were designed to secure balance there would be no variation of tractive pull, no hammer blow, and no swaying couple. Four sets of valve gear would be required as against the two sets with which the four-cylinder locomotive is usually operated.

§ (13) THE BALANCING OF INTERNAL COMBUSTION ENGINES.—The petrol engine,[1] which before the war was used mainly to drive motor cars, has been developed during the war into a powerful prime mover for aircraft. Dynamically aircraft engines can be distinguished into three types:

Type A. An engine with its cylinders ranged in a line along the crank shaft so that the cylinder centre lines and the crank shaft axis lie in a plane.

Type B. The V engine formed by placing engines of type A to drive a common crank shaft and arranged about it so that the planes containing the centre lines of their cylinders intersect in the axis of the common crank shaft. Thus two four-cylinder engines of type A become an eight-cylinder V engine driving a four-crank shaft. Three four-cylinder engines of type A become a double V engine of twelve cylinders driving a four-crank shaft.

Type C. The radial engine in which the cylinder centre lines radiate from the centre of the crank shaft and all lie in a plane perpendicular to the axis of the crank shaft.

Internal combustion engines used in submarines, in factories, and in motor cars belong as a rule to class A.

The balancing of engines of type A has been considered in sections (5), (6), and (7), and from the results there given deductions can be drawn for a few arrangements found in internal combustion engines, but not yet specifically considered.

The four-crank engine of type A with equal reciprocating masses and with cranks set, the middle pair parallel and the outer pair parallel and at 180° with the middle pair, and with the cranks symmetrically pitched along the crank shaft, is the usual arrangement found in a four-crank motor car engine. With these conditions the reciprocating masses are balanced for primary forces, for primary, secondary, and all higher orders of couples, but are unbalanced for secondary forces.

The unbalanced secondary force may be shown to be

$$\frac{4M\omega^2r^2}{gL}\cos 2\theta \text{ lbs.-wt.}$$

acting vertically at the centre of the crank shaft.

M is the mass in pounds of one set of reciprocating parts, r is the crank radius in feet, L is the length of the connecting rod in feet, and ω is the angular velocity in radians per second. This reduces to very nearly $(5Mn^2r^2/L)\cos 2\theta$, using for g, 32·2. $n=$revolutions per second.

An eight-cylinder V engine formed by setting two four-cylinder engines of the above kind together at an angle of 90° is therefore balanced for primary forces, for primary and secondary and all higher orders of couples, but is unbalanced for secondary forces.

The unbalanced secondary force is the resultant of the unbalanced secondary force from each of the four-cylinder engines. This has just been shown to have the value $(5Mn^2r^2/L)\cos 2\theta$.

Combining these together it will be found that the magnitude of the resultant is very nearly $(7Mn^2r^2/L)\cos 2\theta$, and that this alternating force acts horizontally.

The 6-cylinder engine of type A with equal reciprocating masses and cranks set, the inner pair parallel, the next pair parallel and at 120° with the inner pair, and the outer pair parallel and at 240° with the inner pair, and with the pairs symmetrically pitched along the crank shaft, is balanced for primary and secondary forces and higher orders, excluding orders divisible by 3; and for primary and secondary and all higher orders of couples. Practically it is a perfectly balanced engine. V engines made up of six-cylinder engines of this kind are therefore in almost perfect balance.

---

[1] See "Petrol Engine, the Water-cooled"; "Aircraft Engines," Vol. IV.

The radial engine, type C, an equiangular n cylinder radial engine with the connecting rods coupled to one crank pin and with reciprocating masses per cylinder equal to M pounds, is balanced for primary reciprocating forces by a balance weight m opposite the crank pin calculated from

$$m = \frac{nM}{2} \text{ pounds at crank radius.}$$

This is valid for all values of n except 1 and 2.

If further M_1 at crank radius is the equivalent of the unbalanced revolving parts due to the crank arm, crank pin, and the n equal revolving parts of the connecting rods, the actual balance weight to be added at crank radius diametrically opposite the crank pin to balance the reciprocating parts and the revolving parts is $m + M_1$ pounds.

It is shown below that when the number of cylinders exceeds three, the secondary forces along the respective lines of stroke mutually balance.

If there are three cylinders, mutually at 120°, there is an unbalanced secondary force equivalent to that caused by a mass weighing $1\frac{1}{2}\ Mr^2/L$ pounds concentrated at the crank pin of a crank of radius r and revolving twice as fast as the main crank, but in the opposite direction.

These statements are proved as follows.

Let β be the angle between adjacent lines of stroke so that $\beta = 2\pi/n$. Reckoning the crank angle always in the positive direction from any one of the n lines of stroke in the engine, it will be seen from *Fig.* 22 that the crank angle reckoned from the kth line of stroke is $\theta + (k-1)\beta$.

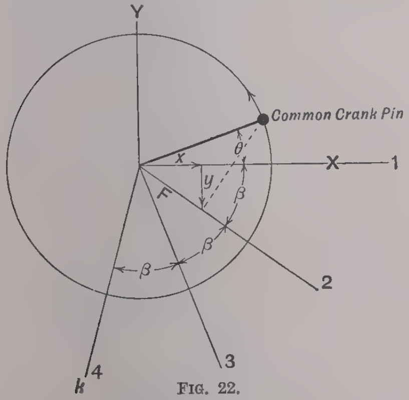

FIG. 22.

The force along the kth line of stroke is therefore

$$F = A\cos\{\theta + (k-1)\beta\} + B\cos 2\{\theta + (k-1)\beta\}$$

$$A = M\omega^2 r \text{ and } B = \frac{M\omega^2 r^2}{L}.$$

The simultaneous values of the force along each line of stroke is found from this equation by substituting in succession $k=1$, $k=2$, to $k=n$.

To find the resultant force on the frame, each of the forces is resolved into components along mutually perpendicular fixed axes and their resultant is determined. The statements made above are easily seen to follow.

These results only apply strictly when the connecting rods are coupled directly to the crank pin. If they are coupled through a floating big end, articulated as it is called, then the expression $A\cos\theta + B\cos 2\theta$ no longer gives the accelerating force in the line of stroke with accuracy.

Whatever be the mechanical arrangement, however, if the engine is balanced the mass centre of all the moving parts remains at rest during the motion. Particular arrangements can therefore be examined from this point of view.

In conclusion a point may be mentioned which is of importance in internal combustion engines. The driving torque on the crank shaft is necessarily accompanied by an equal and opposite reaction on the frame. If the driving torque varies periodically it tends to set the frame in torsional oscillation. This is minimised by increasing the number of cylinders and arranging the sequence of firing so that the torque curve shall be as uniform as possible. The eight-cylinder engine of type A gives a torque curve of least variation. The six-cylinder comes next. The four-cylinder has a large variation per revolution.

The addition of a flywheel, although controlling the variation of speed consequent upon torque variation, has no effect on the torsional reaction on the frame. That must follow every variation of the torque exerted by the crank shaft whether against a resistance or a resistance plus a flywheel. There is no difficulty in securing practical uniformity of torque in a steam engine.[1] W. E. D.

ENGINES, THERMODYNAMICS OF INTERNAL COMBUSTION

§ (1).—IN all fluids the pressure, volume, and temperature are so related that if any two of these be known the value of the third is determined. We may thus take as our independent variables the pressure and volume, or the pressure and temperature, or the volume and temperature. In considering the thermodynamics of internal combustion engines it is in general found most convenient in diagrams to take the pressure and volume as the independent variables.

---

[1] "A Comparison of Five Types of Engines," etc., W. E. Dalby, *Trans. Inst. Nav. Arch.*, 1902.

§ (2) Cycles of Operations.—When a definite quantity of any substance is subjected to a series of operations such that it returns finally to its initial condition in all respects, such a series is termed a "Cycle of Operations."

Carnot's conception of a cycle of operations as a convenient means of considering quantitatively the changes undergone by the working substance of an ideal heat engine has proved invaluable in the development of the modern science of thermodynamics; its special merit is that as the working substance returns exactly to its initial state at the end of the cycle, so also does its internal energy, and hence we avoid the problem of discussing the measure of the change of energy of the working substance from its initial to its final state.

In considering the performance of internal combustion engines it is found convenient to divide cycles of operation into two classes, viz. (*a*) perfect cycles, and (*b*) imperfect cycles.

A cycle is said to be perfect when it is of maximum efficiency for the temperature range within which the engine works.

A perfect cycle is reversible, *i.e.* if the engine be worked backwards the heat transferences at each stage are exactly reversed.

A cycle is said to be imperfect when its efficiency is necessarily less than that of a perfect cycle for the same temperature range.

All the cycles of operation employed in actual internal combustion engines are imperfect in this sense; owing to the nature of the operations performed, their maximum efficiency is in every case necessarily less than the conceivable maximum for the range of temperature involved; the reasons for this are fully discussed later.

§ (3) Isothermal and Adiabatic Changes.[1]—When the supply of heat to a substance is so regulated that its simultaneous changes of pressure and volume take place without change of temperature, the changes are termed isothermal.

When simultaneous changes of pressure and volume take place in a substance completely heat-insulated from all external bodies, so that there can be neither loss nor gain of heat, the changes are said to be adiabatic. Expansion takes place, in general, against some external resistance (as, *e.g.*, that offered by atmospheric pressure, or a loaded piston), and hence mechanical work must be done by the expanding substance in order to overcome this external resistance. Anticipating the first law of thermodynamics, it is evident that if heat be supplied to the expanding substance some, at least, of this will be expended in the external work of expansion. On the other hand, if no heat be supplied to the expanding substance, the heat-equivalent of the external work done must be supplied from the store of energy of the substance itself (termed its internal energy), and its temperature will, in consequence, fall as the expansion proceeds. Clearly, then, on a pressure-volume diagram a curve indicating adiabatic changes from any initial condition is always steeper than a curve indicating isothermal changes from the same initial condition.

§ (4) The Two Laws of Thermodynamics. (i.) *The First Law.*—The first law asserts that heat is a form of energy; when heat is converted into mechanical work, or *vice versa*, the quantity of mechanical work done is simply proportional to the quantity of heat converted.

The British Thermal Unit (B.Th.U.) is the quantity of heat that will raise 1 lb. of water at, or near, its temperature of maximum density, through 1° F. This quantity of heat if wholly converted into mechanical energy will perform 778 ft.-lbs. of work. This, the "mechanical equivalent" of heat, is usually styled "Joule's equivalent" and denoted by the symbol J. If the centigrade scale of temperatures be used the value of the mechanical equivalent, then styled the C.Th.U., becomes approximately 1400 ft.-lbs. (See "Heat, Mechanical Equivalent of," § (9).)

(ii.) *The Second Law.*—This puts on record our experience that heat, unaided, is unable to pass from one body to another at a higher temperature. Clausius' enunciation of this law is as follows: "It is impossible for a self-acting machine, unaided by any external agency, to convey heat from one body to another at a higher temperature." (See "Thermodynamics," § (1).)

§ (5) Carnot's Ideal Cycle.—The cycle imagined by Carnot comprises two isotherms and two adiabatics. During the first operation the working substance—which may be any whatever—is caused to expand isothermally from 1 to 2 at a temperature T (*Fig.* 1), receiving during this operation a quantity of heat which may be denoted by H. At some point 2 the heat supply ceases, and the expansion continues adiabatically until a point 3 is reached. At 3 the third operation commences, viz. that of isothermal compression at some lower temperature *t*, to a point 4, such that on further compressing adiabatically from 4, the point 1 is again reached; during

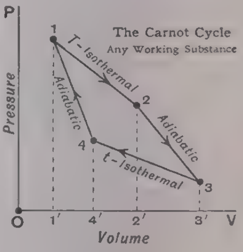

Fig. 1.

---

[1] See also "Thermodynamics," §§ (15), (16).

the isothermal compression $\overline{34}$ a quantity of heat, *h*, is abstracted from the working substance. During the isothermal and adiabatic expansions $\overline{12}$ and $\overline{23}$, mechanical work is done *by* the substance, measured by the areas 122′1′1 and 233′2′2 respectively. During the isothermal and adiabatic compressions $\overline{34}$ and $\overline{41}$, mechanical work is done *on* the substance, measured by the areas 344′3′3, 411′4′4 respectively. The complete cycle of operations leaves, therefore, a quantity of "useful work" done *by* the substance represented by the area $\overline{1234}$ obtained by the expenditure of a quantity of heat H, of which a part, *h*, is rejected. By the First Law of Thermodynamics, therefore, the useful mechanical work U (measured, for convenience, in heat-units) must be given by the relation

$$\mathrm{U}=\mathrm{H}-h. \qquad . \quad . \quad . \quad (1)$$

And the efficiency of the cycle, being the ratio of the useful work obtained to the energy expended, is

$$\text{Efficiency}=\frac{\mathrm{U}}{\mathrm{H}}=\frac{\mathrm{H}-h}{\mathrm{H}}=1-\frac{h}{\mathrm{H}}. \quad . \quad (2)$$

This equation expresses the efficiency of the Carnot cycle in terms of the heat received at the upper limit of temperature T, and that rejected at the lower limit *t*.

Moreover, the cycle is reversible; if the engine be worked backwards and an amount of energy U be given to the working substance, it will draw heat *h* from the sink at temperature *t* and give heat H to the source at temperature T, passing through all the stages passed through during the direct process, and being in the same condition in all respects at each corresponding stage in the two.

§ (6) THE CARNOT CYCLE A "PERFECT" CYCLE.—No conceivable engine, whatever its cycle, working between T and *t* can have a greater efficiency than the Carnot engine. For if it be possible, let there be such an engine X using the same "source" of heat at temperature T, and the same "sink" of heat at temperature *t*.

Let X be so coupled to the Carnot engine as to drive it backwards without doing external work; then during each revolution of the coupled engines the following exchanges take place:

Engine X takes heat H′ from the T-source, rejects heat *h*′ to the *t*-sink, and performs mechanical work U = H′ − *h*′; and

The Carnot engine is reversible, and working backwards takes in heat *h* from the *t*-source, and rejects heat H into the T-source in virtue of mechanical work U done upon it, given by U = H − *h*. Thus, on the whole, no mechanical work is done, and H − *h* = H′ − *h*′; hence H − H′ = *h* − *h*′. But since X is the more efficient engine, it does the work U for a less expenditure of heat from the source than that required by the Carnot engine. Thus H′ is less than H, and hence *h*′ is less than *h*. Thus the source at temperature T gains heat H − H′, and the sink at a lower temperature *t* loses an equal amount of heat *h* − *h*′. Hence by means of an inanimate material agency—the two engines coupled—heat is transferred from a body at temperature *t* to one at a higher temperature T, in violation of the Second Law of Thermodynamics. Thus engine X cannot have a greater efficiency, working between T and *t*, than that of the Carnot engine between the same temperatures.

Hence the Carnot cycle is of maximum efficiency, *i.e.* is a "Perfect" cycle.

It immediately follows that, within the same temperature range, all perfect cycles are of equal efficiency, the value of which in terms of heat received and heat rejected is as given in equation (2).

§ (7) KELVIN'S ABSOLUTE SCALE OF TEMPERATURE.—Equation (2) expresses the efficiency in terms of heat quantities; it is next necessary to show how the efficiency may be expressed in terms of the limiting temperatures themselves.

Let A_1E_1 (*Fig.* 2) represent a portion of an isothermal, at temperature T_1, of the working substance, which may be any whatever. Along A_1E_1 let points B_1, C_1, D_1 be taken such that the expansions A_1B_1, B_1C_1, C_1D_1 correspond to the addition of equal quantities of heat, H_1, at the constant temperature T_1; and through A_1, B_1, C_1 draw a series of adiabatics of the substance.

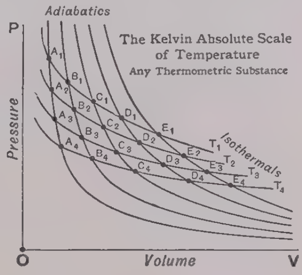

FIG. 2.

Let $A_2B_2C_2$ be a second isothermal of the substance corresponding to some lower temperature T_2.

Then the quadrilaterals A_1B_2, B_1C_2, C_1D_2 are all equal; for each is the useful-work-area, U, of a Carnot engine diagram receiving heat H_1 at the higher temperature T_1, and rejecting heat at the lower temperature T_2. Moreover, since the efficiency is the same for each of these perfect cycles the amount of heat rejected at the lower temperature T_2 is the same for each. Let it be H_2. Hence, also A_2B_2, B_2C_2, C_2D_2

represent the isothermal changes at T_2 due to equal additions of heat, H_2, to the substance. Next suppose there to be drawn a series of isothermals $A_3B_3C_3$, $A_4B_4C_4$ such that the quadrilaterals A_1B_2, A_2B_3, A_3B_4 are all equal; then it is evident that the two series of isothermal and adiabatic curves divide up the whole diagram into quadrilaterals *of equal area.* Now Kelvin defined equal temperature intervals as those between any two consecutive isothermals of this series; as this system of graduating temperatures is independent of the nature of the thermometric substance employed, it is styled the absolute scale of temperature. On this scale it is immediately obvious from the diagram that the efficiency of a Carnot engine working between T_1 and T_3 is twice as great as that between T_1 and T_2; and between T_1 and T_4 three times as great: and, generally, that the efficiency is proportional to the difference between the upper and lower temperature limits *measured in this way, i.e.*

$$\frac{U}{H_1}=C(T_1-T_n), \quad . \quad . \quad . \quad (3)$$

where T_1 and T_n are the upper and lower absolute temperature limits respectively.

The constant quantity C must be independent of T_n, but may be a function of T_1. It is termed Carnot's Function, and its value is immediately determined from the consideration that as equation (3) is to hold whatever T_n may be, let T_n be supposed so reduced (see *Fig.* 3) that the whole of the heat H_1 is converted into useful work U. As U cannot conceivably be greater than this, it can only be inferred that when $U=H_1$ the temperature T_n is the zero of the Kelvin scale; thus $T_n=0$ when $U=H_1$; hence equation (3) gives in this case $1=CT_1$ or

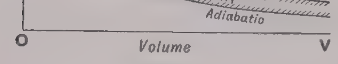

FIG. 3.

$$C=\frac{1}{T_1}. \quad . \quad . \quad . \quad . \quad (4)$$

Thus Carnot's function is the reciprocal of the temperature reckoned from the Kelvin absolute zero.

The efficiency of the Carnot cycle can now be expressed in terms of the absolute temperatures of the limits; for if these be T and t respectively we have from equations (3) and (4)

$$\text{Efficiency}=\frac{T-t}{T}=1-\frac{t}{T}, \quad . \quad . \quad (5)$$

and thus depends only on the *ratio* of the absolute temperatures between which the engine works. From equations (2) and (5) we have at once the important fundamental relation

$$\frac{H}{h}=\frac{T}{t}, \quad . \quad . \quad . \quad . \quad (6)$$

i.e.

$$\frac{\text{Heat received}}{\text{Heat rejected}}=\frac{\text{Abs. upper temp.}}{\text{Abs. lower temp.}} \quad (6')$$

§ (8) TEMPERATURES BY GAS-THERMOMETER.—Anticipating § (14) *et seq.*, we know that for an ideal perfect gas $pv=R\tau$, where τ is temperature as given by the gas-thermometer itself and R a constant; and it is easily shown,[1] by a direct and independent investigation, that with such a gas as working substance, the efficiency of the Carnot cycle is expressed by $1-\tau_2/\tau_1$, where τ_2 and τ_1 are the lower and upper gas-temperature limits respectively. Hence by equations (2) and (6) we have $h/H=\tau_2/\tau_1=t/T$;

$$\frac{\text{Kelvin abs. lower temp.}}{\text{Kelvin abs. upper temp.}}=\frac{\text{Gas-thermometer lower temp.}}{\text{Gas-thermometer upper temp.}}.$$

In the gas-thermometer scale, the temperature interval between the freezing and boiling points of water is divided into 100 equal degrees, and this leads to the zero occurring at 273° below the freezing-point of water. If the same size of degree be adopted for the Kelvin scale, then we shall have $T=\tau_1$ and $t=\tau_2$, and the readings, on either scale, will be identical. As the ordinary permanent gases approximate closely in their properties to those of a perfect gas,—within the temperature range occurring in internal combustion engines,—it is to be expected that the readings furnished by a gas-thermometer will correspond very closely with the temperatures of the Kelvin absolute scale. This is found to be the case, experiments by Joule and Kelvin on the flow of air and other "permanent" gases through porous plugs showing that for all practical purposes the readings of a gas-thermometer sensibly coincide with absolute temperatures on Kelvin's scale.[2]

Callendar (*Phil. Mag.*, 1903) has given tables showing the correction to be made with air, hydrogen, and other gas-thermometers in order to convert their readings to those of the Kelvin absolute scale. The correction is very small, amounting in the constant-volume hydrogen thermometer to not exceeding 1/10th of a degree between −10° C. and

---

[1] See "Thermodynamics," § (20).

[2] *Ibid.* § (12).

1000° C. With a constant-volume air thermometer the correction is slightly greater, but still very small. With gas-thermometers of the constant-pressure type the corrections are again slightly greater.

For all thermodynamic investigations on internal combustion engines, however, the readings of a gas-thermometer may be taken as absolute temperatures.

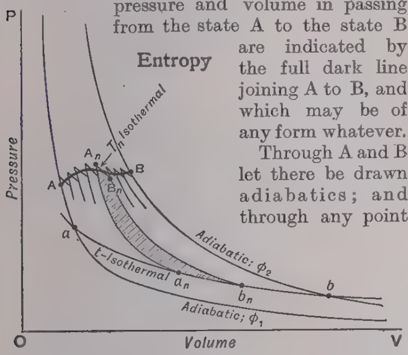

FIG. 4.

§ (9) ENTROPY.—Let AB (*Fig.* 4) be any two points on the pressure-volume diagram of a substance, and suppose that by the addition of heat simultaneous values of its pressure and volume in passing from the state A to the state B are indicated by the full dark line joining A to B, and which may be of any form whatever. Through A and B let there be drawn adiabatics; and through any point below A let there be drawn any isothermal, cutting these adiabatics in *a* and *b* respectively; and let *t* be the absolute temperature corresponding to the isothermal *ab*. Let the path from A to B be divided into a large number of small parts through each of which a small portion of an isothermal is drawn, as A_nB_n, the corresponding temperature being T_n, and through each extremity of each of these small isothermals let adiabatics be drawn cutting the *t*-isothermal ab. as at a_n, b_n. The whole area AB*ba* is thus divided up into a large number of elements, each of which is a Carnot engine diagram receiving heat H_n at temperature T_n during the isothermal expansion A_nB_n, and rejecting heat h_n at temperature *t* during the isothermal compression b_na_n. The work-area $A_nB_nb_na_nA_n$ being denoted by U_n, we have therefore, by equations (2) and (5),

$$U_n = H_n\left\{1-\frac{t}{T_n}\right\},$$

which may be written

$$H_n - U_n = t\frac{H_n}{T_n}. \quad . \quad . \quad . \quad (7)$$

Set out at length, therefore,

$$\{H_1+H_2+H_3+\ .\ .\ .\ \}-\{U_1+U_2+U_3+\ .\ .\ .\ \}$$
$$=t\left\{\frac{H_1}{T_1}+\frac{H_2}{T_2}+\frac{H_3}{T_3}+\ .\ .\ .\ \right\}.$$

But $h_n=(H_n-U_n)$ by equation (1); setting this out at length also we have

$$\{h_1+h_2+h_3+\ .\ .\ .\ \}=\{H_1+H_2+H_3+\ .\ .\ .\ \}$$
$$-\{U_1+U_2+U_3+\ .\ .\ .\ \},$$

and accordingly,

$$\{h_1+h_2+h_3+\ .\ .\ .\ \}=t\left\{\frac{H_1}{T_1}+\frac{H_2}{T_2}+\frac{H_3}{T_3}+\ .\ .\ .\ \right\}.$$

But $h_1+h_2+h_3+\ .\ .\ .\ =h$, the whole quantity of heat rejected by isothermal compression at *t*, from *b* to *a*; so that the result becomes

$$\left\{\frac{H_1}{T_1}+\frac{H_2}{T_2}+\frac{H_3}{T_3}+\ .\ .\ .\ \right\}=\frac{h}{t},\ \text{a constant},$$

whatever H_1, H_2, H_3 may be.

When the number of parts into which the path AB is divided is indefinitely great, each of the quantities H_1, H_2, H_3, etc., is properly denoted by *d*H, and we thus obtain the remarkable and important result

$$\int_A^B\frac{dH}{T}=\frac{h}{t},\ \text{a constant.} \quad . \quad . \quad (8)$$

This is true whatever the form of the path between A and B; it is true wherever A and B be taken on their respective adiabatics; and it is also true wherever the isothermal *ab* be drawn. The result may be expressed verbally as follows: For any working substance let any two adiabatics be drawn; take any point on one and any second point on the other; by means of a heat supply to the substance, varying in any manner whatever, let the condition of the substance be changed from that denoted by the first point to that denoted by the second; divide each very small addition of heat, whatever its source, by the absolute temperature at which it is added. Then the algebraical sum of these quotients is constant in value.

Along any adiabatic $dH=0$ by definition; thus in this case $\int_A^B dH/T=0$.

Hence (*Fig.* 4), $\int_A^B dH/T$ indicates a *quantity* which increases by a constant amount as we pass from one adiabatic A*a* to another B*b*. Clausius gave the name Entropy to the value of the integral $\int_0^A dH/T$ taken from some unknown zero of entropy up to the state A. It is a function only of the state of the body. The zero of entropy is that of a body entirely deprived of heat, a condition unknown to us, but since we are concerned only with the changes of entropy this is immaterial, and equation (8) may be interpreted as expressing the fact that $\int_A^B dH/T$, the difference of the entropies of the two conditions A and B, is a constant. Entropy is usually denoted by the symbol ϕ; if, then, ϕ_1 be that of A and ϕ_2 that of B, we have, starting from any arbitrary zero,

$$\phi_1=\int_0^A\frac{dH}{T},\quad \phi_2=\int_0^B\frac{dH}{T},$$

and hence $$\phi_2-\phi_1=\int_A^B\frac{dH}{T}. \quad . \quad . \quad . \quad (9)$$

Practically entropy is reckoned from some assumed standard condition, as, *e.g.*, for unit mass at one atmosphere of pressure and 0° C. or 100° C. temperature. As along any adiabatic the entropy is of constant value, all adiabatics are also isentropics.

If an element of heat, dH, be added at absolute temperature T to a substance, the corresponding change of entropy is $d\phi$; by equation (8) $d\phi=dH/T$. This may also be written $dH=Td\phi$, and $dH/d\phi=T$. Or, for a finite change,

$$\int dH=\int Td\phi. \quad . \quad . \quad . \quad (10)$$

The value of the entropy is easily determined in any specific case, as is shown later in this article (*vide* § (25)). *Fig.* 5 shows a temperature-entropy diagram; it is usual to take the temperatures as ordinates and entropy as abscissae; let AB be a curve connecting temperature and entropy, and from any points C ($\phi_1 T_1$) and D ($\phi_2 T_2$) on this curve draw ordinates CM and DN respectively; then

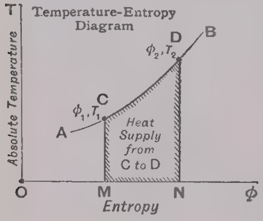

FIG. 5.

$$\int_C^D dH=\int_{\phi_1}^{\phi_2}Td\phi=\text{area MCDNM}.$$

Hence the hatched area measures the heat supply to the substance from condition C to condition D. On the temperature-entropy, or "$T-\phi$" diagram all isothermals obviously appear as horizontal lines, and all adiabatics (isentropics) as vertical lines, as indicated in *Fig.* 6; thus the $T-\phi$ diagram of any engine working on the Carnot cycle, whatever the working substance, is a rectangle as 12341, $\overline{12}$ representing the isothermal expansion at temperature T, $\overline{23}$ the adiabatic expansion from T to t, $\overline{34}$ the isothermal compression at t, and $\overline{41}$ the adiabatic compression from t to T (compare *Fig.* 1). The area M12NM represents H, the heat supplied during $\overline{12}$, while N34MN represents h, the heat rejected during $\overline{34}$; hence the closed area $\overline{12341}$ represents $(H-h)$, *i.e.* U, the heat converted into useful work. And it is immediately obvious from this diagram that the efficiency, U/H, being the ratio of the areas $\overline{12341}$ and M12NM, is also expressed by $(T-t)/T$.

And, generally, the "$T-\phi$" diagram of an engine working on any cycle is represented by an enclosed figure as, *e.g.*, that shown hatched in *Fig.* 7, the area of which represents the useful work performed just as in the case of a *pv* diagram. Through the four extreme points of the boundary of this hatched area let horizontal and vertical lines be drawn as shown. Then the actual engine receives per cycle heat H' represented by the area MABCNM, and rejects heat h', represented by NCDAMN, its efficiency being

$$\frac{H'-h'}{H'},\ i.e.\ 1-\frac{h'}{H'}.$$

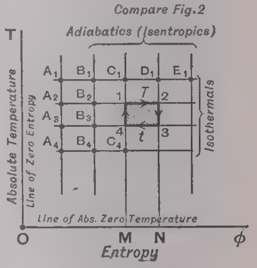

FIG. 6.

Now the temperatures between which this engine works are T and t; and 12341 is the $T-\phi$ diagram of a Carnot engine working between the same temperatures, H being now represented by M12NM, and h by N34MN.

It is obvious that M12NM is greater than MABCNM and that N34MN is less than NCDAMN, that is, that H is greater than H', and h less than h'; thus h/H is less than h'/H'; and, therefore, $(1-h/H)$ is always greater than $(1-h'/H')$; that is, the efficiency of the perfect cycle engine is a maximum, as has already been shown otherwise.

§ (10) ENTROPY IN A COMPLETE CYCLE.—Whatever the cycle of an engine, whether perfect or not, the working substance returns at the end of each cycle to its initial condition in all respects, and thus in a complete cycle there is no change of entropy; or, symbolically, for any complete cycle:

$$\int\frac{dH}{T}=0. \quad . \quad . \quad . \quad (11)$$

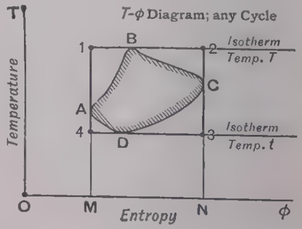

FIG. 7.

In interpreting this equation all heat gained or lost by the substance *as heat*, whatever its source, is to be included. If, for example, the cycle includes processes, as of "unbalanced expansion," any heat generated within the substance itself during the subsidence of its turbulent motions must be included in the summation of equation (11). Any heat so generated is clearly a positive addition to the entropy summation.

If heat acquired by the substance in this, or other analogous manner, be not included in the summation, then it will be necessary to assert that only for any perfect cycle is equation (11) true, and that for an imperfect cycle $\int dH/T$ is negative.

§ (11) TEMPERATURE-ENTROPY DIAGRAMS.—These have proved of much value in studying the action of heat engines using water-steam as the working substance, but have not so far been much used in investigations connected with internal combustion engines.

Among further graphic aids to the study of heat engines may be mentioned the diagrams, introduced by Dr. Mollier in 1904, of total-heat entropy ($H\phi$), and total-heat pressure (Hp); both of these have already been found of service in steam-engine and steam-turbine problems, but they have not yet been employed in connection with internal combustion engines.

§ (12) PERFECT GASES.—For the so-called "permanent" gases, of which (dry) air is the type, experiment has established the following results, termed the Gaseous Laws; they are conformed to by actual gases the more closely as they are raised in temperature the more highly above their condensation-point, that is, the more highly they are superheated. These Gaseous Laws are to be regarded, therefore, as the properties that would be exactly possessed by an absolutely ideal gas.

§ (13) LAW 1 (BOYLE'S LAW).—If temperature remains constant, then the product of pressure by volume is also constant. Hence the isotherms of a perfect gas on a pv diagram are rectangular hyperbolas with the coordinate axes as asymptotes.

§ (14) LAW 2 (CHARLES'S LAW).—Under constant pressure all gases expand at one uniform rate with increase of temperature. As by Law 1, $v \propto 1/p$ when T is constant, and by Law 2, $v \propto T$ when p is constant, it follows that $v \propto T/p$ when both T and p change, *i.e.* $v = R(T/p)$ where R is some constant. This result, combining Laws 1 and 2 in one statement, is usually written

$$pv = RT, \quad . \quad . \quad . \quad (12)$$

and is termed the "Characteristic Equation" of a perfect gas.

If pv and T suffer simultaneous increments Δp, Δv, ΔT respectively, then, as equation (12) always holds, we must have

$$(p+\Delta p)(v+\Delta v) = R(T+\Delta T),$$

i.e.
$$p\Delta v + v\Delta p + \Delta p\Delta v = R\Delta T,$$

and accordingly, in the limit, when the increments are indefinitely diminished,

$$pdv + vdp = RdT \quad . \quad . \quad (12\text{A})$$

is the invariable relation connecting dv, dp, and dT.

Here T is strictly the temperature measured on the absolute scale (§ (7)), but for all practical purposes the reading of a gas thermometer, or a good mercurial thermometer, is sufficiently accurate (*vide* § (8)). From equation (12) it appears that the expression pv/R measures the absolute temperature of a gas, and this property is much used in investigations of the action of internal combustion engines. The value of the constant R is determined in any specific case when the condition of the gas is known at any one instant. Thus for 1 lb. of air at 0° C. (T=273° C. abs.), when p is 14·7 lbs. per sq. in. (=2117 lbs. per sq. ft.), it is found that the volume v is 12·39 cub. ft.; hence from equation (12) $2117 \times 12{\cdot}39 = R \times 273$, whence $R = 96$. Accordingly for air the characteristic equation is

$$pv = 96T. \quad . \quad . \quad . \quad (12')$$

§ (15) LAW 3 (REGNAULT'S LAW).—The specific heat at constant pressure is constant for any perfect gas. This quantity $(\delta H/\delta T)_p$ is commonly denoted by k_p.

Another important mode in which a gas may receive heat is at constant volume. The specific heat at constant volume $(\delta H/\delta T)_v$ is usually denoted by k_v. For air as the result of careful experiment the value of k_p was determined by Regnault[1] as 0·2375 C.Th.U. per lb.; from this the value of k_v is obtained, by calculation, as 0·1689 C.Th.U. per lb.[1]

§ (16) LAW 4 (JOULE'S LAW).—If a gas expands without doing any external work, its temperature remains unaltered. The volume of a gas is always maintained by some external pressure, and if a gas expands mechanical work is necessarily done by it in overcoming this external pressure. If the gas be heat-insulated from all external sources, experience shows that its temperature rapidly falls during expansion; the external work is done at the expense of the internal energy of the gas. When there is no external work done there is no loss of internal energy, and, as Joule's Law shows, no loss of temperature; and this is true whatever the pressure of the gas. Hence it is concluded that the internal energy of a gas is proportional to its absolute temperature. Thus in a perfect gas isothermal curves are also curves of equal internal energy, *i.e.* are "Isenergics."

---

[1] These values are now considered to be too low; *vide* § (73); also in actual gases the values are not constant.

§ (17) SYMBOLIC EXPRESSION OF THE FIRST LAW OF THERMODYNAMICS.—In general, when heat is supplied to a perfect gas, the pressure, volume, and temperature all undergo change, though at each instant the characteristic equation $pv=RT$ remains true. Suppose the addition of a small quantity of heat ΔH, to a gas at p, v, T, to cause these quantities to become $(p+\Delta p)$, $(v+\Delta v)$, $(T+\Delta T)$ respectively. The effect may be considered to be produced in two steps, viz. (1) a rise in temperature of ΔT (with corresponding rise in pressure Δp) at constant volume, and (2) an expansion at constant temperature between T and $(T+\Delta T)$ through a volume Δv.

The heat necessary to produce the first step is $k_v \Delta T$, k_v being by definition the quantity of heat necessary to raise the gas through 1° C. at constant volume. For the second step the expansion at constant temperature requires an amount of heat equivalent to the external work done, which lies between $p\Delta v$ and $(p+\Delta p)\Delta v$. And the sum of these two quantities is ΔH. Hence, in the limiting case we have

$$dH \quad = \quad k_v dT \quad + \quad \frac{pdv}{J}, \quad (13)$$

$$i.e.\ \text{Heat supplied} = \left\{\begin{array}{c}\text{Increase of}\\ \text{internal}\\ \text{energy}\end{array}\right\} + \begin{array}{c}\text{Ext. work}\\ \text{done,}\end{array}$$

where J is Joule's equivalent (§ (4)). This is the symbolic form of the First Law of Thermodynamics in the case of perfect gases.

§ (18).—Several fundamentally important results are immediately deducible from this equation. Thus, in isothermal or "isenergic" expansion T is constant; hence $k_v dT=0$; and accordingly in this case

$$dH=\frac{pdv}{J}, \quad . \quad . \quad . \quad (14)$$

so that the heat supplied is the exact equivalent of the external work done, the internal energy of the gas remaining unchanged. And, conversely, if a gas be isothermally compressed, the heat emitted is the exact equivalent of the work done upon the gas in compressing it. Integrating equation (14) we have, denoting by H, the heat supply necessary to change the volume from V_o to v isothermally:

$$H=\int_{v_o}^{v}\frac{p}{J}dv=\int_{v_o}^{v}\frac{p_o v_o}{J}\,\frac{dv}{v}=\frac{p_o v_o}{J}\log_e\left(\frac{v}{v_o}\right). \quad (15)$$

The volume ratio of expansion (v/v_o) is usually denoted by r; hence (15) is also written

Heat supplied = Ext. work of expansion

$$=\frac{p_o v_o}{J}\log_e r \quad \frac{RT_o}{J}\log r \quad . \quad (15')$$

in thermal units, T_o being the absolute isothermal-expansion-temperature.

§ (19) RELATION OF k_v TO k_p.—With the same initial suppositions as in § (17), if the addition of ΔH to the gas produces a rise of temperature ΔT (and corresponding volume increase Δv) at constant pressure p, then by the definition of k_p we have at once $\Delta H=k_p\Delta T$; and, in the limit, $dH=k_p dT$; and the final state of the gas being exactly the same in each case, we may write

$$dH=k_p dT=k_v dT+\frac{1}{J}pdv.$$

But $pv=RT$, and as p is here constant, $p(dv/dT)=R$, *i.e.* $pdv=RdT$; hence

$$k_p dT=k_v dT+\frac{R}{J}dT,$$

so that

$$k_p-k_v=\frac{R}{J}, \quad . \quad . \quad . \quad (16)$$

that is, of course, the difference of the two specific heats is the thermal value of the external work done in raising 1 lb. of the gas through 1° C. at constant pressure. The constant $R=p(dv/dT)$ is the measure of this external work in ft.-lbs.

(i.) *Value of k_v for Air.*—Regarded as a perfect gas, the constant value of k_v for air can now be calculated; for we have seen (equation (12′)) that $R=96$, also $k_p=0{\cdot}2375$, and J has been experimentally determined as 1400 ft.-lbs. per C.Th.U.: hence by (16)

$$0{\cdot}2375-k_v=\frac{96}{1400},$$

whence $\quad k_v=0{\cdot}1689$ C.Th.U per lb.

as already stated.

(ii.) *Ratio of k_p/k_v; Value of γ.*—The ratio of k_p/k_v, always denoted by γ, is of fundamental importance in all thermodynamic investigations; in the case of air, regarded as a perfect gas, we see that

$$\gamma=\frac{k_p}{k_v}=\frac{0{\cdot}2375}{0{\cdot}1689}=1{\cdot}406.$$

Assuming all heat-quantities to be expressed as energy in ft.-lbs.

Equation (13) becomes

$$dH=k_v dT+pdv, \quad . \quad . \quad . \quad (13\text{A})$$

while from equation (16)

$$R=k_p-k_v=k_v(\gamma-1).$$

Hence by equation (12A)

$$RdT=k_v(\gamma-1). \quad dT=pdv+vdp,$$

so that

$$k_v dT=\frac{1}{\gamma-1}\{pdv+vdp\};$$

and accordingly (13A) becomes

$$dH=\frac{1}{\gamma-1}\{vdp+\gamma pdv\}, \quad . \quad . \quad (13\text{B})$$

which may also be written

$$\frac{dH}{dv}=\frac{1}{\gamma-1}\{v\frac{dp}{dv}+\gamma p\}. \quad . \quad . \quad (13\text{C})$$

This equation is sometimes useful in the analysis of actual indicator diagrams of internal combustion engines.[1]

The following formula giving $H-H_o$ readily in work-units, in terms of quantities easily measured from an ordinary indicator (pv) diagram, is also worthy of notice. We have

$$T=\frac{1}{R}pv;$$

hence $$dT=\frac{1}{R}d\overline{pv};$$

and thus equation (13A) becomes

$$dH=\frac{k_v}{R}d\overline{pv}+pdv,$$

i.e. $$dH=\frac{1}{\gamma-1}d\overline{pv}+pdv.$$

Integrating all across from ($p_o v_o H_o$) to (pvH) gives

$$H-H_o=\frac{1}{\gamma-1}(pv-p_o v_o)+\int_{v_o}^{v}pdv. \quad . \quad (13A')$$

Thus $(H-H_o)$ is determined as p, v, p_o, and v_o are directly measurable, and $\int_{v_o}^{v}pdv$ is readily found by planimetric measurement from the indicator diagram.

If the actual expansion (or compression) curve of a diagram can be resumed by an equation of the form $pv^n=$constant (*vide* § (22) *infra*), we have by differentiation

$$v^n\frac{dp}{dv}+nv^{n-1}p=0,$$

i.e. $$v\frac{dp}{dv}=-np;$$

hence in this case equation (13C) takes the very simple form

$$\frac{dH}{dv}=\frac{\gamma-n}{\gamma-1}p. \quad . \quad . \quad . \quad (13D)$$

If, during expansion, the gas loses heat, dH/dv is negative and hence n must be greater than γ.

If, during compression, the gas loses heat, then as $dH=(\gamma-n/\gamma-1)pdv$ and both dH and dv are negative, n must be less than γ.[2]

When $pv^n=a$, a constant, $p=av^{-n}$, and thus equation (13D) may be written

$$\int dH=\frac{\gamma-n}{\gamma-1}a\int v^{-n}dv;$$

on integration and reduction this gives

$$H-H_o=\frac{\gamma-n}{\gamma-1}\,\frac{1}{1-n}(pv-p_o v_o); \quad . \quad (13E)$$

see also equation (35) *infra.*

§ (20) THE ADIABATIC EQUATION OF A PERFECT GAS.—In adiabatic changes no heat enters or leaves the gas, and hence in equation (13) we symbolise this condition by putting $dH=0$. Thus in adiabatic change we have

$$k_v dT+\frac{1}{J}pdv=0, \quad . \quad . \quad (17)$$

which expresses that in this mode of expansion the external work is done wholly at the expense of the internal energy of the gas.

As $p=RT/v$, and $R=J(k_p-k_v)=Jk_v(\gamma-1)$, we may write (17)

$$k_v dT+k_v(\gamma-1)T\frac{dv}{v}=0;$$

that is $$\frac{dT}{T}+(\gamma-1)\frac{dv}{v}=0. \quad (18)$$

Integrating, $\log_\epsilon T+(\gamma-1)$, $\log_\epsilon v=b$, a constant. If T_o and v_o be datum temperature and volume respectively,

$$b=\log_\epsilon T_o+(\gamma-1)\log_\epsilon v_0.$$

Hence

$$\log_\epsilon\left(\frac{T}{T_o}\right)+(\gamma-1)\log_\epsilon\left(\frac{v}{v_o}\right)=0,$$

i.e. $$\log_\epsilon\left(\frac{T}{T_o}\right)\left(\frac{v}{v_o}\right)^{\gamma-1}=0,$$

and thus $$\left(\frac{T}{T_o}\right)\left(\frac{v}{v_o}\right)^{\gamma-1}=1. \quad . \quad . \quad (19)$$

This is the adiabatic equation of a perfect gas in terms of volume and temperature. As $pv=RT$ always, equation (19) may easily be expressed in one of the following three ways:

$$pv^\gamma=p_0 v_0{}^\gamma \;.\;.\;.\; \text{a constant}, \quad . \quad (20)$$

$$T=T_0\left(\frac{p}{p_0}\right)^{1-\frac{1}{\gamma}}, \quad . \quad . \quad (21)$$

$$T=T_0\left(\frac{v_0}{v}\right)^{\gamma-1}. \quad . \quad . \quad . \quad (22)$$

§ (21) EXPANSION TO INFINITY.—If unit mass of a perfect gas be expanded (1) isothermally and (2) adiabatically, from an initial condition p_o, v_o, T_o, to an infinite volume, the external work done being $\int_{v_0}^{\infty}$, pdv is infinite in the isothermal case, by equation (15′). In the adiabatic case, however, we have

$$\text{Work to infinity}=\int_{v_0}^{\infty}pdv=p_o v_o{}^\gamma\int^{\infty}v^{-\gamma}dv$$

by equation (20); that is,

$$\text{Work to infinity}=-p_o v_o{}^\gamma\times\frac{v_o{}^{-\gamma+1}}{-\gamma+1}=\frac{p_o v_o}{(\gamma-1)}. \quad (23)$$

As $p_o v_o=RT_o=k_v(\gamma-1)T_o$, this may also be written

$$\text{Work to infinity}=k_v T_o, \quad . \quad (24)$$

an obvious truth, as in this case the whole internal energy of the gas is converted into external work.

For 1 lb. of dry air at 0° C. and one atmosphere pressure, regarded as a perfect gas, the external work done in expanding to infinity would thus be $0{\cdot}1689\times273=46{\cdot}1$. C.Th.U. $=64{,}540$ ft.-lbs., or 28·8 ft.-tons. As $v_o=12{\cdot}39$ cub. ft. this may also be expressed by saying that 1 cub. ft. at 0° C. and one atmosphere, expanding to infinity in the circumstances here supposed, would perform about $2\frac{1}{3}$ ft.-tons of work.

---

[2] Ayrton and Perry, *Proc. Phys. Soc.*, 1885.

§ (22) CURVES OF EQUATION pv^n = CONSTANT.—All the curves of this family have a general resemblance to the hyperbola for positive values of the constant index n, the co-ordinate axes being asymptotes. Such curves are frequently of service in the study of heat-engine diagrams as it is often found possible to express actual compression or expansion curves by assigning a suitable value to n.[1] It is thus useful to establish some geometric and thermodynamic properties connected with them.

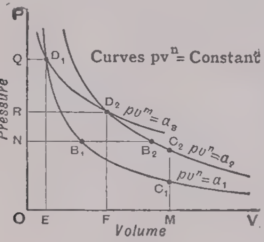

FIG. 8.

Thus (*Fig.* 8), let $D_1B_1C_1$, $D_2B_2C_2$ be two curves whose equations are $pv^n=a_1$, $pv^n=a_2$ respectively.

Property 1.—Let these two curves be cut by any horizontal, *i.e.* constant pressure, line NB_1B_2. Denote NB_1 by v_1, NB_2 by v_2, and ON by p.

Then
$$\frac{pv_2^n}{pv_1^n}=\frac{a_2}{a_1},$$
and therefore
$$\left(\frac{v_2}{v_1}\right)=\left(\frac{a_2}{a_1}\right)^{\frac{1}{n}}, \text{ a constant} \quad . \quad . \quad (25)$$

Hence any horizontal (constant pressure) line cuts the two curves in such manner that the ratio NB_2/NB_1, *i.e.* v_2/v_1, is constant.

Property 2.—Let the same two curves be cut by any vertical, *i.e.* constant volume, line MC_1C_2. Denote MC_1 by p_1, MC_2 by p_2, and OM by v.

Then
$$\frac{p_2v^n}{p_1v^n}=\frac{a_2}{a_1},$$
and therefore
$$\frac{p_2}{p_1}=\frac{a_2}{a_1} \text{ a constant.} \quad . \quad . \quad . \quad (26)$$

Hence any vertical (constant volume) line cuts the two curves in such manner that the ratio MC_2/MC_1, *i.e.* p_2/p_1, is constant.

Property 3.—Let the same two curves be cut by a third curve D_1D_2 whose equation is $pv^m=a_3$. Denote QD_1 by v_1, RD_2 by v_2, ED_1 by p_1, and FD_2 by p_2.

Then
$$p_1v_1^n=a_1,\ p_1v_1^m=a_3.\ p_2v_2^n=a_2,\ p_2v_2^m=a_3.$$

Hence
$$\frac{p_2v_2^n}{p_2v_2^m}\cdot\frac{p_1v_1^m}{p_1v_1^n}=\frac{a_2\times a_3}{a_3\times a_1},$$

i.e.
$$\left(\frac{v_2}{v_1}\right)^{n-m}=\frac{a_2}{a_1},$$

and therefore
$$\left(\frac{v_2}{v_1}\right)=\left(\frac{a_2}{a_1}\right)^{\frac{1}{n-m}}, \text{ a constant.} \quad (27)$$

As this result is independent of a_3, we have the property that all the curves pv^m = a constant cut the pair of pv^n curves in such manner that the value of the ratio (v_2/v_1) is constant.

Lastly, we have
$$\frac{p_2v_2^n}{p_1v_1^n}=\frac{a_2}{a_1}=\left(\frac{p_2}{p_1}\right)\left(\frac{v_2}{v_1}\right)^n=\left(\frac{p_2}{p_1}\right)\left(\frac{a_2}{a_1}\right)^{\frac{n}{n-m}},$$
by equation (27); that is,
$$\left(\frac{p_2}{p_1}\right)=\left(\frac{a_2}{a_1}\right)^{\frac{m}{m-n}}, \text{ a constant.} \quad . \quad (28)$$

This result being also independent of a_3, all the curves pv^m = a constant cut the pv^n pair in such manner that the value of the ratio (p_2/p_1) is constant.

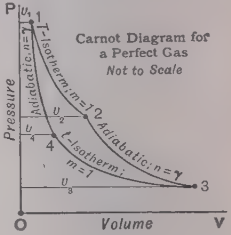

FIG. 9.

§ (23) APPLICATION TO THE CARNOT DIAGRAM.—The diagram of a Carnot cycle engine using a perfect gas as working substance (*Fig.* 9) consists of two isotherms pv = constant, and two adiabatics pv^γ = constant; compare *Fig.* 1.

Here $m=1$, $n=\gamma$; and we have accordingly by equation (27)
$$\left(\frac{v_2}{v_1}\right)=\left(\frac{v_3}{v_4}\right), \quad . \quad . \quad . \quad . \quad (29)$$
or the ratios of isothermal expansion and compression are equal. And from (29) we have immediately also
$$\left(\frac{v_3}{v_2}\right)=\left(\frac{v_4}{v_1}\right), \quad . \quad . \quad . \quad . \quad (30)$$
or the ratios of adiabatic expansion and compression are also equal.

The total expansion ratio is (v_3/v_1); denote this by X, and let r and ρ denote the isothermal and adiabatic expansion ratios respectively. Then as $(v_3/v_1)=(v_3/v_4)(v_4/v_1)$, we have
$$\mathrm{X}=\rho r. \quad . \quad . \quad . \quad (30')$$

Now in this case
$$a_1=p_1v_1^\gamma, \quad a_2=p_3v_3^\gamma,$$
hence by equation (27)
$$r=\left(\frac{p_3v_3^\gamma}{p_1v_1^\gamma}\right)^{\frac{1}{\gamma-1}}=\left(\frac{p_3v_3\times v_3^{\gamma-1}}{p_1v_1\times v_1^{\gamma-1}}\right)^{\frac{1}{\gamma-1}}$$
$$=\left(\frac{\mathrm{R}t}{\mathrm{RT}}\right)^{\frac{1}{\gamma-1}}\times\left(\frac{v_3}{v_1}\right),$$

i.e.
$$r=\mathrm{X}\left(\frac{t}{\mathrm{T}}\right)^{\frac{1}{\gamma-1}}. \quad . \quad . \quad . \quad (31)$$

Hence the isothermal expansion ratio depends upon both the total expansion ratio and the temperature limits. As r is necessarily greater than 1, X must always be taken greater than $(\mathrm{T}/t)^{1/(\gamma-1)}$.

---

[1] The value of n is readily determined by logarithmic plotting.

And as by equation (30) $\rho=\mathrm{X}/r$, we have by (31)

$$\rho=\left(\frac{\mathrm{T}}{t}\right)^{\frac{1}{\gamma-1}}. \quad . \quad . \quad . \quad (32)$$

Thus the adiabatic expansion ratio depends only upon the temperature limits. By aid of equations (30), (31), and (32) the diagram can be completely drawn when T, t, R, and one pressure, say p_3, are given. Lastly, from equations (5) and (32) we have

$$\text{Efficiency}=1-\left(\frac{1}{\rho}\right)^{\gamma-1}. \quad . \quad (32')$$

And thus, in the Carnot cycle the efficiency depends only upon the ratio of (adiabatic) compression.

§ (24) Further Consequences of the Equation pv^n = Constant.—The external work done when a gas expands from an initial volume v_0 to any other volume V being $\int_{v_0}^{v} pdv$, if the law connecting p and v be $pv^n=p_0v_0{}^n$, $pdv=p_0v_0{}^n\times v^{-n}dv$ and hence

$$\text{Ext. work done}=p_0v_0{}^n\int_{v_0}^{v} v^{-n}dv;$$

that is

$$\text{Ext. work}=p_0v_0{}^n\left\{\frac{v^{-n+1}-v_0{}^{-n+1}}{-n+1}\right\}$$

$$=\frac{p_0v_0{}^n}{1-n}\left\{\frac{v}{v^n}-\frac{v_0}{v_0{}^n}\right\},$$

which reduces immediately to the simple form,

$$\text{Ext. work}=\frac{1}{1-n}\{pv-p_0v_0\}. \quad . \quad . \quad (33)$$

As $pv=\mathrm{RT}$ and $p_0v_0=\mathrm{RT}_0$, this equation may also be written

$$\text{Ext. work}=\frac{\mathrm{R}}{1-n}\{\mathrm{T}-\mathrm{T}_0\}. \quad . \quad . \quad (34)$$

This result shows that when a gas expands in accordance with the law pv^n = constant the external work done is simply proportional to the change of temperature of the gas. As the initial temperature is T_0, if n be greater than 1 the temperature falls during expansion, whereas if n be less than 1 the temperature *rises* as the expansion proceeds. When $n=1$ equation (34) assumes an indeterminate form, but this is already known to be the isothermal case, and the temperature remains constant during the expansion.

To determine the heat expended we have by aid of equation (13)

$$\mathrm{H}=k_v(\mathrm{T}-\mathrm{T}_0)+\int_{v_0}^{v} pdv=k_v(\mathrm{T}-\mathrm{T}_0)+\frac{\mathrm{R}}{1-n)}\mathrm{T}-\mathrm{T}_0;$$

as $\mathrm{R}=k_v(\gamma-1)$ this reduces to

$$\mathrm{H}=\frac{\gamma-n}{1-n}k_v(\mathrm{T}-\mathrm{T}_0)=\frac{k_p-nk_v}{1-n}(\mathrm{T}-\mathrm{T}_0), \qquad (35)$$

which shows that the heat expended is also simply proportional to the change of temperature of the working gas, and that this expands with an apparent specific heat which is constant and equal to $\mathrm{K}=(\gamma-n/1-n)k_v$; K is negative for values of n between 1 and γ and positive for all other values of n.

In *Fig.* 10 values of $\gamma-n/1-n$, *i.e.* of K/k_v, are plotted against values of n from $n=0$ to $n=2$.

When $n=0$, $\mathrm{K}=k_p$; when $n=1$, $\mathrm{K}=\infty$, and the expansion is isothermal; when $n=\frac{1}{2}(\gamma+1)$, $\mathrm{K}=-k_v$; when $n=\gamma$, $\mathrm{K}=0$, and the expansion is adiabatic; and when n is greater than γ, K increases with n towards k_v as a limit. The curve is a rectangular hyperbola with asymptotes as indicated in *Fig.* 10.

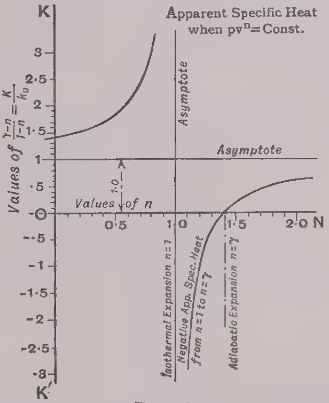

Fig. 10.

It is also to be noted that in expansion of the type pv^n=constant, the change of internal energy, $k_v(\mathrm{T}-\mathrm{T}_0)$, bears a constant ratio to the external work done, $\mathrm{R}/(1-n)\,.\,(\mathrm{T}-\mathrm{T}_0)$. For we have

$$\frac{\text{Internal energy change}}{\text{External work done}}=\frac{k_v(1-n)}{\mathrm{R}}=\frac{1-n}{\gamma-1}. \quad (36)$$

As $(\gamma-1)$ is always positive, the value of this ratio is positive if n be less than 1, and negative if n be greater than 1. When $n=1$, the value is zero and the expansion isothermal; and when $n=\gamma$ the value is -1, and the expansion is adiabatic.

The adiabatic equation (20) is, of course, immediately derived from equation (35) by putting $\mathrm{H}=0$, which obviously requires that $\gamma-n$ shall vanish; thus $n=\gamma$ and the required equation is pv^γ=constant, as already shown.

§ (25) Entropy of a Perfect Gas.—In *Fig.* 11 A_1 and A_2 are any two points on a

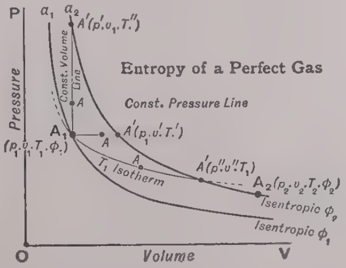

Fig. 11.

pv diagram indicating any two conditions $(p_1, v_1, \mathrm{T}_1, \phi_1)$, and $(p_2, v_2, \mathrm{T}_2, \phi_2)$ respectively of unit mass of a perfect gas. It is required to express $(\phi_2-\phi_1)$ in terms of p_1, v_1, T_1, p_2, v_2, and T_2.

Through A_1 and A_2 draw the isentropics (*i.e.* adiabatics) a_1A_1 and A_2A_2; then $(\phi_2-\phi_1)$ is known if $\int dH/T$ can be calculated for any one path from any point on a_1A_1 to any point on a_2A_2. This can be immediately done if the path be of constant pressure, or constant volume, or constant temperature, and the results in each case will be identical, thus:

(i.) *Constant Pressure Path.*—Through A_1 draw the constant pressure line A_1A', meeting the isentropic a_2A_2 in A'. Let $A\ (p_1vT)$ be any intermediate point; then as $p_1v/p_1v_1=T/T_1$, we have $v=v_1/T_1(T)$, and hence $dv=v_1/T_1(dT)$; thus $p_1dv=p_1v_1/T_1(dT)=RdT$.

Now by equations (9) and (13), expressing work-quantities in heat-units, we have

$$\phi_2-\phi_1=\int\frac{dH}{T}=k_v\int_{T_1}^{T'}\frac{dT}{T}+\int_{v_1}^{v^1}\frac{p_1dv}{T}.$$

or, as $p_1dv=RdT$,

$$\phi_2-\phi_1=k_v\int_{T_1}^{T'}\frac{dT}{T}+R\int_{T_1}^{T'}\frac{dT}{T}=(k_v+R)\int_{T_1}^{T'}\frac{dT}{T},$$

i.e.

$$\phi_2-\phi_1=k_p\log_\epsilon\left(\frac{T'}{T_1}\right). \quad . \quad . \quad (37)$$

But, by equation (21), as A' and A_2 are both on the isentropic a_1A_2,

$$T'=T_2\left(\frac{p_1}{p_2}\right)^{1-\frac{1}{\gamma}};$$

hence (37) becomes

$$(\phi_2-\phi_1)-k_p\log_\epsilon\left(\frac{T_2}{T_1}\right)\left(\frac{p_1}{p_2}\right)^{1-\frac{1}{\gamma}}, \quad (38)$$

which expresses the difference of entropy sought in terms of the pressure and temperature at A_1 and A_2.

As $p_1v_1=RT_1$, $p_2v_2=RT_2$, we have

$$\left(\frac{p_1}{p_2}\right)=\left(\frac{T_1}{T_2}\right)\left(\frac{v_2}{v_1}\right);$$

hence (38) becomes

$$(\phi_2-\phi_1)=k_p\log_\epsilon\left(\frac{T_2}{T_1}\right)^{\frac{1}{\gamma}}\left(\frac{v_2}{v_1}\right)^{1-\frac{1}{\gamma}}, \quad . \quad (39)$$

which expresses the difference of entropy in terms of the volume and temperature at A_1 and A_2.

This may be somewhat simplified; for $k_p-\gamma k_v$: substituting therefore, equation (39) becomes

$$(\phi_2-\phi_1)=k_v\log_\epsilon\left(\frac{T_2}{T_1}\right)\left(\frac{v_2}{v_1}\right)^{\gamma-1}. \quad (40)$$

Or again, as $T_2/T_1=p_2v_2/p_1v_1$, equation (40) may be written

$$(\phi_2-\phi_1)=k_v\log_\epsilon\left(\frac{p_2v_2{}^\gamma}{p_1v_1{}^\gamma}\right), \quad . \quad (41)$$

which expresses the difference of entropy in terms of the pressure and volume at A_1 and A_2.

Equations (38), (39), (40), (41) enable the difference of entropy between A_1 and A_2 to be calculated when any two of the variables p, v, T are known at each point.

As along an adiabatic pv^γ is constant, if the value of this constant be denoted by β, equation (40) takes the simple form

$$(\phi_2-\phi_1)=k_v\log_\epsilon\left(\frac{\beta_2}{\beta_1}\right). \quad . \quad . \quad (42)$$

(ii.) *Constant Volume Path.*—Referring again to *Fig.* 11, consider the change of entropy is proceeding along the constant volume path A_1A' between the two isentropics a_1A_1 and A_2A_2.

In this case $dv=0$, and therefore $pdv=0$, no external work being done, hence we have

$$(\phi_2-\phi_1)=k_v\int_{T_1}^{T'}\frac{dT}{T}=k_v\log_\epsilon\left(\frac{T'}{T_1}\right).$$

But A' and A_2 being on the same isentropic,

$$T'=T_2\left(\frac{v_2}{v_1}\right)^{\gamma-1}$$

and therefore

$$\left(\frac{T'}{T_1}\right)=\left(\frac{T_2}{T_1}\right)\left(\frac{v_2}{v_1}\right)^{\gamma-1},$$

and thus

$$(\phi_2-\phi_1)=k_v\log_\epsilon\left(\frac{T_2}{T_1}\right)\left(\frac{v_2}{v_1}\right)^{\gamma-1}, \quad . \quad . \quad .$$

which is identical with equation (40).

(iii.) *Constant Temperature Path.*—Lastly, consider an isothermal path, as A_1A' (*Fig.* 11) between the two isentropics. Then from equations (15) and (15′) we have at once

$$(\phi_2-\phi_1)=\int\frac{dH}{T}=\frac{H}{T_1}=R\log_\epsilon\left(\frac{v'}{v_1}\right).$$

As before, A' and A_2 being on the same isentropic, we have by equation (22)

$$T_2=T_1\left(\frac{v'}{v_2}\right)^{\gamma-1},$$

whence

$$v'=v_2\left(\frac{T_2}{T_1}\right)^{\frac{1}{\gamma-1}},$$

and accordingly

$$(\phi_2-\phi_1)=R\log_\epsilon\left(\frac{v_2}{v_1}\right)\left(\frac{T_2}{T_1}\right)^{\frac{1}{\gamma-1}};$$

that is, as $R=k_v(\gamma-1)$,

$$(\phi_2-\phi_1)=k_v\log_\epsilon\left(\frac{T_2}{T_1}\right)\left(\frac{v_2}{v_1}\right)^{\gamma-1},$$

which is equation (40) again. Thus, proceeding from A_1 to A_2 by the inter-isentropic paths of constant pressure, constant volume, or constant temperature, we are in each case led to the result that the difference of entropy of A_2 and A_1 is expressed by $k_v\log_\epsilon(\beta_2/\beta_1)$, where β is the adiabatic constant pv^γ.

§ (26) THE INTERNAL COMBUSTION ENGINE "MIXTURE."—All the preceding relations are strictly true only for an ideal perfect gas, which may be defined as a gas of which the absolute temperature is simply proportional to the value of the product *pv*. For all the ordinary "permanent" gases the difference between the actual volume, and the value of RT/*p* is so small that it is unnecessary to take it into account in investigations of the performance of internal combustion engines; in all such investigations it is therefore usual to assume that the effective temperature of the working mixture of gases is given by the value of the expression *pv*/R, with a suitable value assigned to the constant R. Callendar has stated[1] that the experimental evidence available indicates the error of this assumption to be certainly less than 1 per cent for a mixture at 2000° C., the composition of the mixture being known.

All internal combustion engines are essentially air engines wherein the air is very suddenly and very intensely heated by causing chemical action to take place throughout its volume; this is effected by "carburetting" the air, *i.e.* by mixing it with a relatively small quantity of some inflammable gas or vapour in order to produce an explosive mixture, and igniting this explosive mixture at a suitable instant.

Before explosion the mixture consists of air (usually somewhat moist), carburetted with town's gas, blast furnace gas, producer gas, "fuel oil" vapour, kerosene vapour, petrol vapour, benzol vapour, alcohol vapour, acetylene, etc. etc., dependent upon the inflammable agent used, and diluted to a varying degree with some of the exhaust products from the preceding cycle; after complete combustion, and during the working stroke, the mixture consists of nitrogen, steam, carbonic acid gas, and usually some excess oxygen.

§ (27) CYCLES OF INTERNAL COMBUSTION ENGINES.—The very numerous working cycles adopted, or suggested, in actual internal combustion engines are conveniently classified according to the condition in which the working substance receives its heat, thus we have:

Class I.—Cycles of combustion at constant temperature.

Class II.—Cycles of combustion at constant pressure.

Class III.—Cycles of combustion at constant volume.

§ (28) CLASS I.—The Carnot cycle, already fully considered, typifies this class; all heat received is received at constant temperature T, and all heat rejected is rejected at some constant lower temperature *t*. The cycle is perfect, and therefore of maximum efficiency expressed by $(1-t/\mathrm{T})$ (*vide* also equation (32′)).

An indicator diagram drawn to scale for an engine working on this cycle with air between 300° C. and 700° C. only is shown in *Fig.* 12. Although the maximum pressure attained in the case taken is about 525 lbs. per sq. in., the mean effective pressure is only about $11\frac{1}{2}$ lbs. per sq. in., or less than one forty-fifth of the maximum pressure. The engine would necessarily be designed to safely withstand the maximum pressure, and would thus be very heavy in relation to its power output. It has long been recognised, owing to this and other practical drawbacks, that the Carnot cycle is quite unsuitable as an actual working cycle, though within recent years its adoption was seriously proposed by Diesel[2] but soon abandoned in favour of the now well-known constant pressure cycle finally adopted in this type of engine.

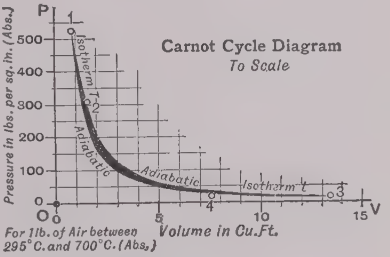

FIG. 12.

§ (29) CLASS II. "*Constant Pressure*" *Cycles.*—In this class are included the American "Brayton" engine (1873), with Simon's modified design, and also engines of the modern highly economical "Diesel" and "semi-Diesel" types.

The Brayton engine included a compressing pump and a working cylinder. The charge of carburetted air, taken in at atmospheric pressure, was first compressed by the pump and delivered into a receiver at a pressure of some 70 lbs. per sq. in. above atmosphere; from this receiver the working cylinder took its charge, the mixture being ignited on entering, inflammation of the contents of the receiver being prevented by the interposition of a fine wire-gauze screen somewhat in the manner of action of the Davy miner's safety lamp.

During the first portion of the working stroke the working cylinder thus received its mixture in an ignited condition at a pressure nearly equal to that in the receiver; at a suitable instant an inlet valve cut off communication with the receiver, the working stroke being then completed by the expansion of the flaming mixture contained in the cylinder. At the end of the stroke the exhaust valve was opened, and during the return stroke the burnt gas was expelled into the atmosphere, thus completing the cycle.

---

[1] *Gaseous Explosions Committee*, 1st Report, 1908.

[2] *The Rational Heat Motor*, Eng. ed. by Spon.

A working impulse occurred in every revolution, *i.e.* in every alternate stroke, so that the Brayton engine worked on what is now termed a "two-stroke" cycle; it will also be noted that in this engine the mode of ignition adopted increased not the pressure but the *volume* of the working mixture, the pressure in the working cylinder never quite equalling that in the receiver.

The cycle comprised five operations, viz.:

(*a*) Charging the pump with carburetted air.

(*b*) Compression of the charge into the receiver.

(*c*) Admitting the (ignited) compressed charge to the working cylinder.

(*d*) Expanding after cut-off in the working cylinder.

(*e*) Expelling the burnt gas during the return (exhaust) stroke.

The ideal diagram of such a cycle is drawn by supposing no heating or throttling of the charge to occur during admission to the pump; no loss of the heat developed during compression into the receiver; no throttling of the charge on entering the working cylinder; no loss of heat by the flame to the working cylinder and piston; no back pressure during exhaust; and complete expulsion of all the burnt gas at the end of exhaust, which implies the supposition of no clearance in the working cylinder.

Though these conditions cannot be actually attained, they may be approximated to by skilled design.

The ideal diagram of the Brayton type of engine will therefore have the form shown in *Fig.* 13, and it is convenient to exhibit the diagrams of the pump and of the working cylinder superposed.

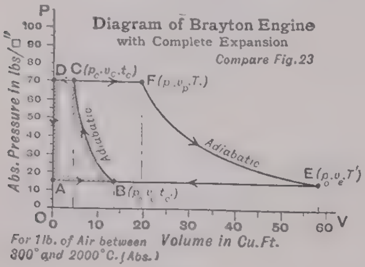

FIG. 13.

AB represents the volume of the pump, AE that of the working cylinder; the carburetted charge is drawn in by the pump at atmospheric pressure AB, and compressed adiabatically along BC to the receiver pressure of about 70 lbs. per sq. in. above atmosphere, and then forced into the receiver at this pressure as indicated by the line CD.

From the receiver it enters the working cylinder at this pressure as indicated by DF, the supply being cut off at F; thence the expansion is adiabatic, and it is first supposed that this expansion is continued until the pressure has fallen to that of the atmosphere, at E. During the return stroke the burnt products are exhausted as indicated by the line EA, and the cycle is then complete.

The area ABCDA represents the work done by the compressing pump *on* the working mixture, while the area DFEAD represents the work done *by* the mixture upon the working piston. The difference, represented by the area BCFEB, accordingly represents the useful work done by the engine per cycle.

The notation adopted is shown in *Fig.* 13; the heat supplied is that corresponding to the line CF, during which the working mixture increases its volume at constant pressure, from v_c to v_p, and is accordingly expressed by

$$H = k_p(T - t_c), \quad . \quad . \quad . \quad (43)$$

while the heat rejected is that during the constant pressure exhaust period EB (regarded as compression at constant pressure), from volume v_e to volume v_o, and is accordingly given by

$$h = k_p(T' - t_o). \quad . \quad . \quad . \quad (44)$$

The efficiency, being the ratio of useful work done to heat supplied, is accordingly $H - h/H$, *i.e.* $(1 - h/H)$, which, by equations (43) and (44), becomes

$$\text{Efficiency} = 1 - \frac{T' - t_o}{T - t_c}. \quad . \quad . \quad (45)$$

But the expansion and compression curves being adiabatics, we have by (22) (Property 1)

$$\frac{v_p}{v_c} = \frac{v_e}{v_o}, \quad . \quad . \quad . \quad . \quad (46)$$

and as the working mixture obeys the law $pv = RT$,

$$\frac{v_p}{v_o} = \frac{T}{t_c} \text{ and } \frac{v_e}{v_o} = \frac{T'}{t_o};$$

and hence by (46)

$$\frac{T}{t_c} = \frac{T'}{t_o}, \text{ and } \frac{t_o}{t_c} = \frac{T'}{T}.$$

Accordingly

$$\frac{T - t_c}{t_c} = \frac{T' - t_o}{t_o},$$

i.e.

$$\frac{T' - t_o}{T - t_c} = \frac{t_o}{t_c}.$$

Thus, by equation (45) the efficiency may be simply expressed in the form

$$\text{Efficiency} = \left(1 - \frac{t_o}{t_c}\right) = \left(1 - \frac{T'}{T}\right). \quad . \quad . \quad (47)$$

Hence when expansion is continued down to atmospheric (*i.e.* pump suction) pressure, the efficiency depends only upon the degree of *compression* BC.

The efficiency may also be expressed in

terms of the equal ratios of adiabatic volume change; for if ρ denotes the ratio of adiabatic expansion v_e/v_p, so that $(1/\rho)$ denotes that of adiabatic compression (v_c/v_o) (by equation (46)), then by equation (22) we have

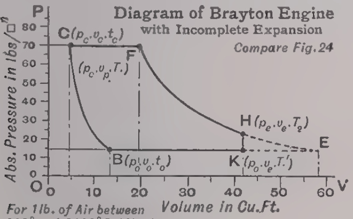
$$\left(\frac{t_o}{t_c}=\frac{v_c}{v_o}\right)^{\gamma-1}=\left(\frac{1}{\rho}\right)^{\gamma-1};$$

whence, by (47),

$$\text{Efficiency}=1-\left(\frac{1}{\rho}\right)^{\gamma-1}, \qquad (48)$$

which expresses the efficiency in terms of the compression ratio alone, and has the same form as for a Carnot cycle. It will be observed that the cycle is *imperfect*, as the efficiency $1-T'/T$ is necessarily always less than $1-t_o/T$.

§ (30) CLASS II. (*continued*).—Actually, it was found to be impracticable to continue the expansion so far that the pressure at release E had fallen to atmospheric, and accordingly the ideal practicable indicator diagram would be as shown in *Fig.* 14. The efficiency is clearly less than in the case illustrated by *Fig.* 13, as, although the heat received remains unchanged, the useful work done per cycle is now reduced by an amount represented by the "toe" of the diagram HEK. As before, the efficiency is expressed by $1-h/H$, where $H=k_p(T-t_c)$. The total heat rejected, h, is, however, now the sum of that rejected during the constant volume period HK, and that rejected during the constant pressure period KB; thus, now



For 1 lb. of Air between 300° and 2000° C. (Abs.)

FIG. 14.

$$h=k_v(T_2-T')+k_p(T'-t_o), \qquad (49)$$

and accordingly (as $\gamma=k_p/k_v$), the efficiency is given by

$$\text{Efficiency}=1-\frac{(T_2-T')\gamma+(T'-t_o)}{T-t_c}. \qquad (50)$$

This expression does not admit of simplification in terms of the temperatures.

We may thermodynamically consider that all the action takes place in a closed working cylinder v_c, being the clearance volume initially filled with a charge of mixture at pressure p_c and temperature t_c, the volume swept through by the working piston being (v_e-v_c) per stroke.

Let the total expansion ratio (v_e/v_c) be denoted by X; the expansion ratio at constant pressure (v_p/v_c) by σ; and the adiabatic compression ratio (v_c/v_o) by $1/\rho$. Then by aid of equations (12) and (22) it is easily found that $T=\sigma\rho^{\gamma-1}t_o$, $T'=(X/\rho)t_o$, $T_2=\sigma^{\gamma}(X/\rho)^{1-\gamma}t_o$, and $t_c=\rho^{\gamma-1}t_o$. Whence, by substitution in equation (50), and reduction, we obtain the result

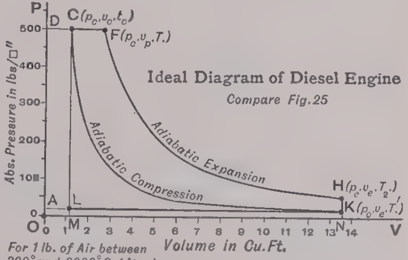
$$\text{Efficiency}=1-\left(\frac{1}{\rho}\right)^{\gamma-1}\times\left\{\frac{\sigma^{\gamma}(X/\rho)^{1-\gamma}+(\gamma-1)(X/\rho)-\gamma}{(\sigma-1)\gamma}\right\}. \qquad (51)$$

§ (31) THE DIESEL ENGINE.—The other important cycle falling within Class II. is that of the Diesel engine in its present form. As already stated, § (28), Diesel originally proposed to use the Carnot cycle, but in a paper read before the Paris Congress in 1900 he announced the cycle finally adopted after extended experiment as comprising the following five operations performed during four strokes of the working piston, the same vessel acting alternately as compression pump and working cylinder (*Fig.* 15):

(1) (1st Stroke).—Suction of air at atmospheric pressure LK.

(2) (2nd Stroke).—Adiabatic compression of this air, KC.

(3) (3rd Stroke; First Portion).—Regulated admission of the carburetting agent (liquid or gaseous fuel) so as to maintain constant pressure during combustion for a portion of the working stroke CF.



For 1 lb. of Air between 300° and 2000° C. (Abs.)

FIG. 15.

(4) (3rd Stroke; Second Portion).—Cut-off of fuel supply and adiabatic expansion of the heated mixture to the end of the working stroke FH.

(5) (4th Stroke).—Opening of exhaust with immediate fall of pressure (and temperature) at constant volume HK, and subsequent expulsion of the burnt gases into the atmosphere during the exhaust stroke KL.

This completes the cycle; it will be observed that one working stroke only occurs in every four, and the cycle is accordingly of the "four-stroke" type.

From *Fig.* 15 it is clear that the areas representing work done on the piston are :

During suction	+LKNM
During compression	−KCMN
During working stroke . . .	+MCFHN
During exhaust	−KLMN
∴ Net useful work per cycle =	+CFHKC

Thermodynamically we may obviously consider that the same mass of air is constantly enclosed within the working cylinder, this being heated at constant pressure during CF, and cooled at constant volume during HK. Thus, in the ideal case, the heat account is as follows :

$$\text{Heat received} = \mathrm{H} = k_p(\mathrm{T} - t_c).$$

$$\text{Heat rejected} = h = k_v(\mathrm{T}_2 - \mathrm{T}').$$

$$\text{Work done} = (\mathrm{H} - h) = k_p(\mathrm{T} - t_c) - k_v(\mathrm{T}_2 - \mathrm{T}').$$

And therefore

$$\text{Efficiency} = 1 - \frac{h}{\mathrm{H}} = 1 - \frac{k_v(\mathrm{T}_2 - \mathrm{T}')}{k_p(\mathrm{T} - t_c)}$$

$$= 1 - \frac{1}{\gamma}\,\frac{\mathrm{T}_2 - \mathrm{T}'}{\mathrm{T} - t_c}. \quad (52)$$

This is immediately deducible from equation (50), which is reduced to the Diesel cycle by putting $t_o = \mathrm{T}'$.

Similarly, referring to equation (51), this reduces to the Diesel case by putting $\mathrm{X} = \rho$; and thus we have for the Diesel cycle :

$$\text{Efficiency} = 1 - \left(\frac{1}{\rho}\right)^{\gamma - 1} \times \frac{\sigma^{\gamma} - 1}{(\sigma - 1)\gamma}, \quad (53)$$

where $1/\rho$ is the ratio of adiabatic compression (v_c/v_e), and σ is the ratio of expansion at constant pressure (v_p/v_c).

This case includes also that of the numerous so-called "semi-Diesel" engines, as, *e.g.*, of the Petter, Blackstone, Ruston, etc., designs.

As the constant pressure expansion ratio, σ, is reduced towards the value unity, the value of the efficiency given by equation (53) continually approaches towards the limiting value $1 - (1/\rho)^{\gamma - 1}$.

This conclusion of theory is apparently realised in practice. In Diesel engines the power is reduced by diminishing the extent of the constant pressure expansion, *i.e.* by reducing σ ; the following figures from tests made by Mr. Ade Clark show the indicated thermal efficiencies obtained :

Engine.	Revolutions per Minute.	Indicated Thermal Efficiency at			
		¼ Load.	½ Load.	¾ Load.	Full Load.
80 H.P. Diesel	160	·375	·412	. .	·389
160 H.P. Diesel	157	·371	·427	·402	·397

The Diesel cycle is clearly of the "imperfect" class.

§ (32) CLASS III. *The "Constant Volume" Cycle.*—In this class is included by far the largest number of actual internal combustion engines, ranging from the early Lenoir and Hugon types to the modern Clerk two-stroke, and de Rochas, or Otto, four-stroke designs. A very large proportion of the enormous number of small internal combustion engines of the present day are worked on the Otto "four-stroke" cycle, while the Clerk two-stroke cycle is extensively adopted in the larger types of stationary gas engines.

The Lenoir Engine.—In the Lenoir gas engine (1860)—now completely obsolete on account of its very low efficiency—the mode of working was evidently inspired by that of the ordinary steam engine. During the first portion of the stroke the working piston drew into the cylinder a charge of coal gas and air at atmospheric pressure ; at an arranged point a slide valve cut off the supply, and simultaneously the charge within the cylinder was ignited, the temperature (and consequently the pressure) suddenly rising greatly ; the working stroke was then completed by the expansion of this mass of heated high-pressure gas ; during the return stroke the burnt gases were exhausted into the atmosphere, thus completing the cycle.

Further following the steam engine, this cycle was caused to occur alternately on each side of the working piston, thus making the engine "double-acting" ; thus a working impulse was obtained in every stroke. The Lenoir engine worked very quietly and smoothly, but was abandoned on account of its very high consumption of gas in favour of more economical types.

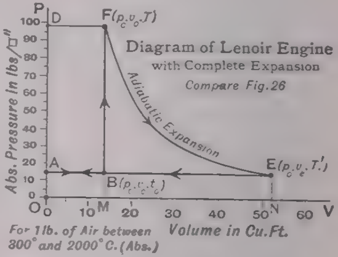


FIG. 16.

The ideal diagram is shown in *Fig.* 16, wherein it is supposed that the cylinder has no clearance and that the expansion is carried so far that the pressure at the end of the stroke is that of the atmosphere. The volume swept through per stroke by the piston is AE ; during the portion AB the carburetted charge is drawn in at atmospheric pressure, doing work on the piston represented by the area + ABMO. At B cut-off occurs, and simultaneously the charge is ignited, explosion takes place, and the pressure suddenly rises as indicated by BF. The heated charge then expands adiabatically, along FE, to atmospheric pressure at the end of the stroke E, doing a further amount of work on the piston represented by the area + MFEN; at E the exhaust opens, and during the return stroke the burnt charge is expelled into the atmosphere, negative work being done upon the piston represented by the area − EAON; this completes the cycle.

The work account is therefore given by ABMO + MFEN − EAON or BFEB; thus the useful work done per cycle is represented by the area BFEB.

Thermodynamically the action is regarded as taking place in a mass of air (regarded as a perfect gas) contained within a closed cylinder having a clearance volume AB, and piston displacement volume BE. Initially, at B, the clearance volume contains air at $(p_o v_o t_o)$; heat is suddenly communicated, raising the pressure, at unchanged volume, to p_c; adiabatic expansion then occurs to E; and during the return stroke heat is abstracted from the air at constant pressure from volume v_e to volume v_o. In this ideal case we have therefore

$$\text{Heat received} = \mathrm{H} = k_v(\mathrm{T} - t_o),$$
$$\text{Heat rejected} = h = k_p(\mathrm{T}' - t_o),$$
$$\text{Useful work done} = (\mathrm{H} - h) = k_v(\mathrm{T} - t_o) - k_p(\mathrm{T}' - t_o),$$
$$\text{Efficiency} = 1 - \frac{h}{\mathrm{H}} = 1 - k_p(\mathrm{T}' - t_o)/k_v(\mathrm{T} - t_o),$$

i.e.
$$\text{Efficiency} = 1 - \gamma\frac{\mathrm{T}' - t_o}{\mathrm{T} - t_o}. \qquad (54)$$

This result may be otherwise expressed in three ways; for by equation (12) $(\mathrm{T}/t_o) = (p_c/p_o) = \Pi$—the ratio of maximum to atmospheric pressure, while $(\mathrm{T}'/t_o) = (v_e/v_o) = \rho$, the ratio of adiabatic expansion. Hence (54) may be written

$$\text{Efficiency} = 1 - \gamma\frac{\rho - 1}{\Pi - 1}. \qquad (55)$$

Again, by equation (22)

$$\mathrm{T} = \left(\frac{v_e}{v_p}\right)^{\gamma - 1}\mathrm{T}' = \rho^{\gamma - 1}\mathrm{T}' = \rho^{\gamma} t_o,$$

as $\mathrm{T}' = \rho t_o$. Hence (54) may also be written

$$\text{Efficiency} = 1 - \gamma\frac{\rho - 1}{\rho^{\gamma} - 1}. \qquad (56)$$

Lastly, as $\rho^{\gamma} = (\mathrm{T}/t_o)$, equation (56) becomes, in terms of the ratio of the explosion temperature to the initial temperature,

$$\text{Efficiency} = 1 - \gamma\frac{(\mathrm{T}/t_o)^{1/\gamma} - 1}{(\mathrm{T}/t_o) - 1}. \qquad (57)$$

In general it was not found practicable to continue the expansion until atmospheric pressure was reached, the more usual case being that in which the pressure at the end of the stroke exceeded that of the atmosphere. The ideal diagram in this case is shown in *Fig.* 17; and it is clear that the heat received, H, is the same as in the preceding case, viz. $\mathrm{H} = k_v(\mathrm{T} - t_o)$; the heat rejected, h, is, however, now the sum of that during the constant volume drop HK, and the constant pressure shrinkage KB, and thus

$$h = k_v(\mathrm{T}_2 - \mathrm{T}') + k_p(\mathrm{T}' - t_o).$$

Hence the efficiency, $1 - h/\mathrm{H}$, is expressed by

$$\text{Efficiency} = 1 - \frac{k_v(\mathrm{T}_2 - \mathrm{T}') + k_p(\mathrm{T}' - t_o)}{k_v(\mathrm{T} - t_o)},$$

i.e.
$$\text{Efficiency} = 1 - \frac{(\mathrm{T}_2 - \mathrm{T}') + \gamma(\mathrm{T}' - t_o)}{(\mathrm{T} - t_o)}. \qquad (58)$$

Denote, as before, the ratio of adiabatic expansion (v_e/v_o) by ρ, and the ratio of explosion pressure to atmospheric pressure by Π. Then $\mathrm{T} = \Pi t_o$; $\mathrm{T}' = \rho t_o$; and by equation (22) $\mathrm{T}_2 = \mathrm{T}(1/\rho)^{\gamma - 1} = \Pi(1/\rho)^{\gamma - 1} t_o$. Accordingly equation (58) may also be written

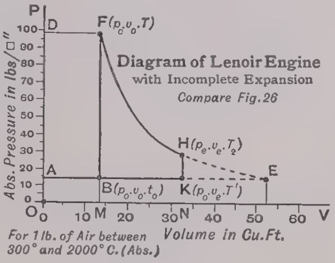

FIG. 17.

$$\text{Efficiency} = 1 - \frac{\Pi(1/\rho)^{\gamma - 1} + \rho(\gamma - 1) - \gamma}{\Pi - 1}; \qquad (59)$$

or again, in terms of the ratio (T/t_o) only,

$$\text{Efficiency} = 1 - \frac{\rho\{\rho^{-v}(\mathrm{T}/t_o - 1)\} + (\rho - 1)\gamma}{(\mathrm{T}/t_o) - 1}, \qquad (60)$$

when $\mathrm{T}_2 = \mathrm{T}'$, $\Pi(1/\rho)^{\gamma - 1} = \rho$, and equation (59) then reduces to equation (55). Also as $\Pi = \mathrm{T}/t_o = \rho^{\gamma}$ when $\mathrm{T}_2 = \mathrm{T}'$, equation (60) then reduces to equation (57). The efficiency is clearly less in this than in the preceding case, since, with the same expenditure of heat, the useful work area is less by the amount KHE, due to the incomplete expansion.

§ (33) CLASS III (*continued*). (i.) *The Free Piston Engine.*—The Lenoir type of engine was superseded by a singular design originally proposed by Barsanti and Mattucci (1857), but first rendered practicable by Otto and Langen in their "Free Piston Engine" of 1867. This essentially comprised a very long vertical cylinder fitted with a heavy *free* piston beneath which a charge of carburetted air was exploded, driving the piston upwards as a projectile is driven from a gun; the heavy piston acquired considerable momentum, and continued its upward motion until the working mixture had expanded to about six times its original volume and to a pressure considerably below that of the atmosphere. During its descent by gravity, and excess atmospheric pressure upon its upper surface, it engaged with, and drove, the crank-shaft through a ratchet and pawl device. The engine was excessively noisy and mechanically unsatisfactory, but the rapid and extended expansion, and subsequent slower cooling, of the working mixture resulted in a considerably increased efficiency compared with earlier types.

An ideal diagram is shown in *Fig.* 18; the charge of carburetted air at atmospheric pressure p_o and temperature t_o is drawn into the cylinder as indicated by AB, and exploded at constant volume v_o (=AB), its pressure rising to p_c and temperature to T as indicated by BF; the piston immediately rises rapidly, the charge expanding adiabatically to E when the piston momentarily stops. The downward (working) stroke now follows under the combined action of gravity and excess atmospheric pressure, the mixture being compressed *isothermally* from E to B—due to the slowness of the working stroke, and finally expelled at constant pressure as indicated by BA. As before, the useful work done is represented by the area BFEB; clearly also the heat supplied, H, is expressed by $H=k_v(T-t_o)$, while the heat rejected, h, is given by $h=Rt_o\log_\epsilon r$, where r is the ratio of isothermal compression (v_e/v_o); *vide* § (18).

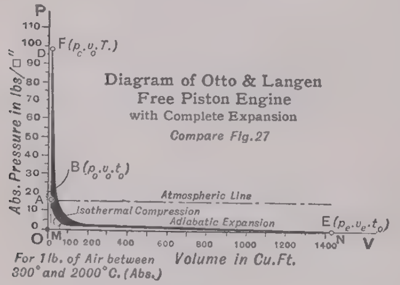

FIG. 18.

Hence the efficiency $=1-\dfrac{h}{H}=1-\dfrac{Rt_o\log_\epsilon r}{k_v(T-t_o)}$,

i.e. as $R=k_p-k_v$,

$$\text{Efficiency}=1-\frac{(\gamma-1)\log_\epsilon r}{(T/t_o)-1}. \quad . \quad (61)$$

This may be further simplified and expressed in terms of the ratio (T/t_o) only; for by equation (22) $(v_e/v_o)^{\gamma-1}=(T/t_o)$, and $\therefore (\gamma-1)\log_\epsilon r=\log_\epsilon(T/t_o)$, and accordingly equation (61) reduces to

$$\text{Efficiency}=1-\frac{\log_\epsilon (T/t_o)}{(T/t_o)-1}, \quad . \quad . \quad (62)$$

which expresses the ideal maximum efficiency of engines of this type.

(ii.) *The Beau de Rochas, or Otto, and the Clerk Cycles.*—Finally there remain to be considered engines working upon the Beau de Rochas, or Otto, "four-stroke," and the Clerk "two-stroke" cycles, which may be considered to include between them all internal combustion engines of the present day. In all these engines combustion is caused to occur at constant volume with previous compression of the working charge.

§ (34) THE CLERK CYCLE.—The first case to be taken is that in which—as in the Clerk cycle—the engine comprises a compression pump and separate working cylinder, the compressing pump taking in a carburetted charge at atmospheric pressure and temperature and compressing this either directly into the combustion chamber of the working cylinder, or into an intermediate receiver from which the working cylinder in turn takes its compressed charge, which is then ignited (exploded) at constant volume, and performs the working stroke by its subsequent expansion.

Six separate operations may be here distinguished, viz.:

(1) Pump suction—Charging the pump with carburetted air.

(2) Pump Compression—Compressing the charge into the receiver, or combustion chamber of working cylinder.

(3) Supply of compressed charge from receiver to working cylinder, when receiver is included.

(4) Explosion of charge at constant volume in working cylinder.

(5) Expansion of exploded charge during working stroke.

(6) Expulsion of exhaust gases at the end of the working stroke.

In considering an ideal diagram for this case the following assumptions are made:

(1) That the charge is compressed adiabatically.

(2) That none of the heat of compression is lost in the receiver.

(3) That the charge is neither heated nor cooled on entering the combustion chamber of the working cylinder.

(4) That the explosion occurs instantaneously, and without any loss of heat to the walls of the combustion chamber.

(5) That the expansion during the working stroke is adiabatic, *i.e.* that no heat exchange takes place with the cylinder walls, or piston crown, during expansion.

(6) That there are no losses by throttling or back pressure.

An ideal diagram embodying these assumptions is shown in *Fig.* 19, wherein it is also supposed that the expansion is continued so far that the pressure has fallen to p_o—that of the atmosphere—a condition not practically attainable, and also that the working cylinder has no clearance; thus the pump volume is AB, and the working cylinder volume AE.

During the pump suction stroke a volume of carburetted air is taken in at atmospheric pressure and temperature represented by AB, doing work +OABK upon the pump piston.

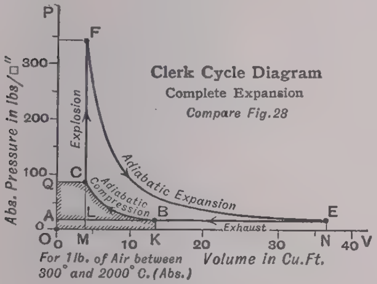

FIG. 19.

This is next compressed adiabatically along BC and delivered into the receiver at the constant pressure p_c along CQ; thus the pump diagram is −OKBCQO.

The charge next enters the cylinder along QC, doing work +OQCM upon the working piston, and is then exploded at constant volume v_c, the pressure instantly rising as indicated by CF, with subsequent adiabatic expansion FE, to atmospheric pressure at E, doing work upon the piston represented by +MFENM. At E the exhaust opens and the burnt gases are expelled at atmospheric pressure p_o, doing work represented by −EAON; this completes the cycle.

The work account is therefore

$$+\mathrm{OABK}-\mathrm{OKBCQO}+\mathrm{OQCM}+\mathrm{MFENM}-\mathrm{EAON}=+\mathrm{BCFEB},$$

and thus the useful work done per cycle is represented by the enclosed area BCFEB.

Thermodynamically the whole action may be conceived as taking place in a closed cylinder of clearance volume AL, LE being the volume swept through by the piston. Commencing at the point C, heat H is added to the charge to an amount given by the equation $\mathrm{H}=k_v(\mathrm{T}-t_c)$; during expansion there is no communication of heat; during exhaust from E to B heat, h, is rejected, given by $h=k_p(\mathrm{T}'-t_o)$; while during compression BC there is no communication of heat.

Hence the efficiency, $1-h/\mathrm{H}$, is expressed by

$$\text{Efficiency}=1-\frac{k_p(\mathrm{T}'-t_o)}{k_v(\mathrm{T}-t_c)}=1-\gamma\frac{\mathrm{T}'-t_o}{\mathrm{T}-t_c}. \quad (63)$$

The efficiency may also be expressed in terms of T, t_o, and the ratio of adiabatic compression $1/\rho=(v_c/v_o)$. For, by equation (22),

$$t_c=\rho^{\gamma-1}t_o;$$

and

$$\mathrm{T}'=\left(\frac{v_c}{v_e}\right)^{\gamma-1}\mathrm{T}.$$

But also

$$\frac{v_c}{v_e}=\left(\frac{v_c}{v_o}\right)\left(\frac{v_o}{v_e}\right)=\left(\frac{1}{\rho}\right)\left(\frac{t_o}{\mathrm{T}'}\right);$$

whence

$$\mathrm{T}'=\left(\frac{t_o}{\rho}\right)^{1-1/\gamma}\mathrm{T}^{1/\gamma}.$$

Thus (63) may be written

$$\text{Efficiency}=1-\gamma\frac{\left(\frac{1}{\rho}\right)^{1-1/\gamma}\left(\frac{\mathrm{T}}{t_o}\right)^{1/\gamma}-1}{\left(\frac{\mathrm{T}}{t_o}\right)-\rho^{\gamma-1}}. \quad (64)$$

As $\rho=(t_c/t_o)^{1/\gamma-1}$, and $\mathrm{T}'=(t_o/\rho)^{\gamma-1/\gamma}\mathrm{T}^{1/\gamma}$, it follows that

$$\mathrm{T}'=\left(\frac{\mathrm{T}}{t_c}\right)^{1/\gamma}t_o, \quad . \quad . \quad . \quad (65)$$

which expresses the relation between the temperatures at the four corners of the diagram.

If, as in previous cases, the total expansion ratio (v_e/v_c) be denoted by X, then

$$\mathrm{T}=\left(\frac{v_e}{v_c}\right)^{\gamma-1}\mathrm{T}'=\mathrm{X}^{\gamma-1}\mathrm{T}';$$

but

$$\mathrm{T}'=\left(\frac{v_e}{v_o}\right)t_o=\left(\frac{v_e}{v_c}\right)\left(\frac{v_c}{v_o}\right)t_o=\left(\frac{\mathrm{X}}{\rho}\right)t_o,$$

whence

$$\mathrm{T}=\left(\frac{\mathrm{X}^\gamma}{\rho}\right)t_o.$$

Hence, as

$$t_c=\rho^{\gamma-1}t_o,$$

we have, on substituting in equation (63) and reducing, the expression for the efficiency in terms of the total expansion and adiabatic compression ratios alone,

$$\text{Efficiency}=1-\left(\frac{1}{\rho}\right)^{\gamma-1}\times\frac{\gamma(\mathrm{X}/\rho-1)}{(\mathrm{X}/\rho)^\gamma-1}. \quad (66)$$

As ρ approaches X in value this expression continually approximates to $1-(1/\rho)^{\gamma-1}$ as a limiting value.

§ (35) THE CLERK CYCLE WITH INCOMPLETE EXPANSION.—Actually it has not been found practicable to continue the expansion so far that the pressure falls to that of the atmosphere; the next case for consideration, therefore, is that in which the pressure at the end of expansion exceeds that of the atmosphere.

An ideal diagram is shown in *Fig.* 20; as before, the heat supplied is $\mathrm{H}=k_v(\mathrm{T}-t_c)$, while the heat rejected is now given by

$$h=k_v(\mathrm{T}_2-\mathrm{T}')+k_p(\mathrm{T}'-t_o).$$

Hence the efficiency, $1-h/\mathrm{H}$, is given by

$$\text{Efficiency}=1-\frac{(\mathrm{T}_2-\mathrm{T}')+\gamma(\mathrm{T}'-t_o)}{\mathrm{T}-t_c}. \quad (67)$$

As $\mathrm{T}_2=\mathrm{T}(1/\mathrm{X})^{\gamma-1}$, $t_c=t_o\rho^{\gamma-1}$, and $\mathrm{T}'=(\mathrm{X}/\rho)t_o$, we have on substitution and rearrangement from equation (67)

$$\text{Efficiency} = 1 - \frac{(\mathrm{T}/t_o)\mathrm{X}^{1-\gamma} + (\gamma - 1)(\mathrm{X}/\rho) - \gamma}{(\mathrm{T}/t_o) - \rho^{\gamma - 1}}, \quad (68)$$

when $\mathrm{T}_2 = \mathrm{T}'$, $(\mathrm{T}/t_o) = \mathrm{X}^{\gamma}/\rho$, and (68) then reduces to the previous case, viz. equation (66).

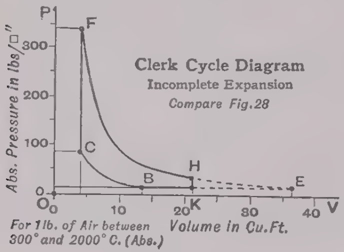

FIG. 20.

§ (36) THE BEAU DE ROCHAS, OR OTTO, CYCLE.—The last and most important of all cycles of internal combustion engines is the "constant volume" cycle first proposed by Beau de Rochas in 1862, and practically realised by Dr. Otto in his famous "Otto Silent" "gas engine" of 1876.

In this cycle there is no separate compressing pump, its function being discharged by the working cylinder itself. The sequence of operations is as follows, "stroke" referring to that of the working piston:

(1) Suction of carburetted charge of air during the whole of the first out-stroke.

(2) Compression of the charge into the combustion chamber of the cylinder during the whole of the first in-stroke.

(3) Explosion of charge at end of first in-stroke.

(4) Expansion of heated charge during the whole of the second out-stroke; this is the "working stroke."

(5) Exhaust of the burnt gases into the atmosphere during the whole of the second in-stroke.

Thus the cycle requires for its performance four consecutive strokes of the working piston, whence the term "four-stroke" cycle; and only one working impulse is obtained for each two revolutions of the crank-shaft.

An ideal diagram is shown in *Fig.* 21. During the first out-stroke the piston draws in the charge at atmospheric pressure, along LK, work being done on the piston represented by the area +MLKN. During the return stroke the volume AK is adiabatically compressed along KC to QC, the work done being represented by −NKCMN.

Explosion is caused to occur at C, and the pressure instantly rises, at constant volume, as indicated by CG; during the second out-stroke the heated gases expand adiabatically along FH, doing work on the piston represented by +MFHNM, and at H the exhaust is opened to the atmosphere causing instant drop of pressure at constant volume HK. During the second in-stroke the burnt gases are expelled along KL into the atmosphere, work being done represented by −NKLM; this completes the cycle. The work account is therefore

$$+\mathrm{MLKN} - \mathrm{NKCMN} + \mathrm{MFHNM} - \mathrm{NKLM} = +\mathrm{CFHKC};$$

thus CFHKC represents the useful work done per cycle.

Thermodynamically the action may be conceived as taking place in the same mass of air always enclosed in the working cylinder, and subjected to the operations indicated by KC, CF, FH, and HK; thus the heat received is $\mathrm{H} = k_v(\mathrm{T} - t_c)$; while the heat rejected is $h = k_v(\mathrm{T}_2 - t_o)$. Hence the efficiency, $1 - h/\mathrm{H}$, is given by the equation

$$\text{Efficiency} = 1 - \frac{\mathrm{T}_2 - t_o}{\mathrm{T} - t_c}. \quad . \quad . \quad (69)$$

This may be simplified and expressed in two other important ways. For by equation (12) and § (22) Prop. 2, we have $\mathrm{T}_2/t_o = p_e/p_o = \mathrm{P}/p_c = \mathrm{T}/t_c$. Hence $t_o/t_c = \mathrm{T}_2/\mathrm{T}$, and also $\mathrm{T}_2 - t_o/\mathrm{T} - t_c = t_o/t_c = \mathrm{T}_2/\mathrm{T}$. Accordingly

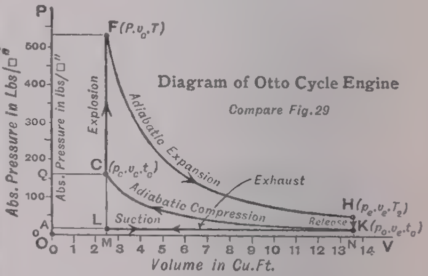

FIG. 21.

$$\text{Efficiency} = 1 - \left(\frac{t_o}{t_c}\right), \quad . \quad . \quad . \quad (70)$$

and thus in this cycle the efficiency depends, in the ideal case, only upon the ratio of the absolute temperatures at the beginning and end of *compression*, and is independent of the explosion temperature. Obviously (70) may also be written

$$\text{Efficiency} = 1 - (\mathrm{T}_2/\mathrm{T}).$$

which expresses it in terms of the ratio of absolute temperatures at the beginning and end of expansion; it is obvious that the cycle is "Imperfect." The second important simplification of (69) is the expression for the efficiency in terms of the (adiabatic) ratio of compression $(1/\rho)$. We have by equation (22)

$$\left(\frac{t_o}{t_c}\right) = \left(\frac{v_c}{v_e}\right)^{\gamma-1} = \left(\frac{1}{\rho}\right)^{\gamma-1};$$

hence by (70)

$$\text{Efficiency} = 1 - \left(\frac{1}{\rho}\right)^{\gamma-1}, \quad . \quad . \quad (71)$$

showing that in the ideal Otto cycle the efficiency depends upon the compression ratio alone.

§ (37) EFFICIENCY FORMULAE.—On comparing equations (32′), (48), and (71) the interesting fact emerges (first pointed out by Callendar) that in the three typical ideal cycles of constant temperature, constant pressure, and constant volume, the efficiency is expressed by the same formula, viz.

$$\text{Efficiency} = 1 - \left(\frac{1}{\rho}\right)^{\gamma-1}, \quad . \quad (71)$$

where $(1/\rho)$ is the ratio of adiabatic compression, and is thus the same, for the same value of ρ, in all three cases.

It must be remembered, however, that in the constant temperature (Carnot) cycle the adiabatic compression raises the temperature of the working substance through the whole range from the lowest to the highest between which the engine works, whence in this case the value of the efficiency is an absolute maximum, as has been shown. In the other two cases the adiabatic compression does not raise the substance from the lowest to the highest temperature, and the expression for the efficiency has a value necessarily less than in the Carnot case, though a maximum in each case for the particular cycle considered; these are, therefore, "imperfect" cycles in the sense as explained in § (2) *supra*.

In the constant temperature cycle all heat is received and rejected at constant temperature; in the cycles of constant pressure and constant volume heat is received at rising, and rejected at falling, temperature; also in the Carnot and Brayton cycles the expansion is "complete," which is not the case in the Otto cycle. Examination of equations (51), (53), and (66) shows the manner in which the value of the efficiency is further diminished by changes in the cycles imposed by practical considerations.

§ (38) TEMPERATURE-ENTROPY DIAGRAMS OF TYPICAL CYCLES.—In *Figs.* 22-29 are shown $T-\phi$ diagrams for the typical cycles of Classes I., II., and III., together with actual numerical values of maximum efficiency for uniform upper and lower absolute temperature limits assumed at 2000° C. and 300° C. respectively. *Fig.* 22 shows the $T-\phi$ diagram for the constant temperature Carnot cycle; as already pointed out (*vide Fig.* 6 and text) this takes the form of a rectangle, and the efficiency—which is independent of the breadth of the rectangle—is here an absolute maximum in value of $1-300/2000=0{\cdot}85$.

§ (39) THE BRAYTON ENGINE.—*Fig.* 23 shows the $T-\phi$ diagram of the constant pressure cycle of the Brayton engine, with complete expansion, as described in § (29) and *Fig.* 13. The entropy along the adiabatic compression is taken as an arbitrary zero; thus on any vertical, as MI in *Fig.* 23, take the point B at the 300° C. level. Then, by aid of equation (21), $t_c=(p_c/p_o)^{\gamma-1/\gamma}$, and taking $p_c=70$ lbs. per sq. in. and $p_o=14{\cdot}7$ lbs. per sq. in., determines $t_c=468°$ C.; this gives the point C on MI and thus determines BC, the isentropic corresponding to the adiabatic compression of *Fig.* 13. Through C draw the curve whose equation is $\phi=k_p \log_\epsilon (t/t_c)$ (see equation (38)), and let this cut a horizontal through 2000° C. in F; then CF on *Fig.* 23 represents the constant pressure expansion line of *Fig.* 13. Through F draw a vertical meeting the curve $\phi=k_p \log_\epsilon (t/t_0)$ in E; then FE is the isentropic corresponding to the adiabatic expansion line in *Fig.* 13, while the curve EB represents the constant pressure compression of *Fig.* 13.

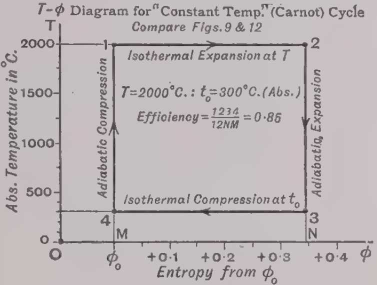

FIG. 22.

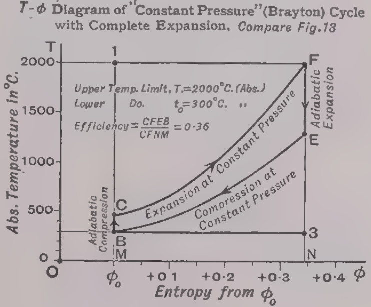

FIG. 23.

Agreeably with equation (10) (see also *Fig.* 5) the efficiency in this case is expressed by the ratio Area BCFE/Area MCFN, which, by direct planimetric measurement—as may be verified by calculation from equation (45)—has here the value 0·36.

The corresponding Carnot engine would take in heat MIFN, and reject heat N3BM, with corresponding efficiency of 0·85. The Brayton engine takes in the smaller quantity of heat MCFN and rejects the larger quantity NEBM, with resultant reduction in the value of its efficiency to 0·36.

§ (40) THE BRAYTON ENGINE WITH INCOMPLETE EXPANSION.—*Fig.* 24 shows the $T-\phi$ diagram of the Brayton engine with incomplete expansion, as shown in the *pv* diagram, *Fig.* 14. The temperature T_2 at release H is taken as 1450° C., and the drop of pressure HK at constant volume in *Fig.* 14 is represented on the $T-\phi$ diagram by the curved line HK calculated from the equation $\phi=k_v \log_\epsilon (T_2/t)$.

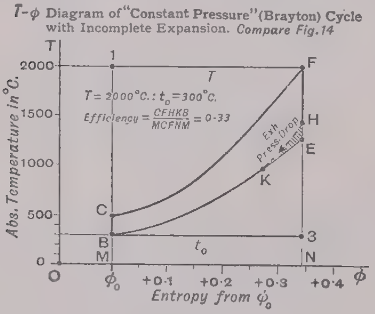

FIG. 24.

Fig. 24 differs from *Fig.* 23 only in the useful heat area being reduced by the amount EHK, which thus represents, in this case, the loss caused by incomplete expansion, and reduces the efficiency from 0·36 to 0·33.

§ (41) THE DIESEL ENGINE.—The $T-\phi$ diagram of the Diesel engine is given in *Fig.* 25. Initially (see *Fig.* 15) $T'=300°$ C., p_o = atmospheric pressure (14·7 lbs.), while p_c is assumed at the value usual in practice, viz. 500 lbs. per sq. in., and T = 2000° C.

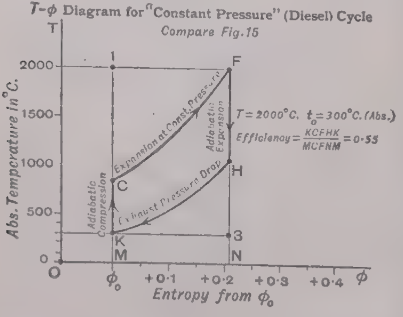

FIG. 25.

Then by equation (21)

$$t_c=(p_c/p_o)^{1-1/\gamma}\times T'=833° \text{ C.};$$

thus the points K and C may be determined, and KC on *Fig.* 25 is then the isentropic corresponding to the adiabatic compression of *Fig.* 15.

Through C the curve $\phi=k_p \log_\epsilon (t/t_c)$ is next drawn, cutting a horizontal through 2000° C. at F, while through K the curve $\phi=k_v \log_\epsilon (t/T')$ is drawn cutting a vertical through F in H. Then FH is the isentropic corresponding to the adiabatic expansion, and HK corresponds to the constant volume pressure drop at release of *Fig.* 15.

For the efficiency in this case, either by calculation from equation (52) or by direct measurement from the diagram of the ratio, we have for the Area KCFHK/Area MCFNM the value 0·55.

§ (42) THE LENOIR ENGINE.—In *Fig.* 26 is shown the $T-\phi$ diagram of the now entirely obsolete Class III. Lenoir engine, with complete expansion, whose *pv* diagram is shown in *Fig.* 16. The diagram is constructed by taking the point B at 300° C. on any vertical and drawing through this point the curve $\phi=k_v \log_\epsilon (t/t_o)$ cutting a horizontal through 2000° C. in F; thus BF represents the constant volume pressure increase due to the explosion (*Fig.* 16). Through F draw a vertical, and through B draw the curve $\phi=k_p \log_\epsilon (t/t_o)$ meeting this vertical in E; then the isentropic FE corresponds to the period of adiabatic expansion, and the curve EB to the constant pressure compression of *Fig.* 16; the point E obviously gives the temperature T′, here 1162° C., as may be verified by direct calculation.

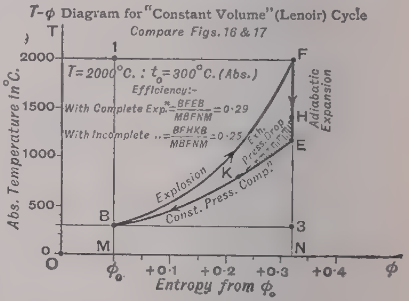

FIG. 26.

$$\text{Efficiency}=\frac{\text{Area BFE}}{\text{Area MBFNM}}=0{\cdot}29,$$

as may also be determined by equation (54).

The dotted line HK on *Fig.* 26 is the modification in the $T-\phi$ diagram due to incomplete expansion (compare *Fig.* 17), the temperature at release H is assumed at 1400° C., and the curve HK is plotted from the equation $\phi = k_v \log_\epsilon (1400/t)$ where ϕ is the defect of entropy below that of H, viz. 0·321. The efficiency, being the value of the ratio Area BFHKB/Area MBFNM, is now reduced to 0·25.

§ (43) Free Piston Engine.—The ideal $T-\phi$ diagram of the Otto and Langen free piston engine is shown in *Fig.* 27, with which *Fig.* 18 may be compared. The initial point is B at 300° C. and the explosion raises the temperature, at constant volume, to 2000° C.; this is represented on the diagram by the curve BF, plotted from the equation $\phi = k_v \log_\epsilon (t/t_o)$, cutting a horizontal through 2000° C. in F. The vertical FE is the isentropic corresponding to the subsequent adiabatic expansion during the rise of the heavy free piston, while the horizontal line EB represents the isothermal compression of the gases during the working down-stroke. The efficiency, either by direct measurement from the diagram of the value of the ratio Area BFEB/Area MBFNM, or by calculation from equation (62), has here the relatively high value 0·66; comparison with the previous diagram (*Fig.* 26) clearly shows the manner in which the efficiency is increased in value as a result of the compression being isothermal instead of at constant pressure.

T-ϕ Diagram of "Constant Volume" (Free Piston) Engine

Compare Fig. 18

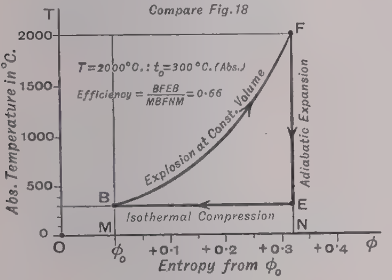

Fig. 27.

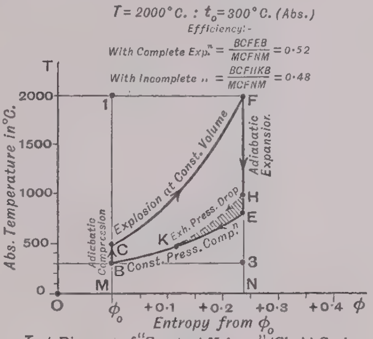
§ (44) Clerk Engine.—The $T-\phi$ diagram for the Clerk constant-volume cycle, both with complete and incomplete expansion, is shown in *Fig.* 28; compare *Figs.* 19 and 20. The initial point B is at 300° C. and the compression temperature t_c is assumed at 500° C.; thus BC is the isentropic of adiabatic compression.

The curve CF representing rise of temperature at constant volume (*i.e.* explosion) is next plotted from the adiabatic equation $\phi = k_v \log_\epsilon (t/500)$, and by its intersection with a horizontal through 2000° C. determines F; a vertical through F then meets the curve $\phi = k_v \log_\epsilon (t/300)$ at E, and FE is then the isentropic of adiabatic expansion, while EB represents the operation of compression at constant pressure.

When the expansion is incomplete, assuming that at release the temperature is 1000° C., the curve HK, plotted from the equation $0{\cdot}235 - \phi = k_v \log_\epsilon (1000/t)$, is the $T-\phi$ line corresponding to the pressure drop at release, with corresponding loss of useful work-heat represented by the area EHK.



T-ϕ Diagram of "Constant-Volume" (Clerk) Cycle

Compare Figs. 19 & 20

Fig. 28.

By measurement from the diagram of the ratio Area BCFEB/Area MCFNM, or by calculation from equation (63), the efficiency with the data assumed, when the expansion is complete, will be found to have the value 0·52. In the case, as taken, of incomplete expansion, the efficiency is reduced in value to 0·48.

§ (45) Otto Engine.—In *Fig.* 29 is shown the $T-\phi$ diagram of the "Otto" or "Beau de Rochas" cycle, of which the *pv* diagram is given in *Fig.* 21. As before, the initial point K is taken, on any vertical, at 300° C.; the temperature of compression, t_c, is assumed at 600° C.; hence the vertical line KC is the isentropic of adiabatic compression.

T-ϕ Diagram of "Constant Volume" (Otto) Cycle

Compare Fig. 21

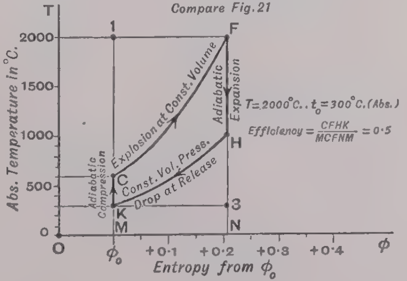


Fig. 29.

From C the curve $\phi = k_v \log_\epsilon (t/600)$ is next plotted, cutting a horizontal through 2000° C.

in F; then the curve CF represents the increase of entropy during the explosion. Through F a vertical is drawn intersecting the curve $\phi = k_v \log_\epsilon (t/300)$ in H; then FH is the isentropic of adiabatic expansion, and the curve HK corresponds to the drop of pressure at constant volume which occurs at release.

The efficiency, either by direct measurement of the ratio Area KCFHK/Area MCFNM, or by calculation from equation (70) has here the value 0·5.

§ (46) IDEAL EFFICIENCIES.—Hence for a temperature range from 2000° C. (abs.) to 300° C., and with the other data assumed in the foregoing paragraphs, the maxima ideal efficiencies in the several cases considered have the following values:

Carnot (constant temperature)	0·85
Otto and Langen free piston (constant volume)	0·66
Diesel (constant pressure)	0·55
Clerk (constant volume), with complete expansion	0·52
Clerk (constant volume), with incomplete expansion	0·48
Otto (constant volume)	0·50
Brayton (constant pressure), with complete expansion	0·36
Brayton (constant pressure), with incomplete expansion	0·33
Lenoir (constant volume), with complete expansion	0·29
Lenoir (constant volume), with incomplete expansion	0·25

§ (47) PRACTICAL CONSIDERATIONS. — Thus the efficiency of the Carnot "Perfect" cycle is substantially greater than that of any of the others, while the Otto and Langen engine has an efficiency—when isothermal compression is realised—second only to that of the Carnot.

For the purposes of practical power production, however, it is not enough that a cycle should be of high ideal efficiency; in order that an engine may be practicable it is necessary, *inter alia*, (1) that its cycle can be effectively performed in a very short time, and (2) that the ratio of mean effective pressure to maximum pressure shall be as high as possible. If (1) cannot be attained the engine can only run slowly, and is thus bulky and weighty in relation to the power developed by it. If (2) is not realised, then since the engine must be designed to withstand the maximum pressure developed it is necessarily weighty and costly relatively to its power output.

These two conditions have, so far, practically excluded all but the Otto, Diesel, and Clerk cycles, and it is of interest to determine in the several cases of § (46), the values of the maximum pressure, the mean effective pressure, and the ratio of these.

The mean effective pressure, p_m, is the average height of the closed figure on the p_v diagram representing the useful work U (ft.-lbs.) done per cycle; if p_m be in lbs. per sq. in., and if V be the greatest, and v the least, volume (in cub. ft.) of the working substance, then

$$p_m = \frac{\mathrm{U}}{144(\mathrm{V} - v)} \text{ lbs. per sq. in.} \quad . \quad (72)$$

The maximum pressure developed will be denoted by P, and in each case it is considered that the engine uses 1 lb. of air, initially at atmospheric pressure p_o of 14·7 lbs. per sq. in. and temperature $t_o = 300°$ C. (abs.), whence, by equation (12′), its volume $v_o = 13{\cdot}6$ cub. ft.

§ (48) MAXIMUM PRESSURES. *The Carnot Cycle; Value of* p_m/P.—The calculation here is conveniently conducted as follows: As T = 2000° C. and $t_o = 300°$ C. we have, by equation (32), for the value of the adiabatic ratios $\rho = (2000/300)^{2 \cdot 45} = 104{\cdot}36$; thus the ratios of adiabatic expansion and compression must *necessarily* each have the enormously large value 104·36. The isothermal ratio r is arbitrary; if it be assumed as 2, then, by equation (30), the total expansion ratio becomes $\mathrm{X} = 2 \times 104{\cdot}36 = 208{\cdot}7$, a value, it is needless to point out, entirely out of the question in any actual engine.

The maximum pressure P is obtained by aid of equation (12) and is given by

$$\mathrm{P} = \left(\frac{\mathrm{T}}{t}\right)\mathrm{X}p_o = \left(\frac{2000}{300}\right) \times 208{\cdot}7 \times 14{\cdot}7$$
$$= \text{about } 20{,}450 \text{ lbs. per sq. in.,}$$

or roundly 1400 atmospheres.

Again, by equation (72),

$$p_m = \frac{\mathrm{U}}{144\mathrm{V}(1 - (1/\mathrm{X}))} = \frac{c(\mathrm{T} - t) \log_\epsilon r}{144\mathrm{V}(1 - (1/\mathrm{X}))}$$

(*vide* equation (12′)); thus

$$p_m = \frac{96 \times 1700 \times \log_\epsilon 2}{144 \times 13{\cdot}6 \times 0{\cdot}995} = 58 \text{ lbs. per sq. in.,}$$

so that the ratio of mean effective to maximum pressure is only 58/20,450, or about 1/353rd part.

Any such maximum pressure as 20,450 lbs. per sq. in. is of course entirely impossible in practice, and it will also be observed that the mean effective pressure is only a small fraction of the maximum pressure. The cycle is entirely impracticable.

The design of an engine is dominated by the maximum pressure to be provided against; if we take this at the value adopted in the modern Diesel engine, viz. about 500 lbs. per sq. in., and also if the upper temperature limit be assumed at the low value of only 800° C. we shall have $\mathrm{X} = 13{\cdot}95$, $\rho = 11{\cdot}06$, $r = 1{\cdot}26$, and $p_m = 6{\cdot}1$ lbs. per sq. in. Thus even here the mean effective pressure is only 1/82nd of the maximum pressure, and has the trifling value of only about 6 lbs. per sq. in. when the Carnot cycle is taken.

§ (49) THE OTTO AND LANGEN "FREE PISTON" CYCLE; RATIO OF p_m/P. — See § (33) and *Figs.* 18 and 27. Here T = 2000° C.,

$t_o = 300°$ C. (abs.), $p_o = 14{\cdot}7$ lbs. per sq. in., and $v_o = 13{\cdot}6$ cub. ft.

The remaining quantities may be thus evaluated:

$p_c/p_o = (T/t_o)$ gives	p_c	$= 98$ lbs. sq. in.,
$p_c v_o^{\gamma} = p_e v_e^{\gamma}$, and $p_o v_o = p_e v_e$ gives	v_e	$= 1419{\cdot}4$ cub. ft.;
and also	p_e	$= 0{\cdot}14$ lbs./sq. in.,
$r = v_e/v_o$ gives	r	$= 104{\cdot}4$,
$U = Jk_v(T - t_o) - ct_o \log_e r$ gives	U	$= 268{,}420$ ft.-lbs.;
then by Eq. (72)	p_m	$= 1{\cdot}326$ lbs./sq. in.,
and $p_m/P = p_m/p_c$ gives	$p_m/P = 1/74$th.	

Thus the ideal cycle in this case requires a total expansion of 104·4 times the initial volume, and gives a mean effective pressure of only 1·326 lb. per sq. in., which is but 1/74th of the maximum pressure developed.

Moreover, in order to approximate even roughly to isothermal compression on the return stroke, it was necessary to run these free piston engines very slowly, and they were in consequence exceedingly cumbrous and furnished but a trifling power relatively to their bulk and weight, notwithstanding their high theoretical efficiency.

A series of tests made by Clerk in 1885 on a 2-h.p. engine with a cylinder 12½ in. in diameter showed that the maximum stroke was 40½ in., and i.h.p. 2·9, with 28 explosions per minute, corresponding to a mean effective pressure of 8½ lbs. per sq. in.; the total expansion ratio attained was, however, only about 6.

The b.h.p. was 2·0, and the mechanical efficiency therefore 70 per cent. The consumption of coal gas was 24·6 cub. ft. per i.h.p. hour, corresponding to an (indicated) thermal efficiency of 0·11. Even this consumption, however, marked a notable improvement upon the results obtained with the earlier Lenoir and Hugon engines; the largest engine made of this very noisy free piston type was only of 3 h.p.

§ (50) THE DIESEL CYCLE; RATIO OF p_m/P.—See § (41) and *Fig.* 15. Here

$$p_o = 14{\cdot}7 \text{ lbs. per sq. in.,}$$

$$v_e = 13{\cdot}6 \text{ cub. ft.,}$$

$$T' = 300° \text{ C. (abs.),}$$

$$p_c = 500 \text{ lbs. per sq. in;}$$

$$\therefore\ v_c = \left(\frac{p_o}{p_c}\right)^{1/\gamma} v_e = 1{\cdot}112 \text{ cub. ft.,}$$

$$t_c = \frac{144 p_c v_c}{96} = 833° \text{ C. (abs.),}$$

$$T = 2000° \text{ C. (abs.),}$$

$$v_p = \frac{RT}{144 p_c} = 2{\cdot}67 \text{ cub. ft.,}$$

$$\sigma = \frac{v_p}{v_c} = 2{\cdot}4,$$

$$\rho = \frac{v_e}{v_c} = 12{\cdot}23,$$

$$\text{and}\quad T_2 = \left(\frac{v_p}{v_e}\right)^{\gamma - 1} T = 1043° \text{ C. (abs.).}$$

Hence (*vide* § (31)), as $U = k_p(T - t_c) - k_v(T_2 - T')$, we have U = 151·67 C.Th.U. of useful work, and therefore, by equation (72),

$$p_m = \frac{151{\cdot}67 \times 1400}{144 \times 12{\cdot}488} = 118 \text{ lbs. per sq. in.}$$

Thus the mean effective pressure has here the high value 118 lbs. per sq. in., and $p_m/P = 1/4{\cdot}24$, a very great advance on previous figures. In actual practice mean effective pressures of 100 to 115 lbs. per sq. in. are ordinarily realised, with an average (indicated) thermal efficiency of 0·4, and revolution speed, in stationary types, of 200 per minute. The Diesel cycle thus satisfies the requirements of actual practice very fully.

§ (51) THE BEAU DE ROCHAS, OR OTTO CYCLE; RATIO OF p_m/P.—See §§ (36) and (45) and *Figs.* 21 and 29. Here also

$$p_o = 14{\cdot}7 \text{ lbs. per sq. in. (abs.),}$$

$$v_e = 13{\cdot}6 \text{ cub. ft.,}$$

$$t_o = 300° \text{ C. (abs.).}$$

t_c is assumed at 600° C. (abs.);

$$\text{whence}\quad v_c = \left(\frac{t_o}{t_c}\right)^{\gamma - 1} v_e = 2{\cdot}489 \text{ cub. ft.,}$$

$$\text{and}\quad \rho = \frac{13{\cdot}6}{2{\cdot}489} = 5{\cdot}47,$$

$$p_c = \frac{96 t_c}{144 v_c} = 160{\cdot}7 \text{ lbs. per sq. in. (abs.),}$$

$$P = \frac{T}{t_c} p_c = 535{\cdot}7 \text{ lbs. per sq. in. (abs.),}$$

$$T = 2000° \text{ C. (abs.).,}$$

$$T_2 = \frac{T}{t_c} t_o = 1000° \text{ C. (abs.),}$$

$$\text{and}\quad p_e = \frac{96 T_2}{144 v_e} = 49{\cdot}0 \text{ lbs. per sq. in.}$$

The useful work done is given by the equation $U = k_v(T - tc/1) - k_v(T_2 - t_0) = 118{\cdot}23$ C.Th.U. whence, by equation (72),

$$p_m = \frac{1400 \times 118{\cdot}23}{144 \times 11{\cdot}11} = 103{\cdot}5 \text{ lbs. per sq. in.,}$$

and the ratio p_m/P has the value 1/4·84, which is of the same order as that obtained in the case of the Diesel cycle.

§ (52) THE CONSTANT-PRESSURE "BRAYTON" CYCLE; VALUE OF p_m, ETC.—See §§ 29, 30, and 39 and *Figs.* 14 and 23; this cycle is practically perfected in the modern Diesel engine, but it is of interest to evaluate p_m, as its ratio to P was, both in theory and practice, very high. As illustrated in *Figs.* 14 and 23 we have here

$$p_o = 14{\cdot}7,$$

$$v_o = 13{\cdot}6,$$

$$t_o = 300° \text{ C.,}$$

$$p_c = 70;$$

whence, by equation (21),

$$t_c = 468° \text{ C.},$$

and therefore

$$v_c = \frac{96 \times t_c}{144 \times p_c} = 4{\cdot}47 \text{ cub. ft.}$$

Again, $v_p = \frac{\text{T}}{t_c} v_c = 19{\cdot}05$ cub. ft.,

and thus $\sigma = 4{\cdot}26$ (*vide* equation 51).

T_2 is assumed at 1450° C., whence, by equation (22), $v_e = 41{\cdot}9$ cub. ft., so that the total expansion ratio $\text{X} = 9{\cdot}4$.

$$p_e = \frac{96 \times t_2}{144 \times v_e} = 23{\cdot}2 \text{ lbs. per sq. in.,}$$

and $\text{T}' = \frac{v_e}{v_o} t_o = 925°$ C. (abs.).

Hence, from § (30), $\text{U} = 126{\cdot}74$ C.Th.U. of useful work, and accordingly, by equation (72),

$$p_m = \frac{126{\cdot}74 \times 1400}{144 \times 37{\cdot}43} = 33{\cdot}0 \text{ lbs. per sq. in.}$$

The effective maximum pressure is $(\text{P} - 14{\cdot}7)$ lbs. per sq. in. $= 55{\cdot}3$, which is only 1·68 times p_m—a very satisfactory feature of the cycle.

A test of a Brayton petroleum engine of about 4 b.h.p., made by Clerk in 1878, showed a maximum pressure in the working cylinder of 47 lbs. per sq. in., a mean effective pressure of 30·2 lbs. per sq. in., and a consumption of petroleum of 2·75 lbs. per b.h.p. hour, corresponding to the very low brake thermal efficiency of only 0·047.

T_2 is assumed at 1400° C. (abs.)., and therefore, by equation (22), $v_e = 32{\cdot}6$ cub. ft.; then

$$p_e = \frac{96 \times 1400}{144 \times 32{\cdot}6} = 28{\cdot}6 \text{ lbs. per sq. in. (abs.),}$$

and $\text{T}' = \frac{v_e}{v_o} t_o = 718°$ C. (abs.).

Hence

$$\text{U} = k_v(\text{T} - t_o) - k_v(\text{T}_2 - \text{T}') - k_p(\text{T}' - t_o)$$
$$= 72{\cdot}67 \text{ C.Th.U. of useful work.}$$

In this case, as the stroke of the piston is AK, we have to write

$$p_m = \frac{1400 \times 72{\cdot}67}{144 \times v_e} = 21{\cdot}7 \text{ lbs. per sq. in.}$$

Thus the ratio of p_m to the maximum effective pressure of $(98 - 14{\cdot}7)$ lbs. per sq. in. has here the satisfactory value 1/3·84; the engine failed commercially, however, on account of its exceedingly great consumption of fuel. Not only is the theoretical efficiency of the cycle low, but even this low efficiency was not nearly attained in practice. The engines were built in sizes of from one-half to three horsepower. An experiment by Tresca on a one-half horse-power engine showed a consumption of 95 cub. ft. of (Paris) coal gas per i.h.p. hour, which is fully eight times as great as that of a modern four-stroke gas engine of moderate power.

§ (54).—Collecting the results obtained in the preceding paragraphs for comparison, we have the following for typical engines, each using 1 lb. of air, and working between the absolute temperatures 2000° C. and 300° C.:

Engine.	Type of Cycle.	Theoretical Efficiency with Conditions assumed.	Maximum Pressure P. Lbs./Sq. In. Abs.	Mean Pressure p_m. Lbs./Sq. In.	Ratio of p_m to (P – 14·7).
Carnot . . .	Constant temperature	·85	20,450	58	·0028
Otto and Langen free piston *	Constant volume	·66	98	1·326	·016
Diesel . . .	Constant pressure	·55	500	118	·243
Otto 4-stroke. .	Constant volume	·50	536	103·5	·200
Brayton . .	Constant pressure	·33	70	33	·600
Lenoir . . .	Constant volume	·25	98	21·7	·260

* With complete expansion.

The modern Diesel engine consumes only about 0·45 lb. of oil fuel per b.h.p. hour, corresponding to a brake thermal efficiency of fully 0·30.

§ (53) THE LENOIR CONSTANT VOLUME CYCLE; VALUE OF p_m.—See *Figs.* 17 and 26 and §§ 32 and 42. Here also

$$p_o = 14{\cdot}7,$$
$$v_o = 13{\cdot}6,$$
$$t_o = 300° \text{ C.},$$
$$\text{T} = 2000° \text{ C.},$$

whence $p_c = 98$ lbs. per sq. in. (abs.).

The relative values and advantages of the various cycles are very fully discussed by Clerk in *The Gas, Petrol, and Oil Engine* (Longmans), vol. i., 1909.

§ (55) LOSSES IN INTERNAL COMBUSTION ENGINES.—In all that precedes it has been assumed that the working substance is dry air—regarded as a perfect gas—and that the conditions are such that each cycle can be perfectly carried out. This is impossible in actual practice, and is due mainly to the following causes:

(1) The working gases lose heat to the surfaces of the combustion chamber, cylinder

and piston crown during and after explosion by radiation and convection.

(2) The unexploded charge is usually heated on entering the cylinder, with consequent expansion and reduction of the mass of charge exploded.

(3) In constant-volume cycles the explosion is never instantaneous, as assumed in theory.

(4) The working substance is not dry air, but a mixture of nitrogen, carbon dioxide, steam, and oxygen, having specific heats which are not constant, but increase with rise of temperature.

(5) The working substance is changed in volume by combustion, so that the volume which is heated and expanded differs from that which is compressed when measured at the same temperature and pressure.

(6) Combustion is not complete when maximum temperature is attained, and is even, in some cases, not complete at release.

(7) Some throttling or "wire-drawing" always occurs during admission, and there is always some degree of back pressure opposing the exhaust.

(8) The working gases lose heat to the cylinder walls during compression.

These several sources of loss may be considered in some further detail.

§ (56) Loss of Heat to Walls during Explosion and Expansion.—The physical properties of cast iron, of which the cylinders of all internal combustion engines, excepting only air-craft engines, are made, renders it necessary that they shall be kept cool either by a water-jacket or, as in many small engines, by a stream of cold air passing over heat-radiating gills formed on the outer surface of the cylinder. In practice it is found that 25 per cent to 50 per cent of the whole heat evolved by the combustion of the working fluid is lost in this way alone. The highly heated gases lose heat to the containing surfaces partly by radiation, and, being in a state of very violent turbulence, also by convection.

The general rule that the better the absorber the better the radiator, and the principle that a perfectly transparent substance, whatever its temperature, could radiate no energy, lead to the conclusion that gases in chemical equilibrium—which then possess nearly perfect transparency—can emit no appreciable radiation. When radiation does take place from gases it appears to arise from the flame due to chemical action proceeding in the gas, and in internal combustion engines any radiation from the flaming mixture is absorbed by the enclosing metal walls of the combustion chamber, cylinder barrel, piston crown, and valve heads, wherein it appears as sensible heat, which is then conveyed by conduction to the jacket and surrounding air. Loss of energy by radiation, in this connection, was first considered by Callendar in 1906. Tests by him on a small petrol engine[1] showed that the loss of heat per cycle could be represented approximately by an expression of the form $a+b\tau$, where τ is the time of one revolution, and a and b are constants. Radiation loss from the burning gases proceeds with very great rapidity near the instant of maximum temperature, and this practically instantaneous loss may be considered as represented by the constant term "a." The second term $b\tau$ represents a loss by radiation and convection-conduction proportional to the time during which the cylinder surfaces are exposed to the burning gases.

§ (57) Radiation from Flames.—R. v. Helmholtz found, when using "solid" flame of about $\frac{1}{4}$ in. in diameter, that a hydrogen flame radiated about 3 per cent, coal gas almost 5 per cent, and CO about 8 per cent of its total heat of combustion. These were very small flames. A large flame radiates more energy per unit of area, since a flame is largely transparent even to its own radiation, and thus radiation is received not only from the surface molecules, but also from all those behind it. Callendar, repeating some of Helmholtz's experiments on a larger scale, found that the radiation from a Bunsen non-luminous coal gas flame 1·2 in. in diameter may amount to as much as 15 per cent of the whole heat of combustion. Experiments made by Julius on different kinds of flame have shown that the radiation is almost wholly due to the CO_2 and H_2O (steam molecules). The explosion of gases in an exhaust vessel, or a gas engine cylinder, differs considerably from any open flame in respect of radiation, as not only is the density of the gas much greater in the closed vessel, but it is also not cooled by mixture with the outside air. Hopkinson (1910) made experiments on the radiation emitted during explosion and subsequent cooling of a mixture of 0·15 coal gas and 0·85 air, by volume, in a closed vessel. He found that the total heat radiated during and after the explosion amounted to over 22 per cent of the whole heat of combustion. The radiation up to the instant of maximum pressure amounted to 3 per cent, and continued at a diminishing rate for a considerable period thereafter. It was still perceptible 0·5 second after maximum pressure, when the gas temperature had fallen to 1000° C.

§ (58).—The conditions existing within a gas engine when working have been vividly described by Clerk, who fitted a cylinder with a stout observation plug of glass. He says: "While the engine is at work, a continuous glare of white light is observed; a look into the interior of a boiler furnace gives a good notion of the flame filling the cylinder of a gas engine." The loss by radiation from the flaming mixture will be greater as the absorbing power of the containing metal surfaces is increased. Hopkinson has coated the interior of an explosion vessel with tin-foil, and compared the results obtained by exploding mixtures of identical composition, firstly with the tin-foil highly polished, and secondly with its surface covered with lamp-black. He found that nearly the same maximum pressure was developed in both cases, but that the fall of pressure during cooling was considerably less with the bright than with the black surface. Further bolometric experiments by Hopkinson consisted in covering a small portion of the inner surface of an explosion vessel with thin copper strip (1) highly polished, (2) blackened, and (3) with the strip protected from direct contact with the flame by a plate of rock-salt. It was found that the rate of increase of temperature of the blackened surface during explosion and the subsequent early stages of cooling greatly exceeded that of the polished strip, the difference between them being roughly equal to the rate of temperature increase observed when the strip was covered by the rock-salt, which transmitted upwards of 90 per cent of the radiant energy to the strip while protecting it against any direct gain of heat by contact with the flaming gas.

---

[1] *Proc. Inst. Aut. Eng.*, 1907.

Using a mixture of 0·15 coal gas to 0·85 air, by volume, giving a maximum temperature of 2150° C., Hopkinson estimated from these experiments that the loss of heat by radiation to the enclosing surface up to the instant of maximum pressure, was about 5 per cent of the whole heat of combustion, and that radiation continued during cooling certainly down to 1400° C. If combustion were complete at the instant of maximum pressure, which is also that of maximum temperature in closed vessel experiments, it would follow from the observed greater loss of energy by radiation during explosion to the black than to the bright surface, and the observed equality of the maximum temperatures attained in each case, that the internal energy of the gas at the same temperature would be greater when the enclosing surface was bright than when blackened. Clerk has shown, however, that combustion is never complete at the instant when maximum temperature is attained, and finds that in gas engine practice in general only some 85 per cent of the heat is evolved at this instant, the remaining 15 per cent appearing during a portion, at least, of the expansion working stroke. Combustion is usually practically complete when release takes place; with weak mixtures, or badly-designed combustion chambers, combustion may be markedly incomplete even at release.

§ (59) Cylinder Temperatures.—Although the maximum temperature of the working gases is of the order of 2000° C., the mean temperature at the inner surface of the metal of the cylinder never exceeds a quite moderate value of, at most, some 200° C. above that of the cooling water in large gas engines; in the thin walls of petrol engine cylinders the difference is much less, and is usually below 50° C. Hopkinson placed patches of tin-foil on the inner surface of the combustion chamber of a gas engine cylinder 11½ in. in diameter, and found these were quite unaffected by the successive explosions, although the heat-flow rate is here a maximum, and the melting-point of tin only 230° C. In this connection it is also of interest to record that, using a rich mixture (1 : 9) of coal gas and air, he found at the instant of maximum pressure in a cylindrical explosion vessel about 23½ in. diameter × 27 in. long, large differences of temperature at different points within the vessel. The following are his results:

Mean temperature of the gases (inferred from maximum pressure) . . .	1600° C.
Temperature at centre of volume of the vessel, near point of ignition of the mixture	1900 „
Temperature at 4 in. from the wall of vessel	1700 „
Temperature at 0·4 in. from wall at end	1100- 1300 „
Temperature at 0·4 in. from wall at side	850 „

A rough approximation to the rate of heat-flow per unit area from the gases to the cylinder surfaces is obtained by dividing the mean area exposed to the heated gases into the total heat appearing in the jacket water plus that lost by ordinary external radiation from the engine as a whole.

Comparing in this way a 35 h.p. four-cylinder 4·62 in. diameter × 5·08 in. stroke Siddeley petrol engine running at 930 revs. per minute, with a 40 h.p. single-cylinder 11½ in. × 21 in. Crossley gas engine running at 180 revs. per minute, Hopkinson [1] obtained the following results:

Item.	Crossley.	Siddeley.
C.Th.U. lost per minute to jacket water, and by general external radiation	2250	2300
Percentage of ditto to total heat supply	34·0	40·5
C.Th.U. lost per cylinder per minute	2250	575
Heat-flow in C.Th.U. per sq. in. of exposed surface per minute at—		
In-centre . . .	6·5	7·0
Out-centre . . .	2·05	3·7
Mean	3·2	4·85

[1] *Proc. Inst. Aut. Eng.* vol. iii.

Thus the maximum heat-flow rate did not exceed 7 C.Th.U. per sq. in. per minute, and the temperature grade necessary for this rate through cast iron is only about 100° C. per in. of thickness. As the walls of the Siddeley engine cylinder were only $\frac{5}{16}$ in. thick, Hopkinson points out that the mean temperature of the internal metal surface, where water-jacketed, never exceeded that of the jacket water by more than about 30° C. The walls of the Crossley engine cylinder were almost four times as thick as in the Siddeley, which would correspond to a mean temperature of inner surface of, at most, 125° C. above that of the jacket water, or about 200° C. actual temperature.

§ (60) Piston and Valve Temperatures.—The pistons and valves of internal combustion engines are rarely water-cooled, and consequently become very hot, their heat having to be conducted through some distance before reaching the jacket water. When working at full load, Hopkinson found in the Crossley engine above cited temperatures at the centres of the piston crown and exhaust valve at about 540° C. For the gas engine mixture used by him the temperature of pre-ignition was slightly above 700° C. With oil engines when run at full load pre-ignition usually soon occurs, and is commonly prevented by the injection of a water-spray into the cylinder during explosion.

In the preceding remarks it has been assumed that the internal metallic surfaces exposed to the heated gases are clean; actually the combustion chamber surface is quickly covered with a deposit of carbon, while the working barrel of the cylinder is coated by a thin film of oil. The carbon deposit on the combustion chamber surface and piston crown increases the loss by radiation from the flaming gases; by polishing the surfaces of the combustion chamber and piston of a gas engine a perceptible increase in mean pressure has been obtained. Again, a thick deposit of carbon, especially on the hot piston crown, by its low conductivity may create incandescent points or patches, and thus cause pre-ignition; thus carbon deposit is obviously to be avoided as far as possible.

§ (61) Radiation Losses.—Clerk (Gustave Canet Lecture, 1913) states that radiation losses increase very rapidly with temperature difference, the loss being approximately proportional to the difference of the fourth powers of the absolute temperatures of the gas and inner wall surface respectively—agreeably with Stefan's Law. He states also that radiation increases with increase in the dimensions of the containing vessel; and he points out that Stefan's Law practically limits the temperatures attainable in gas-engine practice.

§ (62) Heat-flow.—Reference may be made to the fifth report of the Gaseous Explosives Committee at the British Association (Dundee, 1912), which contains a valuable resumé of present knowledge relating to heat-flow from the working gases into the cylinder walls of internal combustion engines.

The general conclusions reached are, briefly:

(i.) The rate of heat-flow from gas to walls is greatest at maximum temperature and pressure, and rapidly diminishes as the piston performs its outstroke; the greater part of the heat-flow has occurred in a comparatively short time, and when the piston has moved but little from its in-position. Hence the bulk of the heat lost by the gases to the cylinder passes into the combustion chamber, piston crown, and valve heads, and but little is received by the working barrel. Clerk has calculated that the actual rate of heat-flow in the first $\frac{3}{10}$ths of the outstroke is equal to six times that of the whole stroke, in ordinary gas engines, when working at full load. If pistons be water-cooled, in considering the cooling of the cylinder it is probably sufficient to neglect altogether the heat-flow into the outer half of the working barrel. When pistons are uncooled a water-jacketed barrel is needed mainly to keep the piston cool.

(ii.) The temperature-gradient necessary to maintain the required rate of heat-flow from the inner surface of a combustion chamber to the jacket water rarely exceeds 50° C. per in., and for such surfaces, kept fairly clean, effective cooling presents no great difficulty. At special points, *e.g.* the centre of the piston crown (when uncooled) temperature is high; with a four-stroke engine of 24 in. cylinder diameter a temperature of almost 600° C. may be found here. With large gas engines the necessary great thickness of the combustion chamber walls, and the practical difficulties of ensuring free circulation of jacket water everywhere may result in the formation of high local internal surface temperatures.

(iii.) An important effect of radiation is the greatly increased heat given to cylinder walls when mean pressure is increased by increasing mixture-strength; the metal temperatures and jacket-water temperature are raised in much greater degree than the fuel consumption, and efficiency is diminished. In large engines this sets a practical limit to power output which, if exceeded, results in rapid overheating of the engine.

(iv.) Another important effect of radiation is the greatly increased heat received by the walls from a large than from a small volume of gas; it results from this, that the difference between the efficiency of a large and a small engine is lessened, and also that the difficulty of adequately cooling very large engines is increased beyond that arising from the necessary great thickness of the cylinder walls by the increased amount of heat received through radiation from the greater volume of glowing gas enclosed.

(v.) *Effect of Density.*—The density of the gas in an internal combustion engine of the Otto-cycle type is from four to seven or eight times that of the atmosphere; in Diesel-cycle engines it is considerably greater; increase in density greatly increases heat-flow as compared with an ordinary closed vessel explosion with atmospheric density before ignition. The total heat lost to the jacket water is found to increase with the density, but not quite in simple proportion; the exact relation seems to be complex, and is not ascertained; it is probable that the combined convection and radiation heat losses in a vessel of given form can be fairly well expressed as increasing according to some fractional power of the density.

The question as to the best compression ratio to adopt is closely connected with that of density. When compression is increased by reducing the volume of the combustion chamber, not only is the density of the gas, and therefore the total heat loss, increased, but the area of enclosing surface is also reduced, and hence the rate of heat-loss per unit of area is increased by both causes combined. Though efficiency is increased in theory by increase of compression ratio, this increase may be more than annulled by the increased heat-loss to the enclosing walls, and there is thus a value of the compression for which the efficiency practically attainable is a maximum. But it may easily happen that even before this maximum efficiency is attained the increased rate of heat-flow per unit area of enclosing walls may give rise to cooling difficulties and pre-ignition trouble. The cause of pre-ignition is commonly the overheating of some point or patch of the metal, or carbon deposit thereon, due to excessive heat-flow following increased density. If the enclosing metal surfaces could be kept clean and cool, compression ratios could have much higher values than are at present practicable.

§ (63) Heating of Charge entering Cylinder.—In large gas engines the ratio of surface to enclosed volume of gas is relatively small, while the thickness of the cylinder walls is necessarily great. In order to avoid setting up dangerous stresses in the metal through heating, it is found necessary to keep the jacket cool by arranging for the circulation of an ample supply of cooling water; the temperature on leaving the jackets, in large gas engines and Diesel engines, is usually between 30° C. and 50° C. In very large gas engines the pistons and valve heads are also water-cooled, and in these engines, therefore, the temperature of the whole enclosing surfaces of combustion chamber, piston, etc., is always low. In the much larger class of gas engines with uncooled pistons and valves, the average temperature of the piston crowns and valve heads is very much greater. In the exceedingly large class of small quick-revolution internal combustion engines of the petrol type, the jacket water temperature is usually between 90° C. and 100° C., while in air-cooled engines of this class, the mean temperature of the whole cylinder is considerably above 100° C., and the pistons and valve heads correspondingly higher.

In every case, when a fresh charge is taken into the cylinder, some increase in its temperature is caused by the higher temperature of the enclosing surfaces; in addition, in the three practical cycles of Clerk, Diesel, and Otto, there is always some high temperature burnt gas from the previous cycle remaining in the combustion chamber at the end of exhaust with which the entering fresh charge mixes, and by which its temperature is always raised. From these two causes, the fresh charge is always heated at the beginning of compression, and in Otto cycle gas engines of the smaller type, and petrol engines, a temperature of 200° C. at this point is not unusual. The rise of temperature results in a lessened density of fresh charge taken in, and the mass of fresh charge is further reduced by the presence of residual burnt gases in the combustion space; apart from any effect of this upon thermal efficiency the heat evolved per cycle is lessened, and the power output of the engine correspondingly reduced.

§ (64) The Diesel Cycle; Effect of Heating before Compression.—Consider the case taken in § (50), with $p_o = 14{\cdot}7$ lbs. per sq. in. (abs.), and $v_e = 13{\cdot}6$ cub. ft., the volume at outstroke. But, due to heating on admission, suppose T′ (*Fig.* 15) to be 400° C. (abs.); then at K we have now 13·6 cub. ft. of air at pressure 14·7, and temperature 400° C., *i.e.* the mass of the charge is reduced from 1 lb. to 0·75 lb., and the value of the constant $R' = p_v/T$ is now 72. The volume of the combustion chamber remains unchanged at 1·112 cub. ft., and hence p_c is also unchanged at 500 lbs. per sq. in. (abs.). But $t_c = p_c v_c / c'$ is now increased from 833° C. to 1111° C. (abs.). Hence as, by supposition, the maximum temperature T remains unchanged at 2000° C., we have $v_p = (T/t_c) \cdot v_c = 2{\cdot}002$ cub. ft., whence σ is now reduced from 2·4 to 1·8, and accordingly, agreeably with equation (53) the thermal efficiency increases. Again, $T_2 = (v_p/v_e)^{\gamma - 1} \cdot T = 915°$ C., instead of 1043° C.; the efficiency, by equation (52), is therefore now increased from 0·55 to 0·59. But the heat converted into useful work has been reduced by the reduction of the charge thus:

$U = 0{\cdot}75\{k_p(T - t_e) - k_v(T_2 - T')\} = 93{\cdot}1$ C.Th.U. Hence in consequence p_m is now reduced to $93{\cdot}1 \times 1400/144 \times 12{\cdot}488 = 72{\cdot}3$ lbs. per sq. in. as compared with 118 lbs. per sq. in. in the previous case; thus the output of power of the engine at the same revolution speed has fallen from 1·0 to 0·613. The figures in the two cases are collected together below, for comparison.

In both cases $p_o = 14{\cdot}7$, $v_e = 13{\cdot}6$, $v_c = 1{\cdot}112$, $\rho = 12{\cdot}23_o$ and $T = 2000°$ C.

T′ °C.	c °C.	V_p Cub. Ft.	σ.	Adiabatic Expansion Ratio.	T_2 °C.	Thermal Efficiency.	v. C.Th.U.	p_m. Lbs./Sq. In.	Relative Power Output.
300	833	2·67	2·4	5·1	1043	0·55	151·7	118	1
400	1111	2·002	1·8	6·8	915	0·59	93·1	72·3	0·613

In this cycle increasing the lower limit of temperature T′, increases the compression temperature t_c in the same proportion; hence t_c approaches more nearly to T, and accordingly the constant pressure expansion ratio σ is reduced with consequent increase in the adiabatic expansion ratio and reduction of the pressure drop at the release point H. The efficiency is increased from 0·55 to 0·59, but owing to the smaller expenditure of heat the power output of the engine is reduced in the proportion of 100 to 61·3.

§ (65) THE OTTO CYCLE; EFFECT OF HEATING BEFORE COMPRESSION.—See § (36) and *Fig.* 21. In this case, as by equation (71), the efficiency is $1 - (1/\rho)^{\gamma - 1}$; where ρ is constant in value for the same engine, it follows that the efficiency, in theory, is unaltered by any change in the temperature of the charge before compression. Raising t_o raises t_c in the same proportion, and *if there be the same expenditure of heat, H, as before,* then as $H = k_v(T - t_c)$ we have $T = H/k_v + t_c$, and thus T is also raised, and consequently so also is T_2 agreeably with the relation $T_2/T = t_o/t_c$. In practice, however, in this case the efficiency is *reduced* owing to the greater heat losses resulting from higher temperature of explosion and during adiabatic expansion. In the case discussed in § (51) suppose that, due to heating on admission, $t_o = 400°$ C. (abs.); then the mass of the charge is reduced from 1 lb. to $\frac{3}{4}$ lb., and t_c rises to 800° C. (abs.) since the ratio t_c/t_o is constant. The efficiency is, in theory, unaltered; two suppositions may now be made as to the supply of heat to the working fluid, viz.:

(i.) Suppose the supply of heat to be three-fourths of the quantity in § (51); and

(ii.) Suppose the supply of heat to be only that necessary to cause the working fluid to attain a maximum temperature of 2000° C. (abs.).

Case (i.).—In this case, as three-fourths of the heat is supplied from t_c to three-fourths of the fluid, the *rise* of temperature will be the same as before, and accordingly the maximum temperature attained will be unaltered and $T = 800 + 1400 = 2200°$ C., while T_2 will correspondingly increase from 1000° C. to 1100° C. Thus the working fluid is at a higher temperature throughout the cycle, the heat losses to the cylinder are greater, and hence, in practice, the efficiency is reduced. The useful work done is $U = {\cdot}75k_v\{T - t_c - T_2 + t_o\} = 88{\cdot}67$ C.Th.U., while as a necessary consequence the mean effective pressure is now reduced from 103·5 to $88{\cdot}67 \times 1400/144 \times 11{\cdot}11 = 77\frac{1}{2}$ lbs. per sq. in. Thus, at the same revolution speed, even if the efficiency remained unchanged, the output of the engine would be reduced from 100 to 75; the reduction in output will be actually greater than this, as the efficiency is lessened through the increased heat losses incurred.

Case (ii.).—In this case the efficiency is also, in theory, unaltered, and the temperature of the working substance is only increased by a relatively small amount during the adiabatic compression period; the practical reduction of efficiency may hence be expected to be smaller in this case. The mass of the charge is reduced, as before, to $\frac{3}{4}$ lb., but the heat supplied is also reduced, and is given by $H = {\cdot}75k_v\{2000 - 800 - 1000 + 400\} = 76$C.Th.U. instead of 88·67. The mean effective pressure, at unchanged efficiency, now drops to $66\frac{1}{2}$ lbs. per sq. in., and the engine output is now represented by the number 64·2 only.

Thus in Otto-cycle engines, heating the incoming charge does not, in theory, affect the efficiency, though in practice some loss of efficiency results from increased heat losses to the cylinder. The reduction in the mass of the charge, with consequent reduction in the heat supply, results, however, in a rapid falling off in the output of power.

§ (66) TIME OF EXPLOSION.—In the preliminary simple theory of the internal combustion engine constant volume cycle, explosion is assumed to occur instantaneously; actually a small, but finite, interval of time elapses between the instant of ignition and that at which maximum pressure is attained. The time of explosion in constant volume experiments may be defined as the interval of time between the commencement of increase of pressure and the attainment of maximum pressure, and numerous experiments upon explosions in closed vessels of constant volume by Bunsen, Berthelot, Bairstow and Alexander, Clerk, Grover, Hopkinson, Langen, Petavel, Mallard and Le Chatelier, and others have furnished results showing clearly the mode of dependence of the time of explosion upon the nature and condition of the "carburetted" charge employed.

Constant-volume explosion experiments by Clerk in 1900 made upon electrically ignited mixtures of London coal-gas and air, initially at atmospheric pressure and temperature, contained in a closed cylindrical vessel 7 in. in diameter and 7 in. long internally, furnished the following results :

Mixture $\frac{\text{Volume Gas}}{\text{Volume Air}}$.	Time of Explosion.
	Seconds.
$\frac{1}{4}$	·045
$\frac{1}{5}$	*·042*
$\frac{1}{6}$	·055
$\frac{1}{7}$	·067
$\frac{1}{8}$	·087
$\frac{1}{9}$	·155
$\frac{1}{10}$	·305
$\frac{1}{11}$	·290

Similar experiments by Bairstow and Alexander on mixtures of coal-gas and air exploded at constant volume but in a much larger cylindrical vessel, viz. of 10 in. internal diameter by 18 in. in length, from atmospheric temperature, but with an initial pressure of 55 lbs. per sq. in. (abs.), furnished results from which the following figures have been deduced :

Mixture $\frac{\text{Volume Gas}}{\text{Volume Air}}$.	Time of Explosion (approximately).
	Seconds.
$\frac{1}{7}$	·04
$\frac{1}{8}$	·07
$\frac{1}{9}$	·20
$\frac{1}{10}$	·5
$\frac{1}{11}$	1·0

Petavel, with a 1 : 6 mixture of coal-gas and air, initially at 18° C., and at a pressure of 1136 lbs. per sq. in. (abs.), exploded within a spherical steel bomb of 4 in. internal diameter, observed a maximum explosion pressure of 9508 lbs. per sq. in. attained in ·058 of a second. From these and other results, it appears that for uniform explosive mixtures initially at rest within a closed vessel, the time of explosion, *caeteris paribus*, is (i.) less as the mixture richness is greater, (ii.) greater, with a single point of ignition, as the volume of the containing vessel is greater, and (iii.) independent of the initial pressure of the explosive charge.

As the mixture richness is increased a point is, however, soon reached at which the time of explosion is a minimum ; the following figures from experiments by Clerk, and the Massachusetts Institute, Boston, illustrate this :

Mixture Ratio.	Time of Explosion with		
	Oldham Coal-Gas.	London Gas.	Boston Gas.
$\frac{1}{4}$	·16	·045	·08
$\frac{1}{5}$	·055	*·042*	*·05*
$\frac{1}{6}$	*·04*	·055	*·05*
$\frac{1}{7}$	·06	·067	·06
$\frac{1}{8}$	. .	·087	·06
$\frac{1}{9}$	·08	·155	·08
$\frac{1}{10}$	. .	·305	·11
$\frac{1}{11}$	·17	. .	·14

While with mixtures of 0·68, petrol vapour and air, the Boston experiments gave :

Petrol Vapour.	Time of Explosion.	Petrol Vapour.	Time of Explosion.
Per cent.	Seconds.	Per cent.	Seconds.
1·79	·109	2·78	*·058*
1·96	·091	3·03	·066
2·17	·082	3·23	·067
2·44	·060	3·45	·100
2·63	*·058*		

On the passage of the igniting spark the gas in its immediate vicinity is instantly inflamed with accompanying sudden expansion ; the inflammation very quickly extends outwards in all directions, the inflamed portion rapidly compressing, and thus heating, the uninflamed portion. Parts of the inflamed gas are also projected into the uninflamed volume, and thus cause the general inflammation to proceed at an increasing rate nearly up to the point when complete inflammation is attained. It is clear, therefore, that the time of explosion will be greater as the volume of gas exploded is greater, and also that it will be lessened by having more than one point of ignition, provided the additional ignition points are effective. Further, if a considerable volume of the gas be ignited at once, by a long and powerful spark, or a large flame, the time of explosion will be reduced ; a small separate chamber connected with the main explosion vessel if filled with explosive mixture, and ignited, will project a rush of flame into the main vessel and so much reduce the time of explosion. The shape of the explosion vessel has also a marked influence, and has also the position within the vessel of the point of ignition. This latter point is well illustrated in Bairstow and Alexander's experiments, using a cylindrical vessel 10 in. diameter × 18 in. long, with the ignition point situated at different points within it; the following are the times of explosion observed:

Depth of Ignition Point from Top of Vessel.	Time of Explosion.
Inches.	Seconds.
0	·160
3	·141
6	·177
9	*·105*
12	·123
15	·140
18	·145

The maximum pressure attained was, in each case, roundly 220 lbs. per sq. in. (abs.), and the explosion was most rapid when the mixture was fired from the centre of the cylinder. Though rapid ignition does not cause any increase in the maximum pressure attained, it is yet of importance in internal combustion engines in order to avoid loss of work from a comparatively slow pressure rise upon a rapidly moving piston. Accordingly in large gas engines, and in the petrol engines of racing cars, it is common to find two or even more igniting points per cylinder. In the case of a petrol engine tested by Professor W. Watson,[1] for example, it was found that with single ignition the time of explosion was 0·0055 second, and that this was reduced by almost one-third, viz. to ·0037 second when double ignition was used. Increased power was obtained when using double ignition, the advantage gained being greater as the revolution speed increased, as the following figures show:

Revolutions per Minute.	Horse-power with Single Ignition.	Horse-power with Double Ignition.
1100	18·4	20·8
1600	26·0	29·2

§ (67) TURBULENCE.—At an early date it was observed by Clerk that gas engines would have been impracticable, through necessarily slow running, had the rates of explosion been as great in actual engine cylinders as in closed vessel experiments. In the case just cited, the time of explosion of the petrol air mixture in an actual engine was only ·0055 second, whereas the shortest explosion time obtained in the Boston experiments—albeit with a larger vessel—was ·058 second, or more than ten times as great. In larger gas engines also the same result is observed; *Fig.* 30 is a reproduction from a diagram taken by Humphrey during a test in 1900[2] of a 500 h.p. Premier engine using Mond gas. The cylinder was 28½ in. diameter and the stroke 30 in.; the average revolution speed was 128·05 per minute. The diagram shows that maximum pressure was attained when the piston had moved forward only about $\frac{1}{20}$ of the outstroke, corresponding to a time interval of only 0·026 seconds, which is, in this case, substantially the time of explosion. Thus even in this large cylinder the time of explosion is only about one-half as great as was observed in the closed vessel coal-gas experiments above cited.

This feature has recently received special attention, and Clerk found in some experiments carried out in 1912 that the time of explosion in the same engine diminished with increase in the revolution speed, and that this resulted mainly from the increased rate of inflammation caused by the violent turbulent motion set up by the sudden rush of the fresh charge into the cylinder during the suction stroke, and which persisted during compression; in gas and petrol engines during the suction stroke the average velocity of the entering fresh charge through the inlet valve is from 100 to 120 ft. per second.

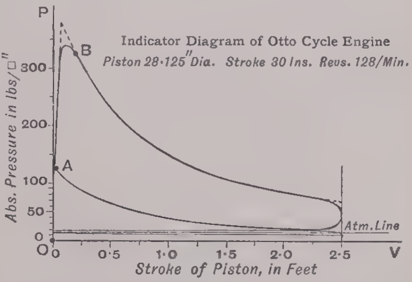

FIG. 30.

Clerk[3] has carried out further experiments showing very strikingly the important part played by turbulence in reducing the time of explosion in actual engines, and thus rendering high revolution speeds practicable. He took indicator diagrams from the same engine: (1) firing the charge in the usual manner, and (2) firing the charge after compressing and expanding it during one or two revolutions of the crank-shaft, thus giving time for the turbulence to largely subside. Comparison of the diagrams so obtained shows at once that the effect of damping down turbulence was to retard the rate of inflammation to a remarkable extent, completely changing the form of the diagram.

Two of the diagrams so taken are shown in *Figs.* 31 and 32; the time of explosion with normal ignition, from A to B,[4] is ·037 and ·033 seconds respectively; while after a third compression of the fresh charge the time of explosion increases to ·092 and ·078 seconds respectively. The cylinder was 9 in. in diameter, with 17 in. stroke, and was run at 180 revolutions per minute under full load conditions with jacket water at 70° C. Two electric igniters were fitted, one in the inlet port at the back of the combustion chamber, the other at the side of the cylinder just clear of the piston, when fully "in." It will be noted that in this case the explosion is more rapid with the side igniter, and that in both cases the time of explosion with partly quenched turbulence is about 2½ times as great as under normal working conditions with undamped turbulence.

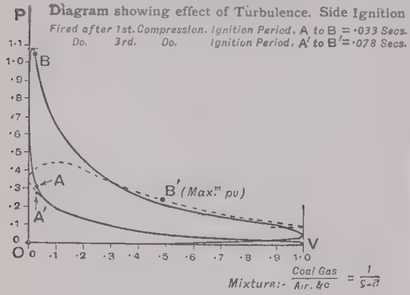

FIG. 31.

Thus, due to turbulence, the time of explosion in the actual engine was only $\frac{1}{4}$th to $\frac{1}{5}$th that observed in the closed vessel explosion experiments of Clerk and Hopkinson, with the mixture at rest, and only about $\frac{1}{8}$th of that observed in Bairstow and Alexander's tests. Hopkinson also carried out tests in 1912 on the effect of turbulence artificially produced by the rotation of a fan within a closed cylindrical vessel 12 in. diameter by 12 in. long; these experiments showed a great reduction in the time of explosion with increase in turbulence. Using a 1 : 9 mixture by volume of coal-gas and air, the following figures illustrate his results:

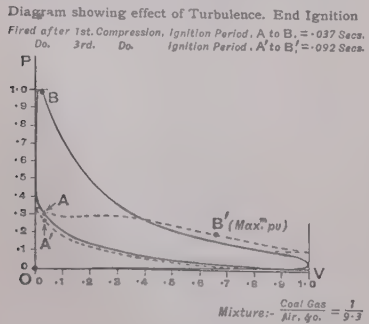

FIG. 32.

§ (68) CALORIFIC VALUES AND SPECIFIC HEATS OF THE WORKING MIXTURES.—As already stated, whatever the fuel used in an internal combustion engine, the working substance after ignition consists of a mixture of nitrogen, steam, carbon dioxide and frequently a small amount of free oxygen. When the chemical formula of the fuel or "carburant" is known, the heat evolved during combustion may be readily calculated. In Table I. some physical constants are given for the substances involved in Internal Combustion Engine practice.

TABLE I

SPECIFIC WEIGHT AND VOLUME OF GASES AT 0° C. AND ATMOSPHERIC PRESSURE

Substance.	Symbol. 1.	Specific Gravity H = 1. 2.	Weight of 1 Cub. Ft. in Lb. 3.	Volume of 1 Lb. in Cub. Ft. 4.
Air	23·0 + 77 N	14·44	·08073	12·387
Oxygen	O_2	16	·08944	11·18
Nitrogen	N_2	14	·07826	12·78

Carbon monoxide	CO	14	·07826	12·78
Carbon dioxide	CO_2	22	·12298	8·13
Methane (marsh gas)	CH_4	8	·04472	22·36
Ethylene (olefiant gas)	C_2H_4	14	·07826	12·78
Acetylene	C_2H_2	13	·07267	13·76
Normal benzene	C_6H_6	39	·21801	4·59

In Tables II. and III. the quantities of heat evolved in the complete combustion of 1 lb., and of 1 cub. ft., of various gases, etc., are given.

§ (69).—From Tables II. and III. it will be noted that a hydrogen-air mixture contracts after combustion to 0·853 of its initial volume, with corresponding reduction in the pressure developed. Further, notwithstanding the very high calorific value of hydrogen *per lb.*, its excessive bulkiness results in a heat evolution of only 164/3·4 = 48 C.Th.U. (app.) per cub. ft.

TABLE II.—APPROXIMATE CALORIFIC VALUES, ETC., OF FUELS PER CUBIC FOOT AT 0° C. AND ATMOSPHERIC PRESSURE

* As 1 cub. ft. of carbon (as gas) forms 2 cub. ft. of CO, and also 2 cub. ft. of CO_2 it follows that in the formation of *1 cub. ft. of CO*, 82 C.Th.U. are evolved; and in the formation of *1 cub. ft. of CO_2*, 270 C.Th.U. are evolved.

of *mixture* with air at 0° C. and atmospheric pressure.

Hydrogen-air mixtures are very sharply explosive and when hydrogen is present in large proportion in a gaseous fuel, this property frequently causes trouble through pre-ignition. The hydrogen alone would be a comparatively poor and troublesome fuel to employ for power purposes, though its presence is often beneficial in conferring sufficiently prompt inflammability upon dilute mixtures of other gases.

Methane is an excellent gaseous fuel for power purposes; its heat value per cub. ft. of mixture with air is 542/10·6 = 51 C.Th.U. (app.), and thus exceeds that of hydrogen, while there is no contraction of volume after combustion.

With normal benzene (the principal constituent of "benzol") and average petrol there is an increase of volume after combustion. With the ordinary coal-gas-air mixtures used in practice, there is, in general, a contraction of volume after combustion of not exceeding about 3 per cent of the volume before combustion.

Table IV. gives the approximate amount of heat in C.Th.U. evolved by the combustion of 1 cub. ft. at 0° C., and atmospheric pressure of *mixture with air* of various gaseous and other fuels.

Excluding acetylene, which is only employed in a few very special cases, this Table shows that the heat evolved per cub. ft. of *mixture* ranges only from about 48 to 58 thermal units notwithstanding large differences in the calorific values *per lb.* of the various fuels tabulated.

In Table V.[1] average figures are given for the gaseous fuels in common use in stationary gas engines.

The heat evolved per cub. ft. of *mixture* here ranges from 33 to 49 C.Th.U., although the heat evolved by combustion of 1 cub. ft. of *gas* ranges from 59 to 295 units.

In these Tables the volumes of air considered are only such as are just sufficient to ensure complete combustion of the fuel. Generally some excess of air is mixed with the fuel; thus the Continental practice is to use about 20 per cent excess of air with blast furnace gas and producer gas from coke or anthracite, and 40 per cent to 50 per cent excess of air with coke oven gas and town gas.

In large gas engines, in order to avoid undue heating troubles, it is found necessary to so dilute the working mixture that the evolution of heat per cub. ft. of working stroke swept by the piston does not exceed about 28 C.Th.U. for cylinders of up to 20 in. in diameter, and from 20 to 22 C.Th.U. for 30 in. cylinders. With gaseous fuels containing a large proportion of hydrogen, as, *e.g.* coke oven gas, pre-ignition trouble is often experienced. Clerk has entirely overcome this by diluting the fresh charge with from 10 per cent to 20 per cent, by volume, of cooled exhaust gases. By this means, the free oxygen is reduced and replaced by a mixture of carbon dioxide and nitrogen. The total mass of the charge is maintained, while the addition to the inert gases reduces its inflammability, and thus prevents the occurrence of pre-ignition even in sustained heavy load running.

§ (70) SPECIFIC HEAT OF GASES.—By aid of these various Tables, the maximum temperature and pressure attained by the explosion of any mixture of known composition could be readily calculated—apart from heat losses to the containing vessel—provided the specific heat of the mixture were accurately known.

For a small range of temperature, as from 0° C. to 200° C., the specific heats of the ordinary "permanent" gases are roughly constant in value, and are given in Table VI.

Consider, for example, 1 cub. ft. of CO-air mixture at 0° C. and atmospheric pressure. From column 6 of Table IV. this evolves on combustion 55·6 C.Th.U. of heat. Also, from Tables I. and IV. its mass is given by $\cdot294/12{\cdot}78+\cdot706/12{\cdot}387=\cdot08$ lb., while from Table VI. it is clear that k_v may be taken at the value 0·17 C.Th.U. per lb. for the mixture. If, then, this 1 cub. ft. of CO-air mixture be exploded at constant volume, with k_v constant in value at 0·17, and no heat loss to the containing vessel, there would be attained a maximum temperature T and pressure p (both abs.), such that $55{\cdot}6=\cdot08\times\cdot17\times(\mathrm{T}-273)$, whence T = 4363° C. (abs.) and

$$\frac{\mathrm{P}}{14{\cdot}8}=\frac{\mathrm{T}}{273}=16,$$

whence $p=236$ lbs. per sq. in. abs.

§ (71) EXPERIMENTAL RESULTS.—The very numerous experiments that have been made upon explosive mixtures of many different kinds all agree, however, in showing that no such high temperature as 4363° C. (abs.) is ever even approached; and that, in general, the maximum temperature (and consequently pressure) realised in constant volume explosion experiments is, roughly, about *one-half* only of that indicated by calculation made in the manner as just illustrated. Thus Table VII. contrasts actual with calculated temperatures and pressures from constant volume experiments by Clerk with Oldham coal-gas-and-air mixtures initially at 290° C. (abs.), and 14·8 lbs. per sq. in.

With reference to the figures given in column 2, which are calculated from the actual maximum absolute pressures attained (column 1) by aid of the formula $\mathrm{T}/t_o=p/p_o$, it may be observed that these do not give the *highest* temperatures existing at the instant of maximum pressure, but are merely *averages*. There is a hot nucleus of gases at considerably higher temperature than those of the portions nearer the cool enclosing walls—as has already been pointed out in § (59); the figures given in column 2 closely approximate, however, to the mean "maximum" temperatures actually attained.

1 : 4	95	1862	..	..	..

§ (72) VARIATION OF SPECIFIC HEAT.[1]—The characteristic equation of an ideally perfect gas is $pv = RT$ . . . (12), where R is the difference of the *constant* specific heats, k_p and k_v, and is therefore also a constant.

But this equation is true for any fluid whereof the specific heat k_v is a function of the temperature only, provided that the difference of the two specific heats remains constant, and such a fluid will obey Boyle's Law exactly at all temperatures; this, however, will only be true if both k_p and k_v are independent of the density of the fluid.

Joly found both for air and CO_2 that k_v appeared to increase slightly with density; thus in the case of CO_2:

At Pressure, Lbs./Sq. In. Abs.	Density (Water = 1).	$k_v =$
106·5	·01153	·1684
320·5	·03780	·1738

an increase of about 3 per cent only. In the case of hydrogen the specific heat appeared to *decrease* slightly with increase of density. The variation with density has, so far, been treated as negligible, and experimentally obtained values of specific heat at various temperatures are resumed by empirically found functions of temperature only.

§ (73) RELATION BETWEEN k_p AND TEMPERATURE.—Regnault examined the relation between k_p and temperature in the case of air and CO_2, and formed the conclusion that between −30° C. and +200° C., the specific heat of air remained sensibly constant, while that of CO_2 increased by nearly 18 per cent.

Mallard and Le Chatelier, and Berthelot, from experiments upon constant-volume explosions of mixtures initially at atmospheric pressure, deduced values of k_v for temperatures up to 2000° C. for air, steam, CO_2, and other gases, and concluded that the specific heat increased considerably with the temperature in all the cases examined by them. It is not clear, however, that combustion had ceased when their measurements were taken.

Early constant-pressure experiments by Holborn and Austin on Air, Oxygen, and Nitrogen, with electrical heating of the gases, temperatures being measured by a thermopile, and heat-quantities by calorimeter, furnished the following results:

TABLE VIII

MEAN k_p FOR AIR, OXYGEN, AND NITROGEN 20-800° C. (ORDINARY)

(Holborn and Austin)

For a Temperature Range from	Mean Value of k_p for		
	Air. 1.	Oxygen. 2.	Nitrogen. 3.
20-440° C.	·2366	·2240	·2419
20-630	·2429	·2300	·2464
20-800	·2430	..	·2497

Thus k_p increases, though but slowly, in each case. Later experiments by Holborn and Austin made at Berlin,[2] using the same method, gave the following results for Nitrogen, Steam, and CO_2, for temperatures ranging from 110° C. to 1400° C.:

TABLE IX

MEAN k_p FOR NITROGEN, STEAM, AND CO_2. 110-1400° C. (ORDINARY)

(Holborn and Austin, 1907)

110-1000	·254	·494	·258
110-1200	·258	·510	·264
110-1400	·262	·532	·272

---

[1] See "Gases, Specific Heat of."

[2] British Association Meeting, 1907.

These results indicate substantial increases in k_p with rise of temperature for all the three gases. Holborn and Austin have also calculated the value of k_p for CO_2 at temperatures from 0° C. to 800° C. from their own results and also from those of Langen's and Mallard and Le Chatelier's experiments. The figures are given hereunder:

TABLE X

VALUES OF k_p FOR CO_2 FROM 0° C. to 800° C. (ORDINARY)

(Calculated by Holborn and Austin)

At Temperature ° C.	Value of k_p from		
	Holborn and Austin. 1.	Langen. 2.	Mallard and Le Chatelier. 3.
0	·2028	·1980	·1880
100	·2161	·2100	·2140
200	·2285	·2220	·2390
400	·2502	·2450	·2840
600	·2678	·2690	·3230
800	·2815	·2920	·3550

Holborn and Austin and Langen's results are concordant, while those of Mallard and Le Chatelier show a much faster rate of increase of k_p with temperature than either of the others.

§ (74) CLERK'S EXPERIMENTS.[1] — In Clerk's experiments both pressure and volume were varied simultaneously, the gas experimented upon being the mixture after explosion in a gas-engine cylinder behind a moving piston.

TABLE XI

APPARENT SPECIFIC HEAT k_v FROM 0° C. to 1500° C. (ORDINARY) PER CUBIC FOOT OF WORKING MIXTURE AT 0° C. AND ATMOSPHERIC PRESSURE

(Clerk)

Temperatures, ° C.		Values of k_v per Cubic Foot.		
		By Experiment.		By Calculation from Equation (73′), in Ft.-lbs. 5.
Ordinary. 1.	Absolute. 2.	In C.Th.U.* 3.	In Ft.-lbs. 4.	
−273	0	..	..	14·0
0	273	·0140	19·6	19·6
100	373	·1409	20·9	21·0
200	473	·0157	22·0	22·2
400	673	·0171	23·9	24·0
600	873	·0180	25·2	25·2
800	1073	·0187	26·2	26·1
1000	1273	·1019	26·8	26·7
1200	1473	·0194	27·2	27·1
1400	1673	·0195	27·35	27·38
1500	1773	·0196	27·45	27·48
∞	∞	(·0200)	..	28·0

* Compare with column 8 of Table VI.

The composition by volume of the mixture after explosion was as follows: Nitrogen, 75·0 per cent; steam, 11·9 per cent; carbon dioxide, 5·2 per cent; oxygen, 7·9 per cent.

Hence from Tables I. and VI. we have for 1 cub. ft. of this mixture at 0° C. and atmospheric pressure:

Constituent.	Cub. Ft. in 1 Cub. Ft. of the Mixture. 1.	Weight, in Lbs. in 1 Cub. Ft. at 0° C. and Atmospheric Pressure. 2.	C.Th.U. per 1° C. Rise of Temperature from 0-200° C. agreeably with Table VI. (at Constant Volume). 3.
Nitrogen	·750	·0587	·010155
Steam .	·119	·0060	·002213
CO_2 .	·052	·0064	·001094
Oxygen .	·079	·0070	·001095
Total .	1·000	·0781	·014557

Thus 1 cub. ft. of the mixture, measured at 0° C. and atmospheric pressure, weighs ·0781 lb. and agreeably with Table VI. should have a mean k_v between 0° C. and 200° C. of ·014557 C.Th.U. or, in work units, 20·38 ft.-lbs.

On referring to Table XI. it will be seen that the value of k_v at 100° C. from actual experiment was 20·90 ft.-lbs.; thus the experimental and calculated results here agree very well.

After explosion the ordinary working stroke was performed, but instead of release taking place near the end of the stroke, both valves were kept closed while the crankshaft continued to revolve through the momentum of the engine fly-wheel, thus alternately compressing and expanding the entrapped mixture. An indicator diagram was taken, recording the changes of volume and pressure undergone by the gases.

The gain of internal energy by the mixture during compression from any point A to B (*Fig.* 33) is equal to the external work (MABN) done upon the mixture in compressing it *minus* the heat lost to the cylinder walls in the interval; while during any expansion period, as BC, the loss of internal energy is equal to the external work (MBCN) done by the mixture in expanding from B to C, *plus* the loss of heat to the cylinder walls.

The external work is readily obtained with considerable accuracy by planimetric measurements of the diagram, while the changes of temperature can be calculated from simultaneous values of p and v taken from the diagram, by aid of the relation $pv/p_o v_o = \mathrm{T}/\mathrm{T}_o$, provided the temperature T_o, at any one point of the diagram be known. The loss of heat to the cylinder walls was estimated by a comparison of the compression curve with the immediately following expansion curve on the assumption that the total heat lost by the mixture during any, the same, part of the stroke is the same during expansion as during compression for the same mean temperature.

---

[1] *Proc. Roy. Soc.* A., 1906, lxxvii. 499.

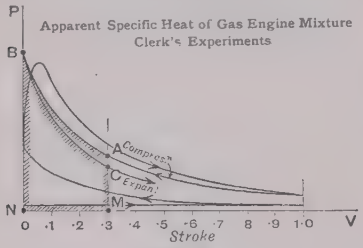

FIG. 33.

Clerk expresses the Apparent Specific Heat, k_v, thus deduced, in ft.-lb. per cub. ft. of mixture at 0° C. and atmospheric pressure; the corresponding values in C.Th.U. per cub. ft. are added in Table XI. His results are very closely resumed by the equation

$$k_v = \left(\frac{d\mathrm{H}}{d\mathrm{T}}\right)_v = a(1 - b\epsilon^{-l\mathrm{T}}), \quad (73)$$

where a, b, and l are constants, and T is absolute temperature in ° C. It will be found that A = 28, $b = \cdot 5$, and $l = \cdot 00186$. For purposes of computation equation (73) is more conveniently written

$$\log_{10}\left(1 - \frac{k_v}{28}\right) = -0\cdot 30103 - \cdot 000808\mathrm{T}, \quad (73')$$

and values calculated from this equation are given in column 5 of Table XI. for comparison with those experimentally determined. The empirical equation (73) makes k_v increase from 14·0 at the absolute zero of temperature, to an asymptotic value of 28·0 when T is infinite.

§ (75).—Integrating equation (73) gives for the increase in internal energy in this case, from temperature T_o to temperature T,

$$\mathrm{H} - \mathrm{H}_o = a(\mathrm{T} - \mathrm{T}_o) - \frac{ab}{l}(\epsilon^{-l\mathrm{T}} - \epsilon^{-l\mathrm{T}_o}). \quad (74)$$

Or, k_v, k_{vo} being values of the apparent specific heats at T, T_o respectively,

$$\mathrm{H} - \mathrm{H}_o = a(\mathrm{T} - \mathrm{T}_o) - \frac{1}{l}(k_v - k_{vo}). \quad (74')$$

By aid of this equation, and of equation (73′), Table XIA has been calculated, giving values of k_v for this gas-engine mixture at every 100 degrees from 0° C. to 2500° C., together with values of the internal energy ($\mathrm{H} - \mathrm{H}_o$), in ft.-lbs. per cub. ft. at 0° C. and atmospheric pressure, relatively to 0° C. as an assumed zero.

TABLE XIA

VALUES OF k_v AND ($\mathrm{H} - \mathrm{H}_o$) FOR GAS ENGINE MIXTURE

(From Clerk's experiments)

Temperature ° C.		k_v in Ft.-lbs. from Equation (73′).	γ from Equation (75A).	$\mathrm{H} - \mathrm{H}_o$ in Ft.-lbs. from Equation (74′)
Ordinary.	Absolute.

On p. 20 of the *7th Report of the Gas Explosions Committee of the British Association* (1914), a curve is given showing the variation of internal energy with temperature for this mixture. This curve is considered to best resume the most reliable experimental results available; it is reproduced in *Fig.* 33A. For comparison there is shown also the curve obtained by plotting ($\mathrm{H} - \mathrm{H}_o$) against T from the figures given in Table XIA. It will be seen that the two curves agree very well from 0° C. to 1600° C., but that at temperatures above 1600° C. the Committee's curve rises somewhat abruptly above the other. The curve of equation (74′) results from Clerk's figures as given in Table XI., and is a regular curve with equation (74) as its Cartesian equation. It has an asymptote $H=28(T-T_o)-4516$, to which it rapidly approaches, as indicated in the diagram.

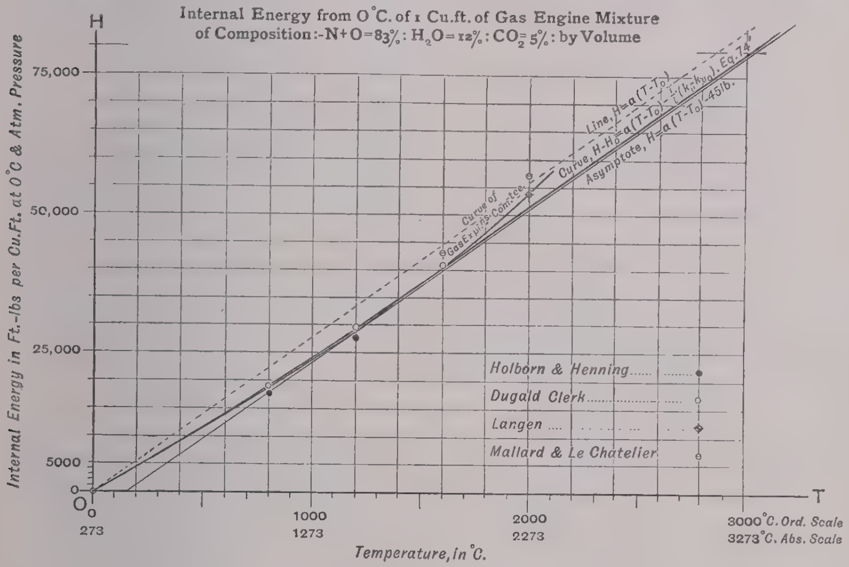

FIG. 33A.

The mean value of k_v between T_o and T is $H-H_o/T-T_o$, and is therefore expressed by

$$\text{Mean } k_v = a - \frac{1}{l}\,\frac{k_v - k_{vo}}{T-T_o}. \qquad (75)$$

Estimation of $H-H_o$ *from the Indicator Diagram.*—From equations (13) and (74′), all quantities being in work-units, we have

$$H-H_o = a(T-T_o) - \frac{1}{l}(k_v - k_{vo}) + \int_{v_o}^{v} p\,dv\,;$$

as $pv=RT$, this may be written

$$H-H_o = \frac{a}{R}(pv - p_o v_o) - \frac{1}{l}(k_v - k_{vo}) + \int_{v_o}^{v} p\,dv. \qquad (74'')$$

As p, v, p_o, v_o, and $\int_{v_o}^{v} p\,dv$ are immediately determinable from the indicator diagram and k_v and k_{vo} are known from, *e.g.*, Table XI. for the values of T corresponding to pv and $p_o v_o$, it is clear that equation (74″) enables $H-H_o$ to be readily ascertained.

If in any specific case the expansion (or compression) curve can be resumed by an equation of the form pv^n=a constant, then in such case we have by aid of equation (33)

$$H-H_o = \left(\frac{a}{R} + \frac{1}{1-n}\right)(pv - p_o v_o) - \frac{1}{l}(k_v - k_{vo}). \qquad (74''')$$

§ (76) VALUE OF γ FOR THE MIXTURE.—Here the relation $pv=c'T$ gives

$$c' = \frac{pv}{T} = \frac{14 \cdot 7 \times 144 \times 12 \cdot 8}{273} = 99 \cdot 25 \text{ ft.-lbs. per lb.}$$

As 1 cub. ft. at 0° C. and atmospheric pressure weighs ·0781 lb., c' per cub. ft. $=99 \cdot 25 \times \cdot 0781 = 7 \cdot 75$ ft.-lbs. Also, heat quantities being expressed in ft.-lbs., $k_p - k_v = c' = 7 \cdot 75$. But $k_p - k_v = k_v(\gamma - 1)$; hence

$$\gamma = 1 + \frac{7 \cdot 75}{k_v}. \qquad (75\text{A})$$

Thus, from Table XI. we have

TABLE XII

VALUES OF γ FROM VALUES OF k_v GIVEN IN TABLE XI

Temperature ° C. Abs.	k_v Ft.-lbs./Cub. Ft.	γ from Equation (75A).
0	14·0	1·553
273	19·6	1·396
373	21·0	1·369
473	22·2	1·349
673	24·0	1·323
873	25·2	1·307
1073	26·1	1·297
1273	26·7	1·290
1473	27·1	1·286
1673	27·38	1·283
1773	27·48	1·282
∞	28·0	1·277

These values of γ are plotted against the corresponding absolute temperatures in *Fig.* 34. For any temperature interval the mean value of γ can be readily obtained either from this curve, or more accurately by aid of equations (75) and (75A). An approximation to the adiabatic curve for the mixture can then be obtained by assuming γ constant at its mean value over a number of successive small ranges of temperature, and drawing a series of curves within each range agreeably with the equation $pv^{\gamma}=\text{constant}$.

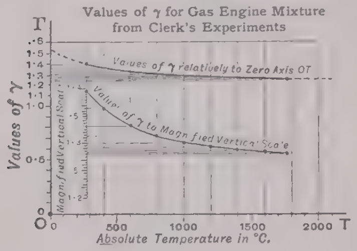

FIG. 34.

From equations (9), (12), (13), and (73) we obtain as the equation of entropy

$$\phi-\phi_0=a\log\epsilon\left(\frac{\mathrm{T}}{\mathrm{T}_0}\right)+c'\log\epsilon\left(\frac{v}{v_0}\right)-ab.\int_{\mathrm{T}_0}^{\mathrm{T}}\frac{\epsilon^{-\iota\mathrm{T}}}{\mathrm{T}}d\mathrm{T}, \quad (75\text{B})$$

whence, putting $\phi-\phi_0=0$, we have for the adiabatic equation

$$c'\log\epsilon\left(\frac{v}{v_0}\right)=ab.\int_{\mathrm{T}_0}^{\mathrm{T}}\frac{\epsilon^{-\iota\mathrm{T}}}{\mathrm{T}}d\mathrm{T}-a\log\epsilon\left(\frac{\mathrm{T}}{\mathrm{T}_0}\right). \quad (75\text{C})$$

The impossibility of expressing the integral $\int\frac{\epsilon^{-\iota\mathrm{T}}}{\mathrm{T}}d\mathrm{T}$ in finite terms renders these two equations unsuitable for arithmetical computation. When $b=0$, equation (75B) reduces, of course, to equation (40).

§ (77) CLERK'S RESULTS.—Referring to these results of Clerk, Callendar[1] remarks: "Since the temperature of a mass of gas when exploded in a closed vessel or in the cylinder of a gas engine is far from uniform, and since the actual distribution of temperature is necessarily somewhat uncertain, it is evident that the variation of the specific heats of the constituents with temperature cannot be *certainly* deduced from a knowledge of the heats of combustion and the effective temperature. . . .

"It is possible, however, by explosion experiments to deduce values of the *apparent* or '*effective*' specific heats which, in so far as they approximate to the conditions existing in an actual gas engine, may be of greater practical utility than the true specific heats. . . . The method of Dugald Clerk in which the specific heat is directly determined from the work done on the charge after ignition, appears to be particularly appropriate for this purpose."

It will be observed that Clerk's results are somewhat higher than those of others; Callendar has stated (*ibid.*) that the values of the specific heats deduced from explosion experiments usually come out higher than those obtained by more direct methods, and considers that the errors incidental to both methods require further investigation.

§ (77′).—According to the kinetic theory of gases, their internal energy is the sum of the translational, rotational, and internal-vibrational energies of their constituent molecules. Of these, the translational motion alone causes the gaseous pressure; the internal-vibrational produces radiation; while the rotational appears to have no external physical effect. Callendar[2] points out also that theory indicates that the energies of molecular translation and rotation should vary directly as the product pv, while the vibrational energy should vary with the temperature agreeably with a formula of the exponential type $\alpha(\epsilon^{\beta/\lambda\mathrm{T}}-1)^{-1}$. This is symbolically expressed by writing

$$\mathrm{H}=\text{internal energy}=\zeta pv+\alpha(\epsilon^{\beta/\lambda\mathrm{T}}-1)^{-1},$$

where ζ, α, β, and λ are constants.

The product pv, though very nearly constant, appears to be expressible as a function of p and T; thus Kelvin (*Math. and Phys. Papers*, vol. i.) found that for the usual permanent gases, including CO_2, an equation of the type $pv=c\mathrm{T}-b(p/\mathrm{T})^2$ will resume the observed facts. Taking this, we have $\mathrm{H}=\zeta c\mathrm{T}-\zeta b(p/\mathrm{T})^2+\alpha(\epsilon^{\beta/\lambda\mathrm{T}}-1)^{-1}$; whence

$$\left(\frac{d\mathrm{H}}{d\mathrm{T}}\right)_p=k_p=\zeta c-2\zeta b\frac{p^2}{\mathrm{T}^3}+\frac{\alpha\beta}{\lambda}\,\frac{\epsilon^{\beta/\lambda\mathrm{T}}}{\mathrm{T}^2(\epsilon^{\beta/\lambda\mathrm{T}}-1)^2}. \quad (\text{A})$$

From these considerations it seems just possible that the extreme closeness with which Clerk's experimental results are resumed by equation (73) may be somewhat more than a coincidence.

§ (78) VARIABLE SPECIFIC HEATS.—In an ideal perfect gas both k_p and k_v are constant, and the quantity R in the characteristic equation $pv=\mathrm{RT}$ . . . (12) being equal to k_p-k_v is also constant. But, as has already been pointed out, equation (12) is also true for fluids for which k_p and k_v are any functions of T, provided only that (k_p-k_v) is constant; and such fluids will obviously obey Boyle's Law, since pv will still be constant when T is constant. Suppose, then, that $k_v=\mathrm{F(T)}$ and $k_p=\mathrm{F(T)}+\mathrm{R}$; if heat $d\mathrm{H}$ be supplied to unit mass of such a fluid we shall have by equation (13) all heat-quantities being expressed in work-units:

$$d\mathrm{H}=\mathrm{F(T)}d\mathrm{T}+pdv. \quad . \quad . \quad (13')$$

If the changes be isothermal, $d\mathrm{T}=0$, and hence whatever F(T) may be, we must have $d\mathrm{H}=pdv=\text{external work}$—as in the case of a perfect gas already considered. As by equation (12) $p=\mathrm{R}/\mathrm{T}/v$, equation (13′) gives at once as the equation of entropy

---

[1] *Gaseous Explosions Committee of British Association, 1st Report*, 1908, p. 27.

[2] *Ibid.* p. 32.

$$d\phi=\frac{d\mathrm{H}}{\mathrm{T}}=\frac{\mathrm{F(T)}}{\mathrm{T}}d\mathrm{T}+\mathrm{R}\frac{dv}{v}. \quad . \quad (76)$$

Putting $d\phi=0$ gives as the differential equation to the adiabatic,

$$\frac{\mathrm{F(T)}}{\mathrm{T}}d\mathrm{T}+\mathrm{R}\frac{dv}{v}=0. \quad . \quad . \quad (77)$$

§ (79) VALUES OF K_v.—It is now fully established that k_v for gases is not constant but that it increases with the temperature (and probably changes slowly also with density), and the results of experiment are very commonly resumed by simple equations of the form

$$k_v=\alpha+\beta\mathrm{T}. \quad . \quad . \quad . \quad (78)$$

Thus Clerk has given the following as fairly resuming Mallard and Le Chatelier's experimental results:

Gas.	$k_v=\alpha+\beta\mathrm{T}=$
Nitrogen	$\cdot171+\cdot0000215\mathrm{T}$
Steam	$\cdot3116+\cdot000182\mathrm{T}$
CO_2	$\cdot1423+\cdot0000834\mathrm{T}$
Oxygen	$\cdot150+\cdot0000188\mathrm{T}$

in C.Th.U. per lb., and T in ° C. (abs.).

It may be pointed out here that in all cases where the efficiency of a cycle is expressible by equation (71), any increase in the value of k_v *diminishes* the efficiency, and *vice versa*. For denoting efficiency by η, and putting R/k_v for $(\gamma-1)$, equation (71) becomes

$$\eta=1-\left(\frac{1}{\rho}\right)^{\mathrm{R}/k_v}; \quad . \quad . \quad . \quad (71\text{A})$$

and differentiating all across with respect to k_v gives

$$\frac{d\eta}{dk_v}=\frac{\mathrm{R}}{k_v{}^2}\left(\frac{1}{\rho}\right)^{\mathrm{R}/k_v}\log_\epsilon\left(\frac{1}{\rho}\right)=-\frac{\mathrm{R}}{k_v{}^2}\left(\frac{1}{\rho}\right)^{\mathrm{R}/k_v}\log_\epsilon\rho. \quad (71\text{B})$$

As R, k_v, and ρ are essentially positive, and ρ is always >1, $d\eta/dk_v$ is always negative, and thus $d\eta$ and dk_v have opposite signs.

§ (80) ESTIMATION OF $\mathrm{H}-\mathrm{H}_o$ FROM INDICATOR DIAGRAMS.—When k_v is expressed in the simple form as given in equation (78), we have for the increase in internal energy at constant volume corresponding to a change of temperature from T_o to T,

$$\mathrm{H}-\mathrm{H}_o=\alpha(\mathrm{T}-\mathrm{T}_o)+\frac{\beta}{2}(\mathrm{T}^2-\mathrm{T}_o{}^2). \quad (79)$$

From equations (13) and (79), when v changes, all quantities being expressed in work-units,

$$\mathrm{H}-\mathrm{H}_o=\alpha(\mathrm{T}-\mathrm{T}_o)+\frac{\beta}{2}(\mathrm{T}^2-\mathrm{T}_o{}^2)+\int_{v_o}^{v}p\,dv.$$

As $pv=\mathrm{RT}$ . . . (12) this may be written

$$\mathrm{H}-\mathrm{H}_o=(pv-p_ov_o)\left\{\frac{\alpha}{\mathrm{R}}+\frac{\beta}{\mathrm{R}^2}(pv+p_ov_o)\right\}+\int_{v_o}p\,dv, \quad (79')$$

and all the quantities on the right-hand side of this equation being immediately determinable from the indicator diagram, the value of $\mathrm{H}-\mathrm{H}_o$ is known when using any working mixture for which α and β and R have been previously ascertained.

Whenever the expansion or compression curve can be expressed in the form $pv^n=$constant, equation (79′) by aid of equation (33) takes the simple form

$$\mathrm{H}-\mathrm{H}_o=(pv-p_ov_o)\left\{\frac{\alpha}{\mathrm{R}}+\frac{1}{1-n}+\frac{\beta}{2\mathrm{R}^2}(pv+p_ov_o)\right\}. \quad (79'')$$

Also equation (76) becomes

$$d\phi=\left(\frac{\alpha}{\mathrm{T}}+\beta\right)d\mathrm{T}+\mathrm{R}\frac{dv}{v}, \quad . \quad . \quad (80)$$

the differential equation of entropy, giving on integration

$$\phi-\phi_o=\alpha\log_\epsilon\left(\frac{\mathrm{T}}{\mathrm{T}_o}\right)+\beta(\mathrm{T}-\mathrm{T}_o)+\mathrm{R}\log_\epsilon\left(\frac{v}{v_o}\right), \quad (81)$$

whence, putting $\phi-\phi_o=0$, we have as the adiabatic equation in terms of v and T,

$$\alpha\log_\epsilon\left(\frac{\mathrm{T}}{\mathrm{T}_o}\right)+\mathrm{R}\log_\epsilon\left(\frac{v}{v_o}\right)+\beta(\mathrm{T}-\mathrm{T}_o)=0, \quad (82)$$

which is also sometimes written in the form

$$\left(\frac{\mathrm{T}}{\mathrm{T}_o}\right)^\alpha\left(\frac{v}{v_o}\right)^{\mathrm{R}}\epsilon^{\beta(\mathrm{T}-\mathrm{T}_o)}=1. \quad . \quad (82')$$

From the relation $pv=\mathrm{RT}$, equations (82) and (82′) may also appear as

$$\alpha\log_\epsilon\left(\frac{p}{p_o}\right)+(\alpha+\mathrm{R})\log_\epsilon\left(\frac{v}{v_o}\right)+\frac{\beta}{\mathrm{R}}(pv-p_ov_o)=0, \quad (83)$$

or

$$\left(\frac{p}{p_o}\right)^\alpha\left(\frac{v}{v_o}\right)^{\alpha+\mathrm{R}}\epsilon^{\beta/\mathrm{R}(pv-p_ov_o)}=1. \quad (83')$$

And

$$(\alpha+\mathrm{R})\log\epsilon\left(\frac{\mathrm{T}}{\mathrm{T}_o}\right)+\mathrm{R}\log\epsilon\left(\frac{p_o}{p}\right)+\beta(\mathrm{T}-\mathrm{T}_o)=0, \quad (84)$$

or

$$\left(\frac{p_o}{p}\right)^{\mathrm{R}}\left(\frac{\mathrm{T}}{\mathrm{T}_o}\right)^{\alpha+\mathrm{R}}\epsilon^{\beta(\mathrm{T}-\mathrm{T}_o)}=1. \quad . \quad (84')$$

On putting $\beta=0$, equations (82), (83), and (84) reduce to equations (22), (20), and (21) respectively.

The adiabatic curve may be drawn from a given initial condition $(p_ov_o\mathrm{T}_o)$ by assuming any T and thence determining the corresponding v from equation (82) or p from equation (84); the remaining quantity is then immediately found by aid of the equation $pv=\mathrm{RT}$.

§ (81) OTTO CYCLE WITH VARIABLE SPECIFIC HEAT.—It is of interest to compare the efficiency of the Otto cycle using a fluid of variable specific heat with that obtained on the usual simplifying assumption that k_v is constant, as in §§ (36) and (45); the data assumed are as in § (51), viz. $t_o=300°$ C. (abs.), $t_c=600°$ C. (abs.), $\mathrm{T}=2000°$ C. (abs.), and $p_0=14\cdot7$ lbs. per sq. in. (abs.); see *Fig.* 21.

Instead of air, the working fluid is now 1 cub. ft. at 0° C., and atmospheric pressure, of Clerk's gas-engine mixture as described in § (74), obeying the law

$$144pv=7\cdot754\mathrm{T}. \quad . \quad . \quad (12'')$$

The variation of k_v with temperature is exhibited in *Fig.* 35, plotted from Table XI., and from this curve the following linear formulae are easily deduced for the value of k_v over the four temperature ranges taken:

Temperature Range in ° C. (Abs.).	k_v in Ft.-lbs./Cub. Ft. $a+\beta$T.
300-600	$16{\cdot}8+{\cdot}011$T
600-1000	$19{\cdot}65+{\cdot}00625$T
1000-1500	$23{\cdot}2+{\cdot}0027$T
1500-2000	$26{\cdot}5+{\cdot}0005$T

Then to obtain points on the adiabatic compression curve we have the relations $v=(300/273)\times 1=1{\cdot}0989$ cub. ft., whence equation (82) becomes, using common logs,

$$16{\cdot}8 \log\left(\frac{\mathrm{T}}{300}\right)+7{\cdot}754 \log\left(\frac{v}{1{\cdot}0989}\right)$$
$$+4343\times{\cdot}011(\mathrm{T}-300)=0.$$

Assuming a series of values of T between 300° C. and 600° C., this equation gives immediately the corresponding values of v; and p is then found from v by aid of equation (12″). Proceeding in this way we get

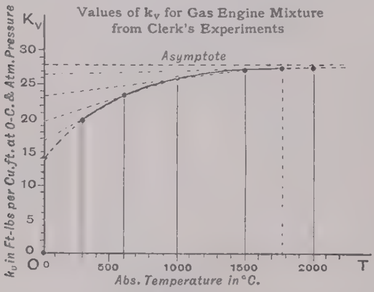

FIG. 35.

T=	300	350	400	500	600
v=	1·0989	0·7330	0·5113	0·2736	0·1599
p=	14·7	25·7	42·2	98·5	202

from which the compression curve can be plotted. The explosion pressure P is obtained from $\mathrm{P}/p_c=\mathrm{T}/t_c$; thus substituting the values $\mathrm{P}=202\times(2000/600)=673{\cdot}3$ lbs. per sq. in.

The adiabatic expansion curve may next be obtained by the same method as that adopted for the compression curve, taking $a=26{\cdot}5$ and $\beta={\cdot}0005$ from 2000° C. to 1500° C., and $a=23{\cdot}2$, $\beta={\cdot}0027$ from 1500° C. to 1000° C.; this furnishes the following figures:

T=	2000	1900	1650	1500	1250	1100
v=	·1599	·1918	·3156	·4413	·8306	1·28
p=	673	532	282	183	81	46

The *pv*-diagram plotted from these results is shown in *Fig.* 36; it will be noted, by comparison with the results obtained in § (51) for the case in which k_v is constant, that working between the same limits of temperature, and with the same temperature of compression, the ratio of expansion with variable specific heat is 6·87, as compared with 5·47, when k_v is constant; while the maximum pressure with variable k_v, due to the greater compression ratio, is also greater than that in the simpler case. In an actual engine the total expansion ratio is fixed: taking this at 5·47, as in the case of § (51), we shall have for the volume during explosion $v_c=1{\cdot}0989/5{\cdot}47=0{\cdot}2009$ cub. ft.; the corresponding compression temperature, from equation (82), will be $t_c=556°$ C. (abs.), and pressure, from equation (12″), $p_c=149$ lbs. per sq. in. abs. (approx.), whence the explosion pressure is now reduced to $\mathrm{P}=(\mathrm{T}/t_c)p_c=536$ lbs. per sq. in. (abs.). The diagram for an expansion ratio 5·47 is shown by dotted lines in *Fig.* 36.

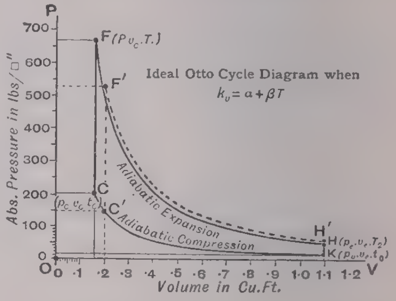

FIG. 36.

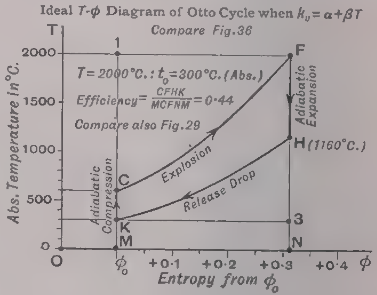

FIG. 37.

§ (82) OTTO CYCLE TEMPERATURE ENTROPY.—The temperature-entropy diagram for the 300°-600°-2000° C. case of *Fig.* 36 is exhibited in *Fig.* 37, the curved portions being obtained by aid of equation (81), using corresponding values of T and v already obtained. The efficiency, being the ratio of KCFHK to MCFNM, may be found either by planimetric measurement of these areas, or by direct calculation of the quantities of heat received and rejected at constant volume from equation (79), the value of T_2 (at H) being taken from the $T - \phi$ diagram; both methods agree in giving 0·44 as the value of the efficiency.

With constant specific heat it has already been shown that for the Otto cycle the efficiency is $1 - (t_o/t_c) = 0·5$ (*vide* equation (70) and § (45)); thus when k_v is expressible in the form $\alpha + \beta T$ and $(k_p - k_v)$ is constant, efficiency is *diminished*.

§ (83) Otto Cycle Ideal Efficiency.—Clerk[1] has calculated by a method of successive approximations values of the ideal efficiency of the Otto cycle when using the mixture of gases whose Apparent Specific Heat is as given in Table XI., and his results are given hereunder; corresponding values of efficiency with constant k_v are given, calculated from equation (71); it will be observed that the efficiency with variable k_v is always *less* than that with k_v constant:

Table XIII

Ideal Efficiencies of Otto Cycle compared. Initial Temperature 273° C. (Abs.); γ for Compression taken as 1·37 (*vide* Table XII.).

$\frac{1}{\rho} =$	Upper Limit of Temperature.		Efficiency with k_v Constant (Equation (71)). 3.
	1873° C. (Abs.). 1.	1273° C. (Abs.). 2.	
$\frac{1}{2}$	·195	·200	·246
$\frac{1}{3}$	·286	·293	·360
$\frac{1}{4}$	·354	·356	·430
$\frac{1}{5}$	·384	·394	·480
$\frac{1}{7}$	·439	·443	·550

§ (84) Efficiency; "Air Standard."—It has already been pointed out (§ (37)) that if $1/\rho$ denote the value of the adiabatic compression ratio in the three ideal cycles of constant pressure, constant volume, and constant temperature, then the efficiency is, in each case, expressed by the same formula, viz.

$$\text{Efficiency} = 1 - \left(\frac{1}{\rho}\right)^{\gamma - 1} . \quad . \quad (71)$$

If the working fluid be air assumed as possessing a constant value of $\gamma = 1·4$, this equation becomes

$$\text{Efficiency} = 1 - \left(\frac{1}{\rho}\right)^{0·4}, \quad . \quad (71')$$

and in this form is termed the "Air Standard" of efficiency, and has been largely employed in the past as representing the theoretical maximum of performance for any given value of ρ. It is clear, however, from the above discussion that when the specific heat is variable, and not constant, that equation (71′) represents an unattainable ideal. Clerk has pointed out that in the cases taken in Table XIII. the "air standard" values are roughly about 20 per cent too high. Much more information is, however, still required before even the apparent specific-heat values are accurately known for the various mixtures of gases and vapours employed in gas and oil engines. When these values become accurately assignable each engine can be separately investigated and the *real* efficiency of its working fluid determined. The proportion borne by the actual thermal efficiency as determined by test to the real efficiency will then give a true measure of the degree of excellence of its performance, and indicate the exact margin remaining for improvement.

On the general question of the values of k_p and k_v for gases and gaseous mixtures reference may be made to the 1st and 2nd Reports (1908–9) of the Gaseous Explosions Committee of the British Association. Clerk (*Proc. I.C.E.*, 1907), however, makes the useful suggestion that if γ be taken at the constant value 1·285 for the expansion curve, and at 1·370 for the compression curve, then for the ranges of temperature met with in gas-engine practice no serious error is introduced.

ENGINES, SOME TYPICAL INTERNAL COMBUSTION

§ (1) The "Internal" Combustion engine is so called because the gaseous or vaporised fuel, mixed with air, is burned or exploded within the working cylinder itself in contrast with earlier types of heat engine in which the working fluid, steam or air, is generated or heated by an external furnace. For the history of the development of the Internal Combustion engine reference may be made to Sir D. Clerk's work on *The Gas, Petrol, and Oil Engine* (Longmans, 1909).

The engineering thermodynamics of Internal Combustion engines are dealt with in the article "Engines, Thermodynamics of Internal Combustion"; in this article some account is given of typical actual engines.

§ (2) The Cycle.—All modern internal combustion engines work on either the four-stroke or two-stroke cycle, with combustion either at constant volume or at constant pressure, or at a combination of both these methods. Of these the constant volume (Otto) four-stroke cycle engines form by far the largest class. A very great deal of attention is, however, now being given to the improvement of the two-stroke cycle engine, which has long been established as a reliable and economical prime mover in large stationary engine practice, and is now rapidly increasing in favour, in single- and two-cylindered designs, in the small quick-speed petrol types used in the propulsion of motor-launches and cycles on account of its great simplicity and relatively low production cost. Its extended adoption in motor vehicles in general is regarded as not unlikely in the near future.

---

[1] *Proc. Inst. C.E.*, 1907.

The constant pressure class, typified by the Diesel engine, in both four-stroke and two-stroke designs, includes also the somewhat numerous so-called "semi-Diesel" engines, of which one is described and illustrated later. In these "semi-Diesel" oil engines the fuel admission is, in general, so regulated that combustion takes place partly at constant volume, and partly at (approximately) constant pressure.

§ (3) THE FUEL.—The fuels now successfully employed are also numerous and various. Among gaseous fuels are:—Coal gas; pressure and suction producer gases (Dowson, Mond, National, Crossley, etc.); coke oven gas; blast furnace gas; natural gas (mainly in the U.S.; principally CH_4); and water gas. Of liquid fuels may be mentioned petrol; kerosene (paraffin, or lamp oil); intermediate oils; gas oils; crude oils (filtered and freed from volatile constituents); residual oils; benzol; shale oils; coal tar oils; lignite oils; and alcohol; and mixtures of these, as, *e.g.*, of petrol, benzol, alcohol, and kerosene. Solid fuels are not yet practicable, though, in the laboratory, Diesel engines have been made to run on coal dust, and engines of the Otto-cycle motor-car type on naphthalene.

§ (4) The following have been selected for description and illustration as typical engines exemplifying present-day practice:

A. CONSTANT VOLUME TYPE

(*a*) As a four-stroke Stationary Horizontal Single-cylindered engine of medium power—the 100 Horse-power "National" gas engine.

(*b*) As a four-stroke Stationary Vertical Multi-cylindered engine of medium power—the Two-crank, 300 Horse-power, Tandem Four-cylindered engine of the National Gas Engine Co.

(*c*) As a four-stroke Stationary Horizontal Two-cylindered engine of large power—the Double-acting Tandem Single-crank 2500 Horse-power Nuremberg gas engine.

(*d*) As a two-stroke Stationary Horizontal Single-cylindered engine of small power—the early Clerk gas engine.

(*e*) As a two-stroke Stationary Horizontal Single-cylindered Double-acting engine of large power—the Körting gas engine.

(*f*) As a special two-stroke Stationary Horizontal Single-cylindered Single-acting engine of large power—the Oechelhauser gas engine.

(*g*) As a typical "Paraffin" engine—the Hornsby-Akroyd oil engine.

B. CONSTANT PRESSURE TYPE

(*h*) A description is given, with illustration, of a normal four-stroke Diesel engine, with some account of the two-stroke Diesel, and an illustrated description of a Ruston "semi-Diesel" engine. The large class of small, usually multi-cylindered, quick-revolution internal combustion engines as used for the propulsion of motor vehicles, launches, aircraft, etc., form the subject of a separate section.

§ (5) (*a*) THE 100 H.P. HORIZONTAL "NATIONAL" GAS ENGINE. (i.) *Description.*—A vertical longitudinal section of this single-cylindered engine is shown in *Fig.* 1. Within the "working barrel" or "cylinder liner" AA slides a cast-iron piston BB attached to the crank-shaft by the connecting rod CC. The piston fits the cylinder very accurately, but complete gas-tightness is ensured by six cast-iron spring rings DD. The piston is oiled by means of the lubricator E, and through the hole shown in the piston "skirt" oil is also enabled to reach the "small end" or "gudgeon bearing" of the connecting rod. At the left-hand end of the cylinder is the combustion chamber H, within which are placed the inlet valve I and the exhaust valve K; holes above these valves, filled by easily removable plugs LL, permit them to be readily withdrawn for examination and repair or replacement.

The working barrel of the cylinder, the combustion chamber, and the valve casings are all well cooled by a water jacket WWW; it will be seen that the combustion chamber is a casting separate from that of the working barrel, and that the inlet valve casing is also a separate casting. By disconnecting these three castings all jacket water spaces are exposed, and can be thoroughly cleansed from deposit; as pointed out in the article "Engines, Thermodynamics of Internal Combustion" (§ (62)), adequate cylinder and combustion chamber cooling becomes a matter of increasing importance as the dimensions of gas engines become larger. The arrangement here adopted necessitates making a double joint; of these the inner is made with asbestos, and is screwed up hard so as to be tight under the explosion pressure; the outer joint, having only to maintain jacket water tightness, is made with yielding rubber. The valve-stem guides are also separate castings easily replaceable after wear; in the case of the exhaust valve it will be seen that the design permits close access of cooling water all round the stem; the exhaust valve seat is also so arranged as to be efficiently water-cooled.

The cylinder has a bore of 16 inches with a piston stroke of 22 inches; the piston and valves are not water-cooled. The working barrel, or cylinder liner, MM, is screwed up hard to the combustion chamber casting at the rear (left-hand) end, while at the front end an expansion joint is provided with the jacket casing PP; the working barrel becomes much hotter than the outer casing of the jacket, and it is very necessary to make provision in this way for the difference of expansion thus arising in order to prevent the creation of large internal straining actions with consequent risk of distortion or rupture of castings.

A light cast-iron oil trough RR fitted in the crank-pit prevents waste oil from saturating the engine foundations.

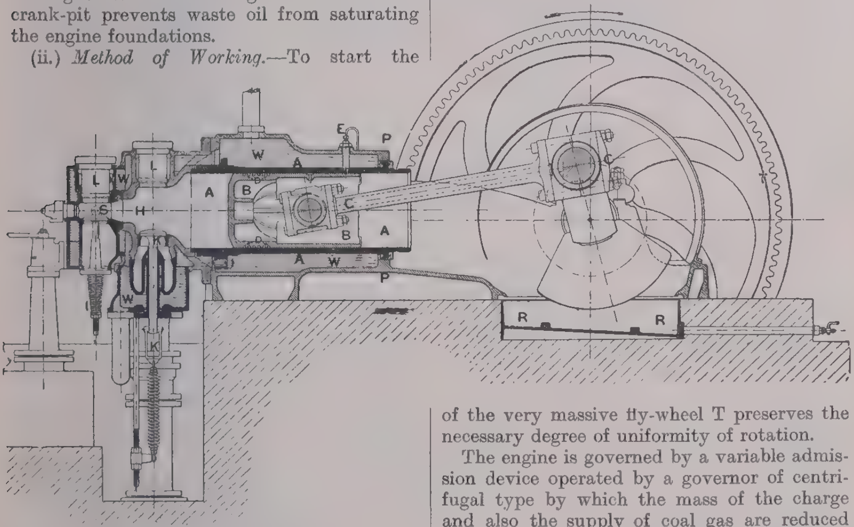

FIG. 1.—National Gas Engine.

(ii.) *Method of Working.*—To start the engine, the fly-wheel is pulled round by hand until the piston has definitely commenced its working stroke; an explosive mixture of coal gas and air is then pumped by hand, through a small auxiliary valve, into the combustion chamber; failing coal gas a small quantity of petrol is used. The explosive mixture thus introduced is then fired by a spark at the ignition plug S obtained by operating the (low-tension) magneto by hand. A working stroke of the piston immediately occurs, and considerable momentum is imparted to the fly-wheel; the subsequent order of operations is as follows:

(1) During the return stroke of the piston the exhaust valve K is lifted and the burnt gases are discharged through the exhaust pipe, and silencing apparatus, into the atmosphere; (2) during the second out-stroke the inlet valve I is open and a fresh charge of gas and air is drawn into the cylinder; (3) the second in-stroke then follows, compressing this fresh charge into the combustion chamber H; (4) at the commencement of the next out-stroke the mixture is ignited by a spark at the ignition plug S, explosion occurs, and the piston is driven forward. This cycle is then repeated continuously so long as the engine runs.

It will be seen, therefore, that the engine works upon the Otto, or four-stroke, cycle, of suction, compression, working, and exhaust strokes, and that the piston accordingly receives *one* working impulse in every *two* revolutions of the crank-shaft; the momentum of the very massive fly-wheel T preserves the necessary degree of uniformity of rotation.

The engine is governed by a variable admission device operated by a governor of centrifugal type by which the mass of the charge and also the supply of coal gas are reduced as the load on the engine is diminished. Below quarter load the governor acts by cutting out ignition.

(iii.) *Details of Working.*—The ratio of compression, $1/\rho$, is about $1/5{\cdot}5$, whence by equation (71′) of the "Engines, Thermodynamics of Internal Combustion," article, the "air standard" efficiency is $1-(1/\rho)^{0{\cdot}4}=0{\cdot}494$; with this value of $1/\rho$, which corresponds to a compression pressure of about 140 lbs. per sq. in. (abs.), pre-ignition is avoided without the necessity of injecting a spray of water into the cylinder at full load running. If p denote the mean effective pressure during the working stroke, in lbs. per sq. in., as ascertained from an indicator diagram, and if

d = Diameter of piston, in inches,
s = Stroke of piston, in inches,
n = Number of revolutions per minute of crank-shaft,

then the work done by the engine is expressed by $\pi/4 \times d^2 \times p \times s/12 \times n/2$ foot-lbs. per minute, and the indicated horse-power (I.H.P.) is 1/33000th of this, whence

$$\text{I.H.P.} = 992 \,.\, d^2snp \times 10^{-9}. \qquad (1)$$

The Brake Horse-power (B.H.P.) is less than the I.H.P. by the power necessary to overcome the frictional and fluid resistances of the engine itself; the ratio B.H.P./I.H.P. is termed the mechanical efficiency of the engine, and is usually denoted by the symbol η; hence, as $\eta = \text{B.H.P./I.H.P.}$, we have from equation (1)

$$\text{B.H.P.} = 992 \,.\, d^2sn\eta p \times 10^{-9}. \qquad (2)$$

The product ηp is termed the "brake mean effective pressure," and is largely used in calculations of the performance of small fast-running internal combustion engines of the petrol motor type with which it is impossible to obtain reliable indicator diagrams under ordinary circumstances.

The total distance, σ feet, covered by the piston in one minute is termed the "piston speed," and is evidently equal to $2n \times s/12$; thus

$$\text{Piston speed} = \sigma = \frac{ns}{6}. \qquad (3)$$

(iv.) *Performance.*—The performance of this 100 h.p. National gas engine has been ascertained by numerous tests in practice, and has been found to be as follows:

Fuel used.	Maximum. I.H.P.	Maximum. B.H.P.	Mechanical Efficiency. η.
Coal gas	111·2	94·2	·847
Benzol	99·5	82·5	·830
Anthracite producer gas	93·7	76·7	·819
Coke producer gas	88·0	71·0	·807

the revolution speed being 210 per minute. It will be noted that at this speed the power required to overcome engine frictional and fluid resistances is 17 I.H.P. From equation (1) the corresponding mean effective pressures are, in lbs. per sq. in.:

Fuel.	$p=$	$\eta p=$
Coal gas	95	80·5
Benzol	85	70·5
Anthracite producer gas	80	65·5
Coke producer gas	75	60·5

while the piston speed corresponding to 210 r.p.m. is 770 feet per minute.

Horizontal single-cylindrical "National" gas engines of this type are built up to a maximum of 185 brake horse-power; for higher powers multiple cylinders are used, in both horizontal and vertical arrangements; one of the latter is next described.

§ (6) (*b*) THE 300 H.P. VERTICAL "NATIONAL" GAS ENGINE. (i.) *Description.*—A transverse section of this four-cylindered two-crank tandem gas engine is shown in *Fig.* 2.

The engine comprises two pairs, each consisting of two cylinders A and B placed one above the other, each pair being connected by a connecting rod C with a crank D; the upper pistons are each 18 inches in diameter and the lower each 17 inches, with a stroke of 18 inches; and the engine runs normally at 300 revolutions per minute, so that the piston speed (equation (3)) is 900 feet per minute.

The upper and lower piston of each pair are connected by a cast-iron sleeve, or distance piece, 4½ inches in diameter, through which passes a long nickel steel bolt by means of which the three pieces are tightly held together; the pistons are not water-cooled but are cast with an internal conical web EE which assists in the conduction of heat from the piston crown—normally one of the hottest parts of an internal combustion engine. Gas-tightness is ensured by the five cast-iron spring rings shown; near the bottom of the skirt of the lower piston is placed a sixth, or "scraper," ring, to prevent the passage past the piston of oil from the crank chamber.

The lower portion of the upper cylinder contains only air, which is alternately compressed and expanded during the running of the engine, and by its "cushioning" action contributes greatly to softness of running by assisting to reverse the motion of the pistons when at the bottom of their stroke; the cranks are also balanced to further aid smoothness in running.

Each cylinder liner with its water jacket casing is a separate casting, but there is a gap at the lower end of each between liner and casing which is fitted with a water-tight packing ring so arranged as to permit any relative movement due to difference of expansion; the lower portions of the cylinder liners are not water-jacketed.

The inlet valves I, I′ and exhaust valves K, K′ open into a common port, and are placed one above the other, the inlets being on top. Both inlet and exhaust valves are of cast-iron, as are also the coned seats in which they rest; the seats are, however, separate rings capable of easy removal and replacement after wear. The inlet valves carry on their stems gas valves M, M′, which have no seats, but slide within a well-fitting cylindrical housing; the gas and air supply passages are formed by the partitioned casing N, N′. The gas valves M, M′ open later and close earlier than the charge inlet valves I, I′; this practice is common to all large gas engines and is adopted to avoid risk of pre-ignition of fresh charge by any residual smouldering or highly heated exhaust gas remaining over from the previous cycle. When the inlet valve opens at the end of the exhaust stroke the combustion chamber contains hot burnt gases from the previous explosion; the first inrush of pure air cools this, and the subsequent supply of mixed gas and air can then safely enter. Towards the end of the suction stroke the gas valve closes, and the final suction is from the lower air chamber N′ only; thus when the charge inlet valve I closes, N′ is filled with pure air in readiness for the commencement of the next suction stroke.

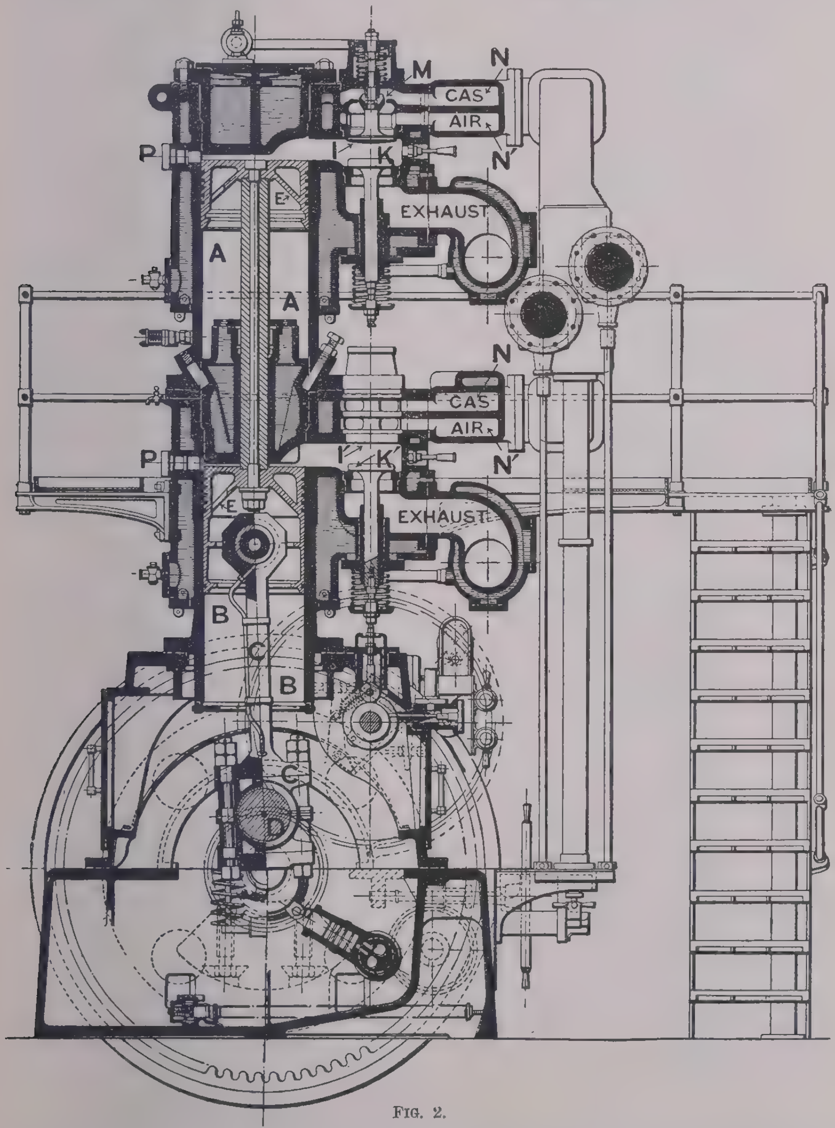

FIG. 2.

A centrifugal shaft governor regulates the supply of mixture to the engine by the "quantity" method, in which the composition of the charge remains sensibly constant, while its mass is varied to suit the load

Forced lubrication is used for all reciprocating and rotating parts, the oil being supplied by engine-driven valveless pumps at a pressure of 20 lbs. per sq. in.; after use the oil returns to the crank casing and drains into a "sump," where it is filtered before passing into the oil pumps by which it is again delivered to the bearings. The lower cylinders are lubricated by the oil which comes from the crosshead or "gudgeon" bearings, while the upper cylinders and metallic-packed joint of the piston rod where it passes between the two cylinders are supplied by a sight-feed lubricator fed by a small pump operated by the engine. Starting is effected by means of compressed air. Ignition is by high-tension magneto, with two "sparking plugs" PP in each cylinder.

The arrangement of the valve-driving shaft, which is gear-driven from the crank-shaft so as to run at half-speed in a four-stroke cycle engine, is clearly indicated in the figure; the cams and rollers by which the valves are operated are of case-hardened steel.

(ii.) *Performance.* — On test, one of these engines developed 404 indicated horse-power, and 362 brake horse-power at 299 revolutions per minute; the power was absorbed by a Heenan and Froude hydraulic brake. These results give the high value ·896 for the mechanical efficiency; to determine the value of ηp, equation (2) must obviously be modified for this case and written

$$\text{B.H.P.} = 2 \times 992 \times 10^{-9} \times sn\eta p \,.\, (\text{D}_1{}^2 + \text{D}_2{}^2 - d^2), \qquad (4)$$

D_1 and D_2 being the respective piston diameters, and d that of the piston rod; all in inches.

For a B.H.P. of 362, this equation gives $\eta p = 57$ lbs. per sq. in. As in this case η has the known value 0·896, we have also for the mean effective pressure, $p = 57/{\cdot}896 = 63{\cdot}6$ lbs. per sq. in.

Tandem single-acting vertical engines of this type are made from 185 to 1000 horse-power; the 1000 H.P. engine has eight cylinders (four pairs) operating four cranks. The cylinders of each pair are 22 inches and 23 inches in diameter respectively; the stroke is 24 inches, and the normal revolution speed is 200 per minute, the corresponding piston speed being 800 feet per minute.

§ (7) Relation of Weight to Power.—In all engines the weight per unit of power developed increases with increase in dimensions, and this is one of the reasons in favour of the adoption in many cases of the multi-cylindered design. The following Table, compiled from actual engines, brings out this point clearly; the rated B.H.P. is given, using blast-furnace gas as fuel; and the engine weights per B.H.P. are given exclusive of weight of fly-wheel. In large horizontal tandem double-acting gas engines the inclusion of the fly-wheel weight adds from 50 to 60 lbs. to the weight per B.H.P. The fly-wheel alone of a 1500 B.H.P. engine of this type commonly weighs about 35 tons.

TABLE I

WEIGHTS PER B.H.P. OF DIFFERENT TYPES OF GAS ENGINES

Rated B.H.P. 1.	Single or Double Acting. 2.	Piston Diameter × Stroke (Inches). 3.	No. of Cylinders and Arrangement. 4.	2-Stroke or 4-Stroke Cycle. 5.	Revolutions per Minute. 6.	Piston Speed Ft./Min. 7.	Weight per Rated B.H.P. (Lbs.). 8.

§ (8) (*c*) The Tandem Horizontal Nuremberg Engine. (i.) *Description.*—The design selected as typifying a modern big four-stroke gas engine is that of the 2500 horse-power, two-cylindered, tandem, double-acting, horizontal, single-crank engine of the Maschinen-Fabrik Augsburg Nurnberg A.G.—usually styled, for brevity, the Nuremberg Co.—of which a longitudinal section is given in *Fig.* 3. The two cylinders A, A′ are placed in line, with their pistons mounted on a common piston rod BB, to one end of which the connecting rod C is attached; the whole power of the engine is transmitted by this connecting rod to the single crank D; the crank-shaft carries a massive fly-wheel, by the momentum of which the necessary degree of uniformity of revolution is maintained. This engine is double-acting, that is, each cylinder is closed at both ends, and both sides of each piston receive power impulses. As a single-acting, single-cylindered, four-stroke engine receives one power impulse in every four strokes of its piston, it is clear that in this case as the power impulses are four times as frequent there is a power impulse at every stroke; the engine thus runs with very little variation in its revolution-speed.

(ii.) *Cooling Arrangements.*—British practice so far has generally favoured the single-acting uncooled piston, on the score of simplicity in details, and this practice has limited piston diameters to a maximum of about 26 inches. With a big double-acting engine, water- or oil-cooling of the pistons, and even also of the exhaust valves, becomes necessary. In this case the pistons only are water-cooled, the water being introduced through the hollow piston rod as shown in the illustration.

The cylinders and cylinder covers are, of course, also water-jacketed; the ample water-spaces provided will be noted in the section, and it will be seen that care has been taken to bring the water close up to the valve seatings; it is found that a water pressure of about 15 lbs. per sq. in. above atmosphere suffices to maintain an efficient circulation through the jackets. For the piston rod and pistons, however, it is found necessary—on account of their reciprocating motion—to provide a water pressure of from 45 to 65 lbs. per sq. in. Water from the main is frequently available at this pressure, but when this is not the case a pump is provided, driven by the engine, which delivers the cooling water at the necessary pressure.

The water-cooling system is well arranged throughout; each cylinder is fitted with an open water-tank into which all water drain-pipes discharge in full view of the attendant, and each discharge is provided with a thermometer and a regulating valve so that the temperature of each part can be adjusted independently as desired. To avoid the necessity of shutting each outlet valve when the engine is stopped, a main stop valve is fitted in the supply pipe, and this valve is closed only when the engine is not running.

(iii.) *Lubrication.*—The lubrication of the external bearings is effected from a large oil-tank situated above the engine from which the oil is conducted through pipes of ample diameter fitted with regulating valves, to the various points. Surplus oil is drained away and collects in a sump in the engine house, where it is automatically filtered and then returned to the supply tank by a pump driven by the engine. Rolling levers and eccentrics are grease-lubricated.

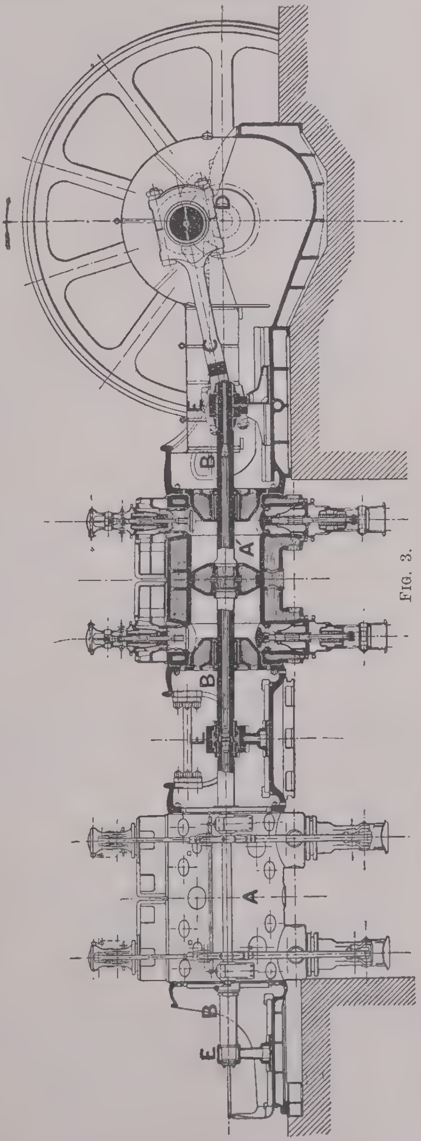

FIG. 3.

For the forced lubrication of the cylinders, piston rod stuffing-boxes, and exhaust valve guides, special oil pumps are provided, and the supply to each point can be independently regulated. The piston rod stuffing-boxes are packed with a series of rings of similar section each in three parts, made alternately of cast-iron and white metal; these are pressed against the surface of the rod by symmetrically disposed circumferential helical springs; lubricating oil under pressure is delivered into the middle of each stuffing-box. Wear is found to be very small, and is confined to the packing rings, which are easily adjusted or renewed.

In illustration of the efficiency of the cooling and oiling arrangements provided in these large engines, it may be stated that a Nuremberg engine of 2000 horse-power working with blast-furnace gas ran day and night for a period of nineteen months. The engine was actually running for 98·3 per cent of the possible working hours, and the 1·7 per cent of stoppages were due to works repairs and in no way to any defect of the engine. At the end of this long period of service the engine was reported as in excellent working order, and continued in operation.

Table II

Test Results from a 1200 B.H.P. Tandem D.A. Nuremberg Engine

Item.	1.	2.	3.	4.	5.	6.	7.
Duration of test, minutes	33·0	28·0	29·0	26·8	25·8	25·8	25·3

C.Th.U. per B.H.P. hour	10,245	7174	5969	5480	5353	5090	4968
Indicated thermal efficiency	·285	·286	·311	·326	·322	·335	·343
Brake thermal efficiency	·138	·197	·237	·258	·264	·278	·285

(iv.) *Piston Rods.*—An important detail of construction is that whereby the heavy water-filled pistons are prevented by their weight from causing "ovalling" or undue wear of the lower portions of the cylinders and stuffing-boxes. The long hollow thick-walled tubes of which the piston rod is built up are turned with a slight upward camber so that the rod, when loaded with the pistons, and supported by the three crossheads E, E, E, is exactly straight; arrangements are also provided in addition whereby each piston can be readily adjusted independently to the exact centre of its own cylinder. The whole weight of the pistons and rod is thus borne by the three external crosshead slides, and the pistons accordingly "float" in the cylinders as does the piston rod in the stuffing-boxes; this not only saves wear but also considerably reduces the internal friction of the engine. Gas-tightness of the pistons is ensured by six self-tightening packing rings.

(v.) *Governors.*—The engine is governed on the "quantity" method, by which the composition remains practically constant, while the mass admitted is proportioned to the power output required. Should the quality of the gaseous fuel vary, the ratio of gas to air can be adjusted by hand while the engine is running.

Two ignition plugs are fitted in each cylinder, actuated by small electromagnets forming part of the plugs.

(vi.) *Performance.* — Table II. gives the results of tests on a 1200 brake horse-power Nuremberg engine using blast-furnace gas having a heat value per cubic foot of about 50 C.Th.U.; the pistons were 33·46 inches in diameter (piston rod about 8⅝ inches dia.), with a stroke of 43·3 inches.

With reference to this Table it may be observed that the revolutions per minute, n, are directly counted, and that the value of the mean effective pressure, p, in lbs. per sq. in. is ascertained from indicator diagrams taken from both cylinders, the average value being tabulated. The indicated horse-power may next be calculated, equation (1) being modified to suit this type of engine by writing

$$\text{I.H.P.} = 4 \times 992 \times 10^{-9} \,.\, snp(D^2 - d^2), \qquad (5)$$

D and d being the diameters in inches of the pistons and piston rod respectively.

The brake horse-power is directly measured, and thence the value of the mechanical efficiency $\eta = \text{B.H.P./I.H.P.}$ is known. It will be observed that the frictional and fluid resistances of the engine itself absorb about

260 horse-power when running at 106 revolutions per minute. The brake mean effective pressure, ηp, is now known and tabulated. The total consumption of gas per hour in cubic feet is directly measured, and dividing the figures obtained by the I.H.P. and B.H.P. gives the consumption in cubic feet per hour per I.H.P. and B.H.P. respectively. The heat value of the gas per cubic feet is determined by calorimetric tests, and thence the heat supplied in C.Th.U. per hour per I.H.P. and per B.H.P. is immediately ascertainable.

Finally, as one horse-power hour corresponds to $33,000 \times 60/1400 = 1414$ C.Th.U. per hour converted into mechanical work, the absolute thermal efficiency of the engine is determined by taking the ratio of 1414 to the heat supplied to the engine in C.Th.U. per horse-power per hour.

Thus, at full load, this engine showed an absolute brake thermal efficiency of ·285; that is to say, 28·5 per cent of the whole heat supplied to the engine appeared as useful external work. In one hour the working volume swept through by the pistons is $\pi/4(D^2 - d^2) \times 120n \times s/1728$ cubic feet; and at full load the heat evolved in C.Th.U. per hour is 1427×4128, whence in this case the evolution of heat in C.Th.U. per cubic feet of working stroke swept out by the pistons has the value 22·6 (see the article, "Engines, Thermodynamics of Internal Combustion," § (69)).

§ (9) (*d*) TWO-STROKE ENGINES: THE EARLY CLERK ENGINE. (i.) *Description.*—The low frequency of but one working stroke in four of the Otto cycle has always been regarded as a serious disadvantage, and very numerous attempts have for long been made to increase the impulse frequency without sacrificing the valuable practical advantages of simply and effectively charging, exploding, expanding, and exhausting—combined with high thermal efficiency—which are possessed by the four-stroke engine; no solution has even yet been found which fully satisfies the commercial conditions for both large and small engines.

The first explosion compression two-stroke or "impulse every revolution" engine was invented and built by Clerk in 1878, and the Clerk two-stroke cycle engine, with improvements in detail suggested by experience, is still, particularly for large engines, that which most successfully satisfies everyday requirements.

A section of the second Clerk two-stroke engine is shown in *Fig.* 4; an engine to this design was shown at the Paris Exhibition of 1881. It was of the horizontal, single-cylindered, single-acting type, and comprised a motor, or working, cylinder A containing exhaust ports E, E′, near its outer end, and a displacer cylinder B; within these cylinders respectively work pistons C and D, suitably connected to a common crank-shaft. The crank-pin driving the displacer piston D was about 90° in advance of that operated by the motor piston C.

(ii.) *Method of Working.*—The order of operations is as follows: Near the end of the working (out)stroke the motor piston C overruns the exhaust ports E, E′, and the burnt gases immediately escape thence into the atmosphere. Simultaneously the displacer piston D, being in advance of the motor piston, has passed the end of its out-stroke and has commenced to return; during its out-stroke it has drawn into the cylinder B an explosive mixture of gas and air through the sliding valve H and pipe W. The commencing return of the piston D causes the mixture in B to become slightly compressed before the complete exhaust of A, but not sufficiently to cause any material resistance; in the delivery pipe connecting the two cylinders is an automatic inlet valve; as soon as the pressure from B slightly exceeds that in A, this valve rises and the fresh mixture then enters the combustion chamber G. The return of the motor piston C then causes the automatic inlet valve to close, and subsequently compresses the entrapped fresh charge into the chamber G; this is then fired at the instant of maximum compression, explosion occurs, and the working stroke follows. Thus every out-stroke of the piston C is a working stroke, and the impulses are therefore one per revolution of the crank-shaft, and are accordingly twice as frequent as in the "Otto" four-stroke cycle.

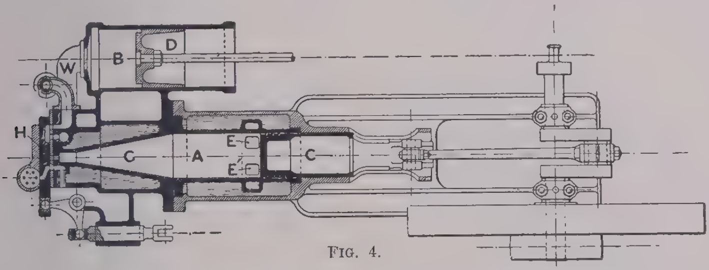

FIG. 4.

(iii.) *Difficulties.*—In the ideal two-stroke motor the operations of charging and exhausting would be performed at least as effectively as in the four-stroke engine, and hence, the working impulses being twice as frequent, a two-stroke engine of given bore and stroke should develop at least twice as much power as the equal four-stroke, with the same thermal efficiency. In practice, however, there are certain fundamental difficulties of the two-stroke cycle which have so far prevented the realisation of this ideal. Thus, in the Otto cycle the inlet valve usually opens slightly before the end of the in-stroke of the working piston and remains open not only throughout the whole suction out-stroke, but also for a short period after its completion; the suction, or "charging" period accordingly continues during about 220° of the crank-shaft revolution. In the two-stroke engine, however, the fresh charge has to be introduced into the motor cylinder while the crank-shaft turns through only about 80°. Hence the duration of the charging operation in the Otto cycle is nearly three times as long as in the Clerk cycle. Though this disadvantage is reduced by providing specially large inlet valves and exhaust port areas, it remains still that the two-stroke engine is not in general capable of being charged so effectively as the four-stroke, and also that more power is absorbed in the charging operation.

A second point is that in the Otto cycle the exhaust valve is open during about 240° of the crank-shaft revolution, and hence the burnt gases have considerable time in which to escape, and are moreover assisted in their exit by the return of the motor piston during the whole exhaust stroke, so that there remains finally only the combustion chamber filled with residual exhaust at, or even slightly below, atmospheric pressure. In the Clerk cycle engine, on the other hand, exhaust has to be accomplished during the very short interval occupied by the motor piston in passing over the last part of its out-stroke and first part of the subsequent in-stroke, so that not only in the combustion chamber but also in the working cylinder there remains some hot exhaust gas. The effect of this is to reduce the quantity of fresh charge that can be introduced into the motor cylinder, *i.e.* to diminish the "volumetric efficiency" of the engine, with consequent diminution in the output of power. Further, the commencement of the introduction of the fresh charge while the exhaust ports are still uncovered causes a loss of unburnt mixture by "short-circuiting" direct through the exhaust ports into the atmosphere, and waste of fuel from this cause is frequently considerable in the very small petrol-type two-stroke motor. In large two-stroke engines, however, this cause of loss is almost completely avoided, (*a*) by providing a combustion chamber of somewhat elongated conical form as shown at G (*Fig.* 4), and introducing the fresh charge at the apex of the cone, and (*b*) by sending first into the motor cylinder a preliminary charge of air only to help in the scavenging (and cooling) of the residual exhaust gases, and following this up by the introduction of a correspondingly rich mixture of gas and air; this practice, initiated by Clerk in 1881, is still followed in all large gas engines. The doubled frequency of working impulses in the two-stroke engine causes necessarily an increase in the mean heat-flow from the cylinder per second, and hence in the design of this type of engine special attention has to be given to the details of the cooling arrangements.

(iv.) *Performance.*—These early Clerk two-stroke engines were constructed in sizes of from 2 to 12 nominal horse-power, and the following test results obtained in 1884 from a series of these engines are still of much interest; the fuel used was Glasgow coal gas, and the figures given are from the usual trials which were carried out on all engines before leaving the manufacturers' works, and thus fairly indicate the performance of the engines in ordinary service.

The mixture delivered by the displacer contained 1 volume of coal gas to 8 volumes of air; on passing through the inlet and mixing with the residual exhaust gases in the motor cylinder it becomes further diluted. The increase of temperature acquired by contact with the exhaust and with the cylinder walls expands the entering fresh gas, a temperature of at least 100° C. being commonly attained before compression commences. The expansion of the entering fresh gases thus caused expels more of the exhaust products through the ports than would correspond to the volume swept through by the motor piston between the closing of the exhaust ports and complete in-stroke. Through "turbulence" mixing occurs to a considerable extent and the net result is the formation of a mixture explosive in every part of it, and of an average composition of 1 volume of coal gas to 9 volumes of other gases; thus the proportion of exhaust gases present is but small; that there is any at all arises from the necessity of preventing any appreciable loss of fresh mixture through the exhaust ports. The mixture employed was a comparatively rich one.

(v.) *Efficiency.*—In these engines the value of the compression ratio, $1/\rho$, was $\frac{1}{3}$, whence the "Air Standard" efficiency is $1-(\frac{1}{3})^{0\cdot4}=0\cdot36$. Regarding this as the highest conceivable efficiency, the degrees of excellence of the engines given in the table are to be estimated relatively to 0·36 and not to unity; thus we have

Absolute nett indicated thermal efficiency	·134	·166	·165	·194	·203
Air standard	·36	·36	·36	·36	·36
Efficiency relative to air standard	·372	·462	·460	·54	·56

so that in the case of the engine of 12 nominal horse-power the relative nett indicated thermal efficiency was 56 per cent of the air standard. Actually, as explained in the previous article, the air standard—obtained on the assumption of constant specific heat—represents an impossibly high ideal, the maximum attainable, with varying specific heat, having the lower value for $1/\rho=\frac{1}{3}$ of only about 0·29; hence the comparison of performance is properly made between an actual thermal efficiency of ·203 and an ideal thermal efficiency of ·290; and thus the actual engine in this case realised no less than ·203/·290, *i.e.* 70 per cent of the attainable ideal.

Table III

Test Results of Clerk Two-stroke Engines in 1884

No.	Item.	Nominal Power.				
		2 H.P.	4 H.P.	6 H.P.	8 H.P.	12 H.P.
1	Diameter of motor piston, ins.	5	6	7	8	9
2	Stroke of motor piston, ins.	8	10	12	16	20
3	Diameter of displacer piston, ins.	6	7	$7\frac{1}{2}$	10	10
4	Stroke of displacer piston, ins.	9	11	12	13	20
5	Revolutions of engine per minute	212	190	146	142	132
6	Mean effective pressure in lbs./sq. in. from motor cylinder diagram	43·2	63·9	53·2	60·3	64·8
7	I.H.P. from motor cylinder diagram	3·62	8·68	9·05	17·38	27·46
8	H.P. absorbed by displacer	0·40	0·80	0·86	1·50	2·00
9	Nett I.H.P. of engine (item 7 – item 8)	3·22	7·88	8·19	15·88	25·46
10	B.H.P. of engine	2·70	5·63	7·23	13·69	23·21
11	Nett I.H.P. – B.H.P.	0·52	2·25	0·96	2·19	2·25
12	Mechanical efficiency $\eta=\frac{\text{B.H.P.}}{\text{nett I.H.P.}}$	·84	·72	·88	·86	·91
13	Approximate calorific value of gas, C.Th.U./cub. ft.	320	320	320	320	320

15	Gas consumption per nett I.H.P. hour; cub. ft.	33·0	26·6	26·8	22·9	22·1
16	Gas consumption per B.H.P. hour; cub. ft.	39·4	37·2	30·2	26·6	24·1
17	Absolute thermal efficiency on nett I.H.P.	·134	·166	·165	·194	·203
18	Absolute brake thermal efficiency	·112	·119	·146	·166	·184
19	Compression pressure, lbs./sq. in. (abs.)	53	70	63	64	72
20	Maximum explosion pressure, lbs./sq. in. (abs.)	170	251	210	210	253

§ (10) (*e*) The Körting Engine. (i.) *Description.*—The Clerk two-stroke cycle is very successfully utilised in the special design of large horizontal gas engine made by Messrs. Körting of Hanover, and the De La Vergne Co. of New York; a typical section is shown in *Fig.* 5. The engine is of the single-cylindered double-acting type, and working on the two-stroke cycle, thus furnishes two impulses per revolution of the crank-shaft as in an ordinary steam engine. It comprises a closed, water-jacketed, cast-iron cylinder AA provided with a ring of exhaust ports BB at the middle of its length, and containing a very long piston CC which overruns the ring of exhaust ports in its reciprocations, opening these ports to the one end of the cylinder and the other alternately. The piston is attached to a piston rod which passes through a stuffing box in the cylinder cover and is connected to an external crosshead as in ordinary steam-engine practice; thence the

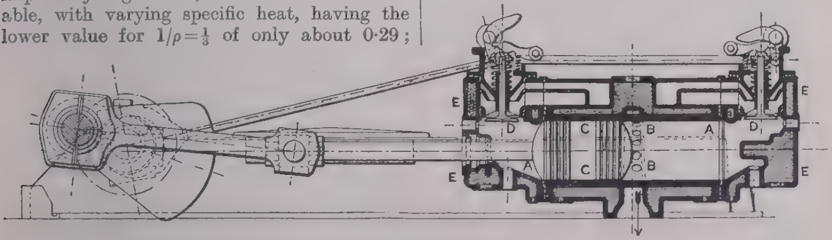

Fig. 5.

power is transmitted to the crank-shaft by a connecting rod as usual. The external crosshead not only keeps the "gudgeon" bearing or "small end" bearing of the connecting rod cool, but also relieves the piston of the lateral thrust due to connecting-rod obliquity, and thus much reduces cylinder and piston wear. Large gas engine cylinders adequately lubricated, and using gas free from dust, show but little wear, a 400 B.H.P. cylinder after one year's working, for example, showing an average wear of only ·013 of an inch. The cylinder is closed by deep cast-steel well water-jacketed covers EE, in which are housed the cages containing the mixture inlet valves DD, normally held up against their seats by helical springs, and opened during the necessary intervals by a simple arrangement of rods and levers operated by a single eccentric on the crank-shaft.

In these large engines, instead of the single "mixture pump" or "displacer" of the Clerk engine, separate double-acting pumps are provided, one of which supplies air only and the other gas only. The displacer crank is placed about 100° in advance of the main crank, as in the Clerk engine, and thus the air pump piston has travelled a short way on its discharge stroke when the inlet valve opens. The gas pump, however, is so arranged that gas is not delivered until somewhat later. Thus a considerable volume of air only flows into the cylinder at first, displacing and cooling the hot exhaust gases, so that when the fresh unburnt gas enters later it mingles with the relatively cool air in the cylinder, and thus risk of pre-ignition is minimised. It is very important in large gas engines to arrange that no explosive mixture shall be formed in chambers or passages; in the Körting engine the gas meets and mixes with the air just above the inlet valve. In small gas engines the gas and air may be mixed in the pump or "displacer," a back-fire into the pump being of little importance; in a large engine, however, in similar circumstances, the result of a back-fire might easily prove a serious matter.

(ii.) *Method of Working.*—The charge having entered the cylinder—first air only and then mixed gas and air—the exhaust products having been thereby displaced, the working piston has closed the ring of exhaust ports by a crank movement of 40° to 45° from the dead centre. Compression then occurs, followed by ignition and subsequent expansion. The air pump valves are so arranged as to deliver a full charge of air at every stroke whether the engine be light or loaded, but the gas delivered by the gas pump varies in amount as determined by the governor. Ignition is electric, and occurs at two points at each end of the cylinder, and means are provided by which the time of ignition can be regulated by hand while the engine is running; poor gases, as *e.g.* blast furnace gas, require earlier ignition than producer gas, and this, in like manner, earlier than coal gas. Where the gas is liable to variation in quality this adjustable ignition arrangement is very useful. Running at light loads, the mixture of gas and air admitted after the preliminary charge of air only being of practically constant composition, a readily ignitible charge always exists at the ignition plugs, and thus regular firing is ensured at light loads.

(iii.) *Performance.*—Körting engines having an aggregate of fully a quarter of a million horse-power have been built, and they compete strongly against the four-stroke type; they are built in sizes of from about 400 B.H.P. with a 22½ inch cylinder and 39½ inches stroke, running at 110 revolutions per minute, to 2000 horse-power from a single cylinder of 43 inches diameter, the stroke being 55 inches, and speed up to 90 revolutions per minute.

The following results were obtained on test with a 600 B.H.P. Körting engine in 1904 (Junge):

Power piston, 29·7 in. diameter—stroke, 55·1 in.

Piston rod, 8·1 in. diameter—revolutions per minute, 80.

Diameter of double-acting air pump, 31·4 in.—stroke, 42·5 in.

Diameter of double-acting gas pump, 27·6 in.—stroke, 42·5 in.

Fuel: producer gas from anthracite.

I.H.P. developed in working cylinder: 845.

B.H.P. of engine: 673.

Fluid resistance I.H.P. of pumps: 88.

Ratio of pump resistance to total I.H.P.: 0·104.

Power—Piston speed: 735 ft. per minute.

Mean effective pressure, p, on power piston: 55·6 lbs./sq. in.

Brake mean effective pressure, ηp: 44·3 lbs./sq. in.

Anthracite burned per B.H.P. hour: 0·8 lb.

Estimating the mechanical efficiency as the value of the ratio B.H.P./Total I.H.P. gives $\eta = 0{\cdot}8$, which is rather low, and is due to the somewhat high pumping resistances which in this particular engine amounted to 10·4 per cent of the total I.H.P.; in later designs the pumping resistances have been much reduced and the mechanical efficiency correspondingly increased. For weight per B.H.P. of this type of engine see Table I. (*supra*).

§ (11) (*f*) THE TWO-STROKE OECHELHAUSER ENGINE. (i.) *Description.*—A second type of successful large two-stroke gas engine working on a modified Clerk cycle is that of Dr. Oechelhauser, of which a diagrammatic section is shown in *Fig.* 6. The engine is of the horizontal, single-cylindered, single-acting type, but the cylinder AA is open at *both* ends and contains two pistons B, B′, working in opposite directions. Just before reaching the extreme "out" position piston B overruns the ring of exhaust ports C, while piston B′ next overruns first a ring of air inlet ports D, and very shortly afterwards a second ring of gas ports E. The burnt exhaust gases immediately escape through the ports C and are assisted in their exit by the charge of fresh air under slight pressure which enters through the ports D. This fresh air mingles with, and cools, the residual exhaust gases, thus minimising risk of pre-ignition and also avoiding appreciable loss of fresh fuel through the exhaust ports when the gas is subsequently admitted through the ports E. The mutual approach of the two pistons eclipses the ports and the entrapped mixture is next compressed between them; at the end of the in (compression) stroke, the mixture is fired electrically as usual, and the expansion (working) stroke then follows.

The double-acting pump H acts on one side as an air pump and on the other as a gas pump; gas and air are separately pumped into the separate reservoirs K and L respectively, wherein they are stored at a pressure of 5 to 6 lbs. per sq. in. above atmosphere.

It will be seen that with this arrangement no gas and air mixture exists anywhere but actually *within* the working cylinder. To further diminish loss of unconsumed gas through the exhaust the maximum quantity of gas and air delivered into the cylinder is only about 0·7 of the cylinder volume. Governing is effected, as in the Körting engine, by reducing the gas charge at light loads.

The crank-shaft has three throws; to the middle throw piston B is linked by the usual connecting rod, while the two side throws are linked by side connecting rods M, M′ to crossheads O, O′, which are coupled up by rods P, P′ to the bridge-piece Q carried on the piston rod R of piston B′; thus the crank-shaft is subjected to a practically simple torque, and the cylinder is not required—as in all other engine designs—to supply the reaction to the actions on the working pistons; as a consequence the engine frame and cylinder can be made lighter than usual.

In the design illustrated the gas and air pump is shown driven directly by the piston rod R, but in later designs the engine dimensions are much reduced and weight diminished by placing the pump at the side of the working cylinder and driving it from a disc crank-pin on the end of the crank-shaft. The cylinder also has been much shortened by the ingenious device of fitting spring rings in each of its ends, which rings bear upon the piston surfaces; in this way the pistons can be arranged to protrude from the cylinder ends by a considerable amount at out-stroke, much as in the case of an ordinary plunger pump. To prevent "canting" of the pistons both are rigidly attached by short piston rods to sliding crossheads guided both vertically and horizontally.

(ii.) *Working.*—The two large pistons alternately issuing from and receding into the working cylinder set up pulsations in the atmosphere of the engine-house, and these may cause troublesome rhythmic vibrations of windows, partitions, etc.; this action is greatly reduced in cases where two engines are installed in the same engine-house with crank-shafts so arranged as to differ in phase by 180°.

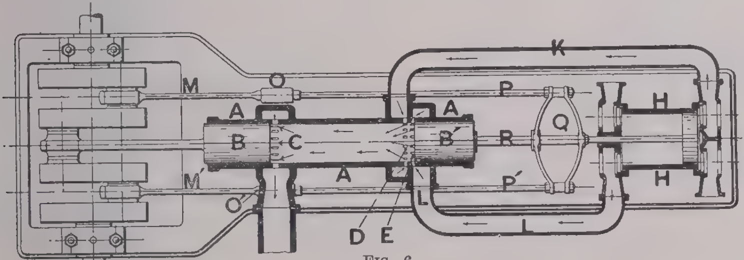

FIG. 6.

The *two* moving pistons cause the rates of compression and expansion of the working gases to be twice as rapid as usual, which is thermodynamically advantageous.

(iii.) *Performance.*—Tests by Professor Meyer in 1903 of a 500 h.p. Borsig-Oechelhauser engine furnished the following results:

DIMENSIONS OF ENGINE

Diameter of cylinder	26·6 in.
Stroke of front piston	37·5 "
Stroke of back piston	37·3 "

Double-acting Air Pump

Diameter of cylinder	44·9 "
Stroke of piston	19·7 "
Diameter of front piston rod . .	3·45 "
Diameter of back piston rod . .	2·78 "

Single-acting Gas Pump

Diameter of cylinder	23·2 "
Stroke of piston	19·7 "

Blower

Diameter of cylinder	65 "
Stroke of piston	37·3 "
Diameter of piston rod	5·9 "

No.	Item.	Number of Trial.				
		VIII.	IX.	X.	VI.	VII.
1	Duration of test, minutes	20	19·95	40	15	19·95
2	Revolutions per minute, average	103	107	106·1	108·2	107·4
3	Mean effective pressure p in lbs./sq. in.	75·0	73·8	69·3	62·3	62·0
4	Total I.H.P. from working cylinder	821	839	780	715	707
5	B.H.P. estimated from blowing cylinder	616·2	626·6	574·8	488	473·8
6	Air pump, mean effective pressure, front, lbs./sq. in.	5·09	5·38	5·12	5·56	6·09
7	Air pump, mean effective pressure, back, lbs./sq. in.	3·36	3·58	3·41	3·73	3·94
8	H.P. absorbed by air pump	68·3	75·2	71·1	79·0	84·5
9	Gas pump, mean effective pressure, lbs./sq. in.	3·53	3·50	3·58	3·73	3·84
10	H.P. absorbed by gas pump	7·7	7·8	7·9	8·5	8·6
11	Total H.P. absorbed by charging pumps	76	83·1	79·1	87·5	93·2
12	Mechanical efficiency of blower	·839	·842	·833	·792	·785
13	H.P. absorbed in engine friction	117·3	117·3	115·4	129·2	129·2
14	Calorific value of gas, C.Th.U./cub. ft. (lower)	221·5	218·5	212·2	218·5	220·3
15	Heat supplied, C.Th.U. per total I.H.P. hour	3660	3637	3616	3703	3682
16	Heat supplied per B.H.P. hour	4872	4870	4910	5420	5480

The fuel used was coke oven gas having the average composition by volume:

Hydrogen	44·7
Carbon monoxide	11·0
Marsh gas (CH_4)	19·5
Heavy hydrocarbons	2·0
Nitrogen	17·5
Oxygen	0·3
Carbon dioxide	5·0
	100

and the average consumption on these tests was 16·8 cubic feet per total I.H.P. hour.

The absolute thermal efficiencies realised were:

Absolute indicated thermal efficiency	·386	·389	·391	·382	·384
Absolute brake thermal efficiency	·290	·290	·288	·261	·258

The mechanical efficiency, taken as the value of the ratio B.H.P./Total I.H.P., varied from 0·67 to 0·75, a somewhat low result; the joint pumping resistances ranged from about 9 per cent at full load to 13 per cent at the lowest test load—calculated relatively to the total I.H.P.

The consumption of lubricating oil in the working cylinder was at the average rate of 1·19 lb. per hour. At full load 4·4 gallons of water were used per total I.H.P. hour; the cooling water temperature on entering was 22° C., and on leaving 42° C.; hence $44 \times 20 = 880$ C.Th.U. of heat were carried off by the cooling water per I.H.P. hour; so that, at full load, the heat expenditure account was roughly:

Heat Expenditure per Total I.H.P. Hour, C.Th.U.

		Per cent.
Converted into mechanical work	1414	39
Carried off in cooling water	880	24
Carried off in exhaust gases and general heat losses	1343	37
	3637	100

(iv.) *Indicator Diagram.*—In obtaining indicator diagrams from an engine it is usual to so connect up the recording drum that the angle turned through by it is always proportional to the distance travelled by the piston along its stroke. In the case of the Oechelhauser engine a special procedure becomes necessary, as the two pistons do not move exactly alike. In the explosion position the middle throw of the crank-shaft—which is driven by the front piston—is at its inner dead centre while the two side throws—driven by the back piston—are at their outer dead centre. When the double working stroke commences, due to connecting-rod obliquity, the front piston travels more rapidly than the back piston, and this continues until nearly half stroke; thereafter the front piston moves more slowly than the back. Thus *Fig.* 7 shows by the inner heavy line the diagram obtained from an engine with reference to the *back* piston; when the back piston has moved through OA the pressure upon it is given by AB. But at the same instant the front piston has described more of its stroke and has reached some point, as C; drawing a vertical through C to meet a horizontal through B in B′, it is evident that B′ is a point on the diagram corresponding to the front piston. In this way the front piston diagrams can be constructed, as shown by the outer full line; midway between is drawn in dotted lines the "corrected" diagram from which the true mean effective pressure is deduced. In some cases the true M.E.P. is as much as 10 per cent greater than that deduced from the single diagram as given by the indicator.

§ (12) DAY'S ENGINE. (i.) *Description.*—The ingenious two-stroke cycle valveless engine invented by Day in 1891 may be briefly referred to here as it is largely used at the present day in very small sizes, as *e.g.* in the (petrol) engines of motor bicycles, launches, etc. The engine is not of high volumetric efficiency and its fuel consumption is, in general, rather heavy, due to the escape of a portion of each fresh charge through the exhaust. Its simplicity of action and relatively low manufacturing cost, however, are resulting in its increasing use in the smallest class of engine.

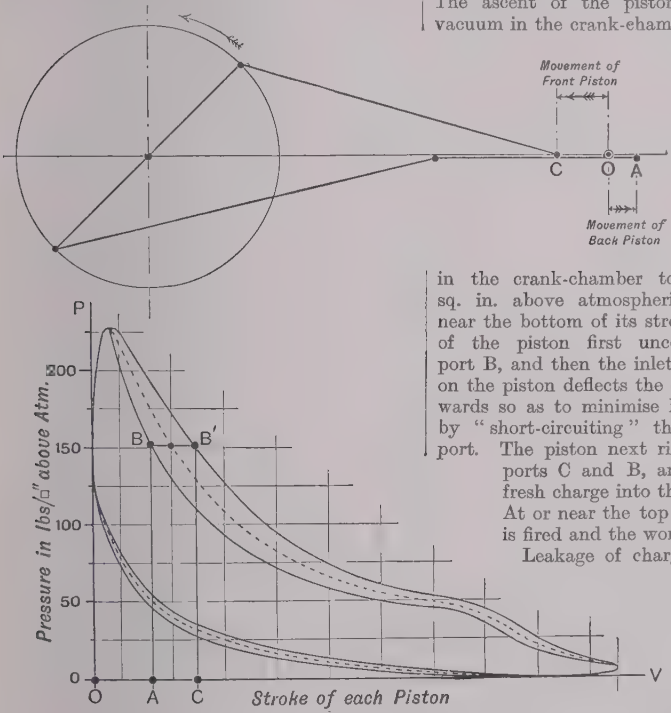

FIG. 7.

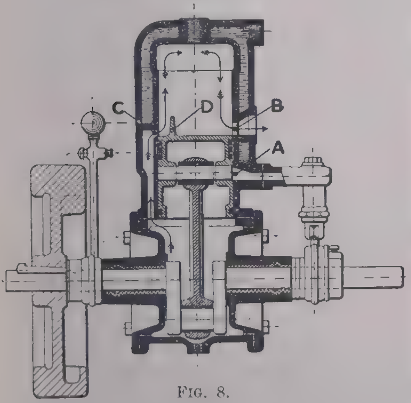

FIG. 8.

A diagrammatic section of the usual "three-port" Day engine is shown in *Fig.* 8. The ascent of the piston causes a partial vacuum in the crank-chamber, and when near the top of its stroke its lower edge uncovers the port A, thus allowing an inrush of carburetted air. The subsequent descent of the piston first closes A and then compresses the charge in the crank-chamber to 3 or 4 lbs. per sq. in. above atmospheric pressure. When near the bottom of its stroke, the upper edge of the piston first uncovers the exhaust port B, and then the inlet port C; the lip D on the piston deflects the entering stream upwards so as to minimise loss of fresh charge by "short-circuiting" through the exhaust port. The piston next rises, cutting off the ports C and B, and compressing the fresh charge into the combustion head. At or near the top centre the mixture is fired and the working stroke follows.

Leakage of charge from the crank-chamber is commonly prevented by making the crank-shaft bearings very long, and grease is sometimes used in these as lubricant.

(ii.) *Performance.*—Experiments on an engine of this type by the late Professor W. Watson and Mr. Fenning in 1910 showed that the proportion of each fresh charge which escaped unburnt through the exhaust port was considerable at low speeds, but diminished as the speed increased, as shown hereunder:

At Revolutions per Minute.	Per cent of Fresh Charge lost.
600	36
1200	20
1500	6

The mean effective pressure was much higher at low than at high speeds, ranging from about $62\frac{1}{2}$ lbs. per sq. in. at 600 r.p.m. to $44\frac{1}{2}$ lbs. per sq. in. at 1500 r.p.m. The volumetric efficiency was only about 40 per cent, and varied but little with speed, the greater loss of fresh charge through the exhaust port at low speeds approximately counterbalancing the larger volume of charge then entering the cylinder.

Owing to the relatively large proportion of burnt exhaust gases in the charge when fired, the "mixture" supplied to this type of engine needs carefully adjusting within somewhat narrow limits in order to obtain regular ignition; otherwise ignition only occurs at every alternate out-stroke, and the engine is said to "four-stroke" in ordinary parlance, the intermediate stroke having only a "scavenging" action. When alternate firing takes place much higher explosion pressures are attained, due to the richer mixture then present. The power output of these small engines, due largely to their low volumetric efficiency, is usually only from about 10 per cent to 30 per cent greater than that of a well-designed four-stroke cycle engine of the same bore, stroke, and speed.

It may be noted that these engines will run equally well in whichever direction they may be started, and this feature is of value when they are used for the propulsion of motor launches, and in other cases where ready reversibility is required.

§ (13) Heavy Oil Engines. *Details of Fuels.*—With the volatile liquids or "oils" of specific gravity less than about 0·76, and flash-point usually lower than the ordinary atmospheric temperature of 15° C., as naphtha, petrol, benzol, etc., the formation of an explosive mixture with air is a simple matter, and the earlier engines accordingly used such "light oils" as they were termed. The problem of readily forming an explosive mixture of uniform composition of the heavier petroleum oils with air proved much more difficult, though it has now been fully solved, very many types of "heavy oil" engine being in everyday service using as fuel "kerosene" ("paraffin" or "lamp oil"), gas oils, intermediate oils, crude oils, residual oils, and even tar oils.

The following table gives some figures obtained from tests of samples of the more usual oil fuels:

Table IV

Description of Fuel.	Specific Gravity.	Composition by Weight, per cent.			Calorific Value in C.Th.U./Lb. (Lower).
		C.	H.	O.	
Crude coal tar	1·05	82·0	7·6	10·4	8,550
Italian refuse petroleum oil	·947	..	..	..	9,800
A heavy Russian crude oil	·938	86·6	12·3	1·1	10,200
A Russian petroleum refuse	·928	87·1	11·7	1·2	10,130
Texas fuel oil	·922	..	..	..	10,120
Blast furnace oil	·920	83·6	10·6	5·8	8,420
Astatki (Russian residual fuel oil) . . .	·906	84·9	14·0	1·1	10,500
An American heavy crude oil	·886	84·9	13·7	1·4	10,000
Benzol (a by-product in coal-gas manufacture)	·88	..	..	..	9,600
A light Russian crude oil	·884	86·3	13·6	0·1	10,800
	·875	..	..	..	10,000
"Russolene" (a refined Russian petroleum) .	·825	86·0	14·0	0	10,600
Broxburn lighthouse oil (from shale) . .	·810	86·01	13·90	0·09	10,300
"Royal Daylight" (a refined "lamp oil") .	·797	85·7	14·2	0·1	11,090
An American "Kerosene" (lamp oil) . .	·796	85·13	14·21	0·66	10,140
A heavy petrol	·760	..	..	..	10,300
A light petrol	·719	85·2	14·8	0	10,250

Figures for petrol are given to enable a comparison to be made with the heavier oils; it will be observed that for the heavy American and Russian petroleum oils the average (lower) calorific value in C.Th.U. per lb. varies but little from a mean of 10,300.

§ (14) (*g*) The Hornsby - Akroyd Oil Engine. (i.) *Description.*—Numerous devices are employed in heavy oil engines to vaporise the charge of oil forming the explosive mixture with air. The type here selected for description and illustration is that in which a combined vaporiser and explosion chamber is formed as a prolongation of the cylinder combustion chamber; of this type the best-known example is the Hornsby-Akroyd engine, of which a longitudinal section is shown in *Fig.* 9.

The engine is of the usual horizontal, single-acting, single- (or double-) cylindered, four-stroke type, but is provided at the combustion chamber end with a partly or wholly uncooled smaller vessel A, termed the "vaporiser" or "hot-bulb," which is constantly in free communication with the cylinder through a relatively narrow neck or "choke" B; the cylinder is also provided with an air inlet and an exhaust valve of the usual type, both cam-operated, which are not shown in the figure.

The oil tank is formed in the engine bed-plate; a centrifugal governor regulates the engine speed by opening a by-pass when the speed increases, thus permitting a portion of the oil delivered by the oil pump to pass back into the oil tank.

(ii.) *Method of Working.*—To start the engine the unjacketed portion of the vaporiser is first heated by a blow-pump for about 10 minutes; the fly-wheel is next turned by hand and the piston performs its suction stroke, drawing, through the inlet valve, a charge of air only into the cylinder. This air enters the cylinder direct, without passing through the vaporiser. Simultaneously a charge of oil is sprayed into the "hot-bulb" by the oil pump shown, and this at once vaporises. On the return stroke of the piston the air is compressed, and a portion passes through the neck B and mixes with the vaporised oil. The mixture is at first too rich to ignite, but the engine is so adjusted that just as compression is completed the correct explosive mixture is reached in the hot-bulb; the heat of the walls then causes explosion and the piston moves outward and performs its working stroke; this is followed by the exhaust in-stroke, and the cycle then recurs. The whole device is eminently simple and has proved very successful, and a great number of internal combustion engines, both of four-stroke and two-stroke type, are now made on the "hot-bulb principle."

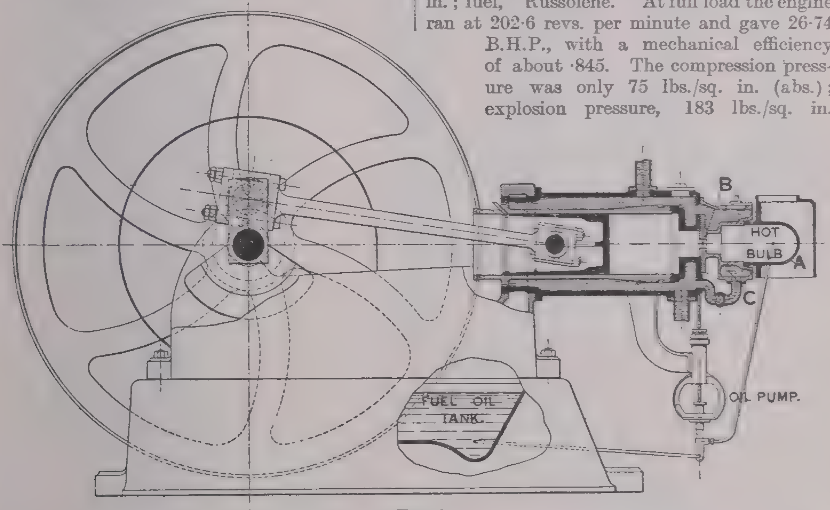

Fig. 9.

After running for a few minutes it is found that the blow-lamp may be removed, the hot-bulb temperature being thereafter sustained by the heat communicated to it from the successive explosions; the ignition then becomes completely automatic. If the vaporiser be allowed to become too hot pre-ignition occurs, and the oil may also be "cracked," with resulting deposition of carbon, which in time chokes up the vaporiser. The temperature is regulated by admitting more or less water to the jacket C which surrounds the neck and part of the vaporiser itself. In many hot-bulb engines, however, pre-ignition at heavy loads is avoided by allowing a few drops of water to enter the chamber during the later stages of compression. On the other hand, the vaporiser may become too cool when the engine is run at light load, and in this case the lamp must be used.

(iii.) *Performance.*—A test of a 25 horse-power Hornsby-Akroyd oil engine made by Professor Robinson in 1898 gave results as follow: Piston diameter, 14·5 in.; stroke, 17 in.; fuel, "Russolene." At full load the engine ran at 202·6 revs. per minute and gave 26·74 B.H.P., with a mechanical efficiency of about ·845. The compression pressure was only 75 lbs./sq. in. (abs.); explosion pressure, 183 lbs./sq. in. (abs.); and mean effective pressure about 44 lbs./sq. in.

The oil per B.H.P. hour was 0·74 lb., corresponding to an absolute brake thermal efficiency of ·185. The best compression pressure for use with any given oil is found by experience; thus "Russolene" was found to permit a higher compression, and to give 15 per cent to 20 per cent more power than "Royal Daylight." Compression may be varied by fitting different-sized vaporisers, and in engines of over about 50 B.H.P. by fitting distance-pieces to the crank-pin end of the connecting rod in addition. These engines run best on kerosenes, and particularly with the standardised Russian oil of ·825 sp. gr. and 30° C. flash-point by Abel close test; they have, however, also been run on crude, gas, and residual oils.

Later tests have furnished still better results; thus in 1908 Professor Robinson obtained from a 32 B.H.P. Hornsby-Akroyd engine using Russolene (cal. value in this case 10,250 C.Th.U. per lb.) a consumption of only 0·613 lb. per B.H.P. hour, corresponding to an absolute brake thermal efficiency of ·226. Single-cylindered engines are constructed up to 185 B.H.P., and with two cylinders to 370 B.H.P.

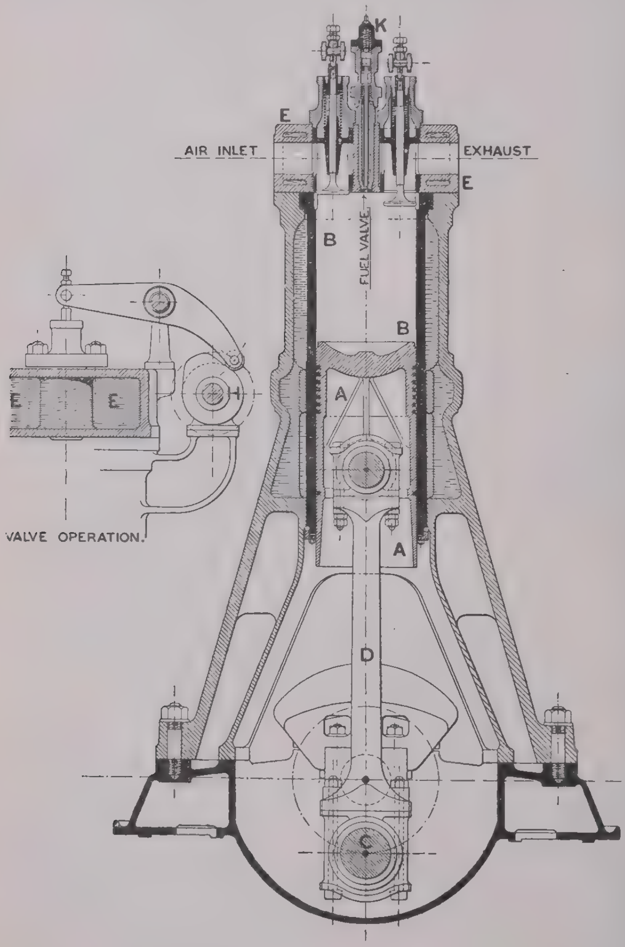

FIG. 10.

§ (15) (*h*) THE "CONSTANT-PRESSURE" CYCLE DIESEL ENGINE. (i.) *Description.*—The leading characteristics of the Diesel engine are: (1) the compression of air only up to the maximum pressure attained in the cylinder, usually from 450 to 500 lbs. per sq. in.; and (2) the regulated admission of the fuel, usually a heavy mineral oil—blown into the combustion chamber by a blast of very high pressure air—in a state of extremely fine spray, during the first part of the working stroke, so that it burns at approximately constant pressure, the ignition occurring automatically from the high temperature developed in the adiabatically compressed air. The cycle has been considered from the thermodynamic standpoint in the article on "Engines, Thermodynamics of Internal Combustion."

A section through a usual type of four-stroke Diesel engine is shown in *Fig.* 10. It will be seen that the engine is of the inverted vertical single-acting type, comprising a long and heavy piston A working within a well water-jacketed cylinder B, and driving the crank-shaft C through the usual type of connecting rod D. In the deep water-cooled detachable cylinder head E are situated the air inlet and exhaust valves (not shown in the diagram), which are of the usual "poppet" or "mushroom" type, normally held up to their seats by springs and opened inwards by cams on an overhead shaft H through the agency of roller-ended rocking levers as indicated. The shaft H is of course driven at half the speed of the crank-shaft. The fuel ignition valve K is also located in the cylinder head, and in recent designs is generally placed in the centre; it is a fundamental difficulty in all internal combustion engines wherein the fuel is sprayed into the combustion chamber at or near the instant of maximum compression to secure a uniform mixture giving rapid and complete combustion, and some of the earlier Diesel designs failed largely from this cause alone. By placing the fuel injection valve in the centre of the cover, and so forming its orifice—and often the upper surface of the piston crown also—as to assist in the instant formation and uniform dispersion of the cloud of spray throughout the combustion chamber space, this difficulty is overcome.

(ii.) *Method of Working.*—The engine is started as follows: By means of a hand lever the crank-shaft is racked round until the crank-pin is just over the top centre; next a starting lever is operated by which a starting cam is brought into working position. The fuel blast reservoir valve and starting reservoir valve being next opened, air from the latter at a pressure of 700 to 900 lbs. per sq. in. enters the cylinder through a small starting valve situated in the cover, and the engine immediately moves off. After a few revolutions under the compressed air from the reservoir the starting lever is moved back, and the engine at once takes up its normal working cycle and continues to run. The full revolution rate is attained at once, but the normal power output is not reached until the cylinder is well warmed up.

In the case of a new engine the air reservoir for starting is sent out fully charged; thereafter its pressure is maintained by a small pump driven by the engine itself.

The charge of fuel is also blown into the cylinder through the fuel injection valve by a blast of air from this reservoir.

The fuel injection valve comprises a needle valve held down on its seat by a spring and lifted by a cam-operated lever. A fuel force-pump delivers the charge of oil fuel into a narrow annular space surrounding the needle which is also in constant communication with the air-blast reservoir during the running of the engine. Hence immediately the needle valve is raised the charge of oil is blown with great velocity into the combustion chamber through an expanding nozzle, in the form of a uniformly diffused cloud of mist which instantly inflames in the adiabatically compressed air where temperature is at this instant from 500-550° C. The fuel is caused to enter the combustion chamber just before the completion of the compression stroke, and at full load the injection is continued during the first 20° to 30° of crank-shaft revolution, the mixture burning at approximately constant pressure during admission. Engine speed is controlled by a governor actuating a by-pass valve in the fuel pump supply whereby a variable proportion of the pumped oil is returned into the suction pipe as the engine load is varied.

The fuel injection needle valve must be regularly cleaned at intervals of about a fortnight; a sticky needle valve may cause pre-ignition through leakage of fuel oil during the compression stroke; such a defective valve, moreover, allows the very high pressure blast air to enter the cylinder in abnormal quantities, and this also may cause rupture of the cylinder through excessive pressure caused by its subsequent further compression by the rising piston. Provision is sometimes made against excessive pressure by fitting relief valves in the cylinder head.

The high-compression and air-blast pressures employed necessitate workmanship of the highest quality in the construction of the Diesel engine, and the necessity of providing against occasional abnormal pressures in the cylinder renders this type of engine somewhat heavy in relation to power output. The high compression also necessitates the fitting of very heavy fly-wheels in few-cylindered four-stroke engines in order to attain the requisite uniformity in rotation of the crank-shaft. For land Diesel engines up to 200 B.H.P. the weights per B.H.P. (including fly-wheels) are, roundly, as follows (compare Table I.):

For single-cylindered engines .	600 lbs.
For two-cylindered engines .	520 „
For three-cylindered engines .	350 „
For three-cylindered engines (without fly-wheels)	275 „

(iii.) *Fuels.*—Experiments have been conducted with a great variety of fuels, including petrol, kerosene (lamp oil), gas oil, crude Russian, American, and German mineral oils, Astatki, shale oils, coal-tar oils, lignite oils, palm and nut oils, castor oil, fish oil, alcohol, coal gas, producer gas, and coal dust. The greatest success has been attained with the kerosenes and heavier petroleum oils, and it is on these, and particularly on the heavy dark-brown crude Texan fuel oil of sp. gr. about ·925, flash point about 85° C., and (lower) calorific value about 10,100 C.Th.U. per lb.—as largely used for firing steam boilers—that most Diesel engines in Great Britain are run. Dr. Allner, in a paper read before the German Gas Association in 1911, stated that the tar produced in large quantities in the coal-gas and coke oven industries can be used successfully as a fuel for Diesel engines, provided a small quantity of a readily ignitable "pilot" fuel, as Texas oil, be injected either just before, or simultaneously with, the admission of the tar to the combustion chamber; the combustion of the pilot fuel starts that of the heavier fuel. Using gas oil as the pilot fuel, Dr. Allner affirms that crude tar may be used in Diesel engines. In general, however, it is held to be a desideratum that the fuel employed should be free from tar, sulphur, and acid impurities. Coal dust, injected with a proportion of "lean gas," has been used — under experimental conditions only—as a fuel, and furnished indicator diagrams of normal type; but the difficulties of utilising any solid substance as a fuel under ordinary conditions of working have yet to be overcome.

(iv.) *Performance.*—The economy of fuel with the four-stroke Diesel engine is very marked; a trial of a two-cylindered, 160 horsepower, four-stroke Diesel engine by Mr. Ade Clarke in 1903 furnished the following results:

Piston diameter, 15·75 in.—stroke, 23·6 in.

Fuel—Texas oil, 0·922 sp. gr.; calorific value, 10,720 C.Th.U. per lb. (higher value).

The outlet temperature of the cooling water, at full load, was 67° C. In the "No load" trial only one cylinder was producing power, the other pumping idly.

TABLE

TEST RESULTS OF TWO-CYLINDER, FOUR-STROKE, 160 H.P. DIESEL ENGINE

No.	Item.	At Load.				
		0.	¼.	⅜.	½.	Full.
1	Duration of trial, minutes	30	60	61	60	60
2	Average revolutions per minute	159	158	158	157	154·5
3	Average mean effective pressure, p, in lbs./sq. in.	43·0	42·1	56·3	69·4	114·0
4	Total I.H.P.	39·6	74·9	100·0	126·8	204·4
5	H.P. absorbed by air compression pump	2·98	2·97	3·0	3·25	3·30
6	Net I.H.P.	36·62	71·93	97·0	123·6	201·1
7	Estimated B.H.P.*	0	35·3	60·4	87·2	164·8
8	Mechanical efficiency, η per cent †	0	47·2	60·4	68·8	80·7
9	Oil per (total) I.H.P. hour, lbs.	·384	·342	·299	·321	·328
10	Oil per B.H.P. hour, lbs.	..	·725	·496	·467	·406
11	Rise of temperature of cooling water in ° C.	57	56	51	43	52·5
12	Temperature of exhaust gases ° C.	..	158	197	240	384
13	Total indicated absolute thermal efficiency	·344	·386	·441	·412	·403
14	Absolute brake thermal efficiency	..	·183	·266	·283	·326

* The B.H.P. was taken as total I.H.P. − 39·6.

† The mechanical efficiency was taken as B.H.P./total I.H.P.

In May 1909 Mr. A. J. Pfeiffer stated before the Inst. of Electrical Engineers that there was then in service a four-cylindered, inverted-vertical, single-acting four-stroke Diesel engine giving 800 B.H.P. at 150 revs. per minute, and that this was about the largest that will run satisfactorily without water- or oil-cooling the pistons and exhaust valves.

§ (16) (*i*) TWO-STROKE DIESEL ENGINES. (i.) *Description.*—Marine Diesel engines are usually of the two-stroke type, single-acting, which possess advantages over the four-stroke of reduced weight and space, lower production cost, and greater simplicity in reversing. There are two principal types of two-stroke, single-acting Diesel engines, in both of which the piston overruns a ring of exhaust ports when near the bottom of its stroke—as in the Clerk engine. In the one type—which is rather the more efficient—air inlet valves are provided in the cylinder head which are opened just after the exhaust ports are overrun, and effect a very complete scavenging action, leaving the cylinder filled with nearly pure air which is compressed by the piston during its return stroke as usual. In the other type, which has been developed largely by Messrs Sulzer Bros., of Winterthur, the air inlet valves are dispensed with, and inlet ports provided in the lower parts of the cylinder which are overrun by the piston shortly after the opening of the exhaust ports; the scavenging is not quite so good, but the engine is of greater simplicity in construction. As in all Diesel engines the fuel is not admitted until nearly the end of compression, any short-circuiting of air through the exhaust ports during its admission is immaterial. In 1911 a four-cylinder, two-stroke, inverted-vertical, single-acting engine of 2400 B.H.P. of Sulzer type was installed in an electric generating station in France.

(ii.) *Difficulties.*—One of the most serious troubles with Diesel engines arises from the loss of compression pressure due to the wear of piston and cylinder walls in the usual design, wherein the piston is directly connected to the connecting rod. This wear is mainly caused by the side thrust due to the obliquity of the rod, and hence in large engines, and especially in marine service, the external crosshead is favoured, as with this the cylinder is relieved of all side pressure. Attention is being given to the production of satisfactory designs of *double*-acting, two-stroke Diesel engines for marine service; the chief difficulty to be overcome is that of providing adequate cooling arrangements.

§ (17) THE RUSTON "COLD STARTING" ENGINE. (i.) *Description.*—Messrs. Ruston, Proctor & Co. have recently produced a valuable design of Diesel type in respect of the high compression of the air and automatic ignition of the fuel, but in which the costly, complicated, and sometimes troublesome air compressor used in the Diesel engine in connection with the fuel injection is completely eliminated.

A section through the cylinder of the 1915 design of "cold starting" engine is given in *Fig.* 11[1]; the engine is of the horizontal, single-cylindered, single-acting, four-stroke type, and is built in sizes ranging from 20 to 170 horse-power.

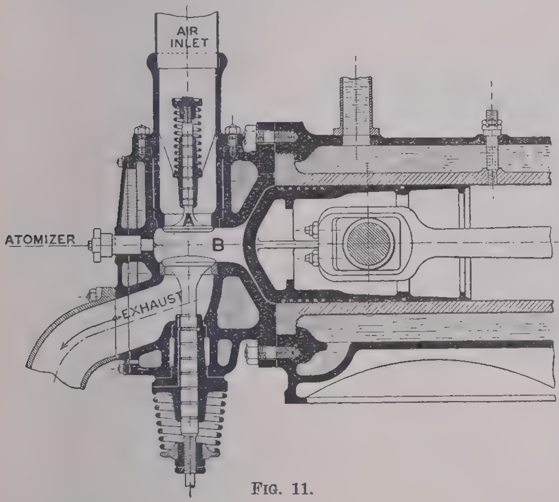

FIG. 11.

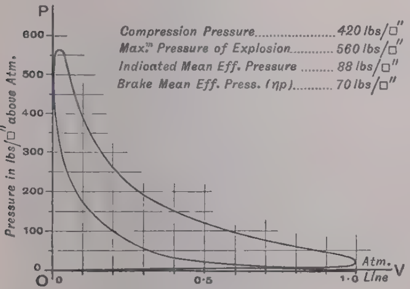

FIG. 11A.

On the suction stroke the piston draws in air only through the valve A, subsequently compressing this into the small explosion chamber B to a pressure of about 430 lbs. per sq. in., which is regarded as giving a sufficiently high temperature to ensure the ignition of any fuel oil. Just before compression is completed the charge of oil is injected directly into the explosion chamber through an "atomiser," whereupon it immediately ignites, and the working stroke then follows; a normal full-load indicator diagram is shown in *Fig.* 11A.

Very perfect "atomisation" of the fuel is essential to high engine efficiency; the Ruston atomiser comprises a spring-closed needle valve and a number of small oil ducts converging to a central orifice. A small fuel force-pump operated by a quick-acting or "steep" cam compels the charge of oil delivered by it to lift the spring-closed needle valve; the charge is by this means caused to enter the explosion chamber in the form of an exceedingly fine spray or "mist"; the lift of the needle valve is of the order of two- or three-hundredths of an inch only.

(ii.) *Method of Working.*—By means of air stored at a pressure of 200-300 lbs. per sq. in. in a reservoir the engine is readily started, and after one or two revolutions picks up its working cycle; starting is thus effected from cold, and the engine may be run on any of the usual grades of fuel oil. When tar oils are employed it is necessary to use about 5 per cent of a more readily ignitable or "pilot" fuel to initiate combustion; this is introduced by a special atomiser fitted with a small needle valve inside a tubular, main fuel needle valve, served by a pilot oil pump. The spring-loaded plunger of this pilot pump is operated by fluid pressure from the main fuel pump in such manner as to absolutely ensure the injection into the cylinder of the pilot igniting charge immediately before that of the main charge. Test results show that, using a fuel of 0·92 sp. gr. and calorific value of about 10,000 C.Th.U. per lb. (lower value), the consumption per B.H.P. hour ranges from 0·48 lb. in the 20 horse-power engine, down to 0·40 lb. in the 170 horse-power size. This corresponds to an absolute brake thermal efficiency of about 0·29 to 0·35, which compares favourably with ordinary Diesel practice.

§ (18) "SEMI-DIESEL" ENGINES.—The great economy of fuel consumption of the Diesel engine has caused many attempts to be made to produce designs in which, without much sacrifice of mean effective pressure and economy, production cost and weight are saved without having recourse to the high-compression pressure used in the Diesel engine, and further, by dispensing altogether with the costly and complicated high-pressure air blast which has so often proved a source of trouble and even danger.

As such designs have been evolved from a study of the performance of Diesel engines they have come to be styled "semi-Diesel," though, as they employ a hot-bulb to ensure ignition of the sprayed charge of oil, they would be more justly described as "Akroyd" engines.

---

[1] From Livens on Oil-engines, *Proc. I. Mech. E.*, July 1920.

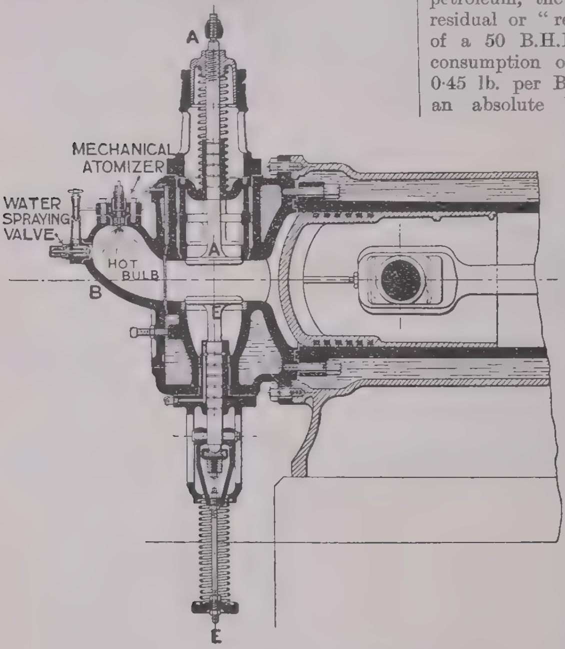

Fig. 12.

(i.) *The C.C. Engine.*—A good example of this class is the "C.C." engine of Messrs. Ruston, Proctor & Co., of which a section through the combustion chamber end of the cylinder is shown in *Fig.* 12; the engine is of the horizontal, single-acting, four-stroke type.

Through the inlet valve A, air alone is drawn during the suction stroke, and this is next compressed into the combustion chamber and hot-bulb B. Nearly at the instant of maximum compression the charge of oil fuel is injected into this hot-bulb by a force-feed pump and atomiser as in the case of the "cold starting" engine described in § (17). The mixture is automatically ignited by the hot-bulb as in the Hornsby-Akroyd engine, § (14), and after performing the working stroke the burnt gases are discharged through the exhaust valve E. The compression pressure employed is only about 275 lbs. per sq. in., and mean effective pressures as high as 95 lbs. per sq. in. are attained at full load. These engines are built in single-cylindered type up to 80 B.H.P. running at 190 revolutions per minute, and in two-cylindered designs up to 130 B.H.P. at 200 revolutions per minute. As fuel, crude petroleum, the ordinary fuel oils, and even residual or "refuse" oils are used. A trial of a 50 B.H.P. engine in 1910 showed a consumption of crude Russian oil of only 0·45 lb. per B.H.P. hour, corresponding to an absolute brake thermal efficiency of ·314.

Starting is effected by compressed air; the time occupied in starting from cold, owing to the necessary heating of the hot-bulb by a blow-lamp, is 10 to 15 minutes. After a short period of running the blow-lamp is removed, and the hot-bulb temperature is then maintained by heat derived from the successive explosions; the ignition is then automatic, as in the Hornsby-Akroyd engine. To prevent pre-ignition "knock" from occurring, a water drip is used at three-quarters full load and above; the water-spraying valve is indicated in *Fig.* 12. After prolonged running at light loads the bulb may become too cool, and recourse must then be made to the heating lamp in order to maintain its temperature. In this class of engine the combustion of the fuel is, in general, partly at constant volume and partly at constant pressure.

FLASH-POINT DETERMINATION

§ (1) Introduction.—The "flash-point" of a substance may be defined as that temperature at which it begins to evolve vapour in such quantity that, on the application of a flame, a momentary "flash" occurs, due to the ignition of the vapour. This temperature is not a definite physical property of the material, but varies with a number of subsidiary factors, such as the rate of heating, the amount of ventilation, the size of the applied flame, and so forth, and is thus dependent on the apparatus used and the conditions under which the determination is made.

Notwithstanding the empirical nature of this "constant" for an inflammable substance, it serves to classify such materials into varying degrees of danger with regard to fire risk, and from this point of view the determination of flash-point has been the subject of legislation and of official regulations.

A short consideration of the phenomena occurring when a sample of oil is slowly heated will serve to distinguish flash-point, burning-point, and ignition-point. If the oil is placed in a small metal basin or crucible and slowly heated, vapour is evolved at a rate depending upon the nature of the oil and its temperature. If a small test flame be applied periodically just above the surface of the oil, no result will be apparent so long as the temperature is well below the value known as the "flash-point" of the oil, but as this is approached the test flame will enlarge when in the neighbourhood of the surface of the oil, and at a temperature a few degrees higher this enlargement becomes more apparent and a flame rapidly travels over the surface of the oil and immediately dies away. This transient ignition of the vapour is termed the "flash," and the lowest temperature at which it is manifest is known as the "flash-point" of the oil. If the heating of the oil and the periodic application of the test flame be continued flashing will also continue, and it will be noticed that the duration of the flash becomes longer as the temperature is raised, until a point is reached when the vapour burns continuously instead of merely flashing; the lowest temperature at which this occurs is known as the "burning-point" of the oil. In general the heat generated by the combustion will rapidly raise the temperature and the combustion will become more violent, and will be maintained without the application of any external source of heating.

If now the experiment is repeated without the application of a test flame, there will be no apparent result until a temperature higher than the burning-point is reached, when the oil will spontaneously take fire and will continue to burn. The lowest temperature at which this takes place is known as the "ignition-point."

The above phenomena are dependent on the accumulation of sufficient vapour in the atmosphere above the oil to form a combustible mixture, and this will be largely influenced by any circulation which is taking place in the surrounding air. If the air is in motion, even to a small extent, some of the vapour will be carried away, and it will be necessary to raise the oil to a higher temperature to secure the same concentration of vapour as would be obtained in perfectly still air. In consequence it is not easy to obtain concordant values for the flash-point, burning-point, and ignition-point by the heating of the oil in an open cup as above described, and other types of apparatus have been designed to reduce the difficulty of making reasonably accurate determinations. In most forms of this apparatus the oil cup is provided with a cover having suitable apertures for the introduction of the test flame and for ventilation purposes. For distinction the two types of test are usually referred to as the "open test" and the "closed test" respectively.

The first apparatus of the "closed test" type was introduced by Sir Frederick Abel in 1876, and was subsequently known as the Abel Flash-point Apparatus. A large number of tests were made to connect the results obtained by the use of this apparatus with those given by the open test then in use. It was found that the mean value of the difference between these results was 27° F. for an oil which flashed at 100° F. on the open test.

Later, in 1880, a modification of this instrument was made by Pensky, who applied a clockwork device to the oil cup cover to perform the opening and closing of the shutter and introduction of the test flame. This apparatus is referred to as the Abel-Pensky Flash-point Apparatus. The provision of this mechanism is probably advantageous from the point of view of ease of operation, but, as will be seen later, it does not tend to any increased accuracy of determination of the flash-point.

The two apparatus above referred to were designed with special reference to the measurement of flash-points over the approximate range 60°-110° F. in connection with the legislation relating to the sale, storage, and transport of illuminating oils; later, however, a demand arose for the determination of the flash-point of oils for lubricating and other purposes, leading to the evolution of such types of apparatus as the Gray and Pensky-Martens flash-point apparatus, which may be employed up to much higher temperatures. The essential difference between these and the earlier forms of apparatus intended for the lower range only is the provision of stirrers in the oil cups.

§ (2) Abel Flash-point Apparatus.—The official specification for the Abel flash-point apparatus will be found in the schedule to the Petroleum Act of 1879 (42 & 43 Vict. c. 47); full details as to the construction and use of the apparatus are also to be found in the several text-books relating to oil and oil testing.[1] The principal dimensions are shown in *Fig.* 1.

An investigation was carried out at the National Physical Laboratory to ascertain the differences existing between the Abel and other types of flash-point apparatus.[2]

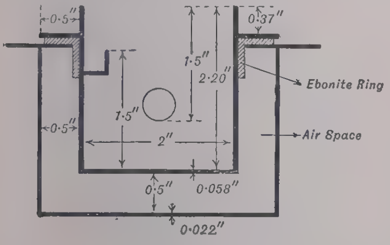

Fig. 1.

An important consideration that arises in the determination of the flash-point is the limit of accuracy attainable. The legal specification directs that the test flame should be applied to the oil every 1° F., and consequently the accuracy of any single determination is limited to 1° F. Departure from the specified conditions gives a different value for the resulting flash-point, as will be seen later. Difficulty, however, arises in the interpretation of a set of results for any one sample of oil, since even when the greatest care is taken individual readings may differ by 1° or 2° F. Furthermore, changes in the barometric pressure produce variations in the resulting flash-point, and Sir Frederick Abel investigated this matter and found that the flash-point was raised by 1·6° F. for an increase of 1 inch in the barometric reading. Hence it is usual to correct all flash-points to a standard barometric reading of 30 in. Corrections for errors of the thermometer, if any, must also be taken into account; the most satisfactory way, therefore, of dealing with a set of observations is to obtain the mean result and apply the necessary corrections for pressure and for the thermometer. The true flash-point is then taken as the next higher whole number of degrees, since the flash-point of a substance as defined in the official regulations cannot be other than a whole number of degrees.

Before intercomparisons between the several types of flash-point apparatus could be carried out it was found necessary to investigate the conditions of use of the Abel apparatus more fully than appeared to have been done previously. Among the points to which attention was given were:

(*a*) Frequency of application of the test flame.

(*b*) Variations in the time of opening of the slide.

(*c*) Variations in the temperature of the water bath.

(*d*) Variations in the depth of the thermometer bulb below the surface of the oil.

(*e*) Size of the test flame.

The results of these experiments led to the following conclusions:

(*a*) Increasing the frequency of application of the test flame raises the flash-point; for example, if the test flame is applied every ½ degree the resulting flash-points are a degree higher, while if applied every ¼ degree the flash-point is raised by over 3 degrees; conversely, a lower flash-point is obtained if the test flame is applied at intervals greater than 1° F.

(*b*) Contrary to the general opinion, the effect of increasing or decreasing the time for which the slide is open does not affect the results except for extreme changes. Thus the provision of an automatic mechanism to secure constancy in this condition is not essential. It is interesting to note in this connection that a number of the Abel-Pensky automatic covers were investigated and it was found that their times of opening differed to a considerable extent. This might well be expected, as it is improbable that the strength of the spring would remain constant under the conditions of use.

[2] *Collected Researches, N.P.L.*, 1912, viii. 19.

(*c*) A change in the temperature of the water bath produces a corresponding change in the flash-point, the general effect being that the flash-point is lowered by 1° F. for each 13° F. rise in the temperature of the water bath above the normal temperature 130° F.

(*d*) and (*e*). The depth of immersion of the thermometer bulb below the surface of the oil and the size of the test flame were seen to play very important parts in flash-point determinations, and the question will be considered later.

§ (3) THE ABEL-PENSKY APPARATUS.—The apparatus adopted in 1880 by the German Government as the official standard design of instrument for flash-point determinations was based upon the Abel apparatus, but modifications were introduced by Pensky, who substituted an automatic device for opening and closing the ventilation holes and applying the test flame in place of the simple slide in the English Abel apparatus. In addition, the dimensions were slightly altered and were expressed in metric units instead of inches, as in the Petroleum Act of 1879. *Fig.* 2 indicates the important dimensions of the Abel-Pensky apparatus in accordance with the German schedule. Very complete details are published in the official specification[1] and will not be further dealt with here.

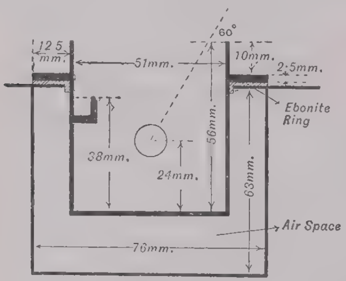

FIG. 2.

The Abel-Pensky apparatus was also adopted by the British Colonies and India under the Indian Petroleum Act of 1889, the German type of apparatus being used although the dimensions of the Abel apparatus were retained. Two modifications have been made to the Colonial type of apparatus for special purposes; these provide for a small additional thermometer and a stirrer in the oil cup for use when obtaining the flash-point of inflammable substances such as rubber solution, metal polishes, etc., which may fall within the scope of petroleum legislation. In both these types of apparatus the effects of variations in the methods of procedure are the same as are described for the Abel apparatus.

§ (4) THE GENERAL THEORY OF FLASH-POINT DETERMINATION.—The general theory of flash-point determination depends on the hypothesis that flashing takes place when the space above the oil contains a definite percentage of oil vapour mixed with air. This condition will be reached for a definite temperature of the oil surface from which evaporation is taking place, and it is generally assumed that it is this temperature which is given by the thermometer and is the temperature taken as the flash-point. The rate of evaporation, however, depends upon the temperature of the surface of the oil, and investigation showed that this temperature differed appreciably from the thermometer reading throughout the course of a determination. Furthermore, the temperature at different points throughout the oil varied by several degrees at any one moment. The temperature distribution depended in part on the form and dimensions of the apparatus and on the relative amounts of heat reaching the oil from different sources. The method of investigation employed was to ascertain these temperature differences by means of differential thermocouples of very fine wire introduced in such a way as to avoid interference with the usual conditions of test. The main source of heat through which the rise of temperature of the oil is derived is of course the water bath surrounding the oil cups through the intermediary of the air space; but it was found that the temperature at the surface of the oil and that of the vapour were materially influenced by the heating derived from the test flame itself. The importance of the size of the test flame is therefore obvious, and as the result of a special series of experiments it was found that an increase of 2° F. in the flash-point was obtained when the size of the oil-burning test flame in an Abel apparatus was decreased to about half the normal diameter. Similar results were found for the gas test flames also in general use. The explanation of this difference is that with the smaller test flame the oil surface does not receive so much heat indirectly, and consequently the temperature of the bulk of the oil has to be raised to produce the same surface temperature; thus the flash-point is apparently higher. For exact work it may be remarked that the ivory bead on the cover of the apparatus is inadequate as a gauge for the adjustment of the size of the test flame. It is therefore preferable to employ a gas jet to which the supply of gas is controlled by a gas meter. In the experimental work to which reference is being made the gas rate adopted was 0·10 cub. ft. per hour.

Investigation of the three types of apparatus, namely, the Abel, and the Colonial and the

---

[1] *Die Vorschriften betreffend den Abel'schen Petroleumprober und seine Anwendung*, published 1883 by Carl Hermann, Berlin.

German types of Abel-Pensky apparatus, showed that the temperature distribution in each varied, so that for any definite reading of the thermometer the temperature of the surface of the oil was different in each of the three apparatus. It was further found that the temperature of the surface of the oil at the moment when flashing took place was the same in each of the three apparatus although the thermometer readings differed; the difference in flash-point recorded in the three types of apparatus is therefore completely explained by the consideration of the temperature distribution in the oil cups.

The general results of the investigation showed that the Colonial type of Abel-Pensky apparatus gave a flash-point 1° F. higher than the original form of Abel apparatus, while the German type of Abel-Pensky gave results approximately 4° F. higher; further, these differences are sensibly constant over the range 70°-100° F. Incidentally there is a systematic difference amounting to about 0·5° F. (taking the mean values for a large series of observations) between apparatus of the same type but fitted with oil and gas test flames respectively. As might be expected from the previous remarks, the gas test flame gives the lower flash-point, the flame supplying more heat to the surface of the oil, when adjusted to the specified size.

Further light is thrown upon the mechanism of flash-point determination by the results of a series of tests carried out at the National Physical Laboratory at a later date.[1] The tests in question were carried out on a number of fuel oils, using the Gray and Pensky-Martens apparatus, and also a modified form of apparatus on a much larger scale, which dealt with about 50 gallons of oil instead of the usual quantity. The latter apparatus was designed with a view to ascertaining whether a large quantity of oil would flash at a temperature appreciably lower than the value obtained in the usual types of apparatus. The conditions were varied over a wide range in order to study the effect of different methods of ignition and the importance of ventilation of the vapour space above the oil. Dealing with the latter point, it was clearly seen that combustion of the vapour occurred prior to an actual flash being obtained; this is shown by the enlargement of the applied test flame at temperatures below the flash-point. If the space above the oil is not adequately ventilated it becomes charged with the products of combustion, which may lead to the extinction of the test flame or give an apparently high result. On the other hand, forced ventilation of the surface by the passage of a current of air apparently raised the flash-point, as in this case the oil vapour is swept away before ignition can occur. Consequently the oil has to be raised to a higher temperature in order to evolve vapour fast enough to maintain an inflammable mixture.

A variation of this question was also investigated. In this instance the oil was maintained at a constant temperature and the vapour was allowed to collect for periods of varying length, the test flame being applied after definite intervals had elapsed. Between such applications of the test flame the space above the oil was completely cleared of accumulated vapour by blowing a current of air through the space. The result of such tests was to show that the higher the temperature of the oil the shorter the interval that was necessary for the vapour to accumulate before the flash could be produced. At the lowest temperature at which it was possible to obtain any ignition of the oil vapour a comparatively long period (from 5 to 10 min.) was required before sufficient vapour had accumulated, and in these instances the flash, when it did occur, was generally of a violent nature. With regard to the effect of different methods of ignition, it was found that the most satisfactory results were obtained with a moderate-sized gas flame. Electric sparks or hot wires generally necessitated a higher temperature of the oil before flashing took place, and with the high temperatures a violent, in some cases almost explosive, flash was obtained. Throughout these tests the oil was stirred continuously at such a rate that the temperature throughout the bulk of the oil was fairly uniform, but not so vigorously as to break the surface or to produce splashing. Under these conditions it was found that the temperature in the vapour space immediately above the oil surface was sensibly the same as that indicated by the thermometer immersed in the oil; in other words, the question of temperature distribution met with in the Abel and allied apparatus does not arise here.

The ultimate deduction from these tests was that the Gray and Pensky-Martens apparatus indicate within a few degrees the lowest temperature at which it is possible for a flash to be obtained over this very wide range of conditions; and furthermore the Abel and Abel-Pensky types of apparatus could with advantage be modified by the introduction of a stirrer in the oil vessel and possibly in the vapour space above the oil. A small change in the indications of these apparatus would no doubt result, but the determination of flash-point would become an operation involving considerably less care and would not depend to any marked extent upon the exact form and dimensions of the apparatus employed. In any case the flash-point of a substance must be regarded as an empirical constant, but the modification suggested would render the determination less dependent on any particular design of apparatus.

---

§ (5) High Temperature Flash-point Determinations.—The limiting temperature at which a flash-point determination can be made in the Abel types of apparatus is about 110° F. if the normal procedure be followed. For higher temperatures than this a modification of the normal procedure may be made in that the water bath itself, instead of being set initially to 130° F., is heated continuously throughout the test until a limiting temperature of about 180° F. is attained. In addition a small quantity of water is placed in the air jacket to facilitate the rise of temperature of the oil in the oil cup. This method is liable to give discordant results if the rate of heating be too rapid, again owing to the unequal distribution of temperature in the oil cup. Two modified apparatus were introduced to overcome this difficulty and at the same time to extend the range of temperatures over which a test may be made. These apparatus are referred to as the Pensky-Martens [1] and the Gray [2] flash-point apparatus respectively.

In both these apparatus the water bath is dispensed with and the oil cup is supported in a cavity in an iron casting heated from below. The Pensky-Martens apparatus has an oil cup similar to that of the Abel-Pensky apparatus, while that of the Gray apparatus is of the same dimensions as the oil cup of the Abel apparatus. The covers in each apparatus differ somewhat in detail, but both are provided with a rotating plate by means of which the ventilation holes are opened and the test flame depressed into the vapour space. Each instrument has a rotary stirrer provided with vanes which agitate both oil and vapour. In carrying out an observation the stirrers are worked continuously between the intervals at which the test flames are applied. The provision of these stirrers ensures that the thermometers indicate the true temperature of the vapour, and in practice it is found that both types of apparatus give sensibly the same flash-point. In carrying out a determination care should be taken that the rate of heating of the oil is slow and regular. The thermometers employed should be calibrated for the degree of immersion obtaining in the apparatus, otherwise it is necessary to apply a correction to allow for the emergent column. This correction is by no means negligible, as under the conditions of immersion in a flash-point apparatus the correction will amount to as much as 15° C. at 300° C.[3]

In carrying out the determination of flash-point of an oil the presence of moisture gives rise to considerable uncertainty, and even a small quantity may prevent the oil flashing until the water has been driven off. The temperature at which this occurs may be well above the normal flash-point of the oil and the resulting flash may be very violent. The drying of oil prior to testing the flash-point is a matter of considerable difficulty, as heating the oil to 100° C. may change it and thereby vitiate subsequent tests. Various methods have been suggested, such as drying with anhydrous calcium chloride or by exposing the moisture-containing oil to a high-tension discharge; neither of these methods is entirely satisfactory in removing every trace of moisture, but undoubtedly helps in preparing an oil for a flash-point determination.

§ (6) Ignition Points.—Although not of importance in connection with the legal aspect of flash-point determination, the ignition points of oils are frequently required in connection with internal combustion engine problems. A number of methods have been devised from time to time to carry out this determination without danger to the operator. The simplest form consists in allowing drops of oil to fall upon a heated iron plate. This method has been modified by H. Moore.[4] In this apparatus the iron plate is replaced by a grooved block of steel which may be heated from below; in the upper part of the block a cavity is provided into which a platinum or nickel crucible fits exactly. The crucible is covered by means of a perforated plate, one hole of which permits the introduction of the substance to be tested while the other serves as an inlet for air or oxygen. The gas employed is heated before admission to the crucible by being allowed to circulate through passages in the steel block. In operation the apparatus is raised to a definite temperature and one drop of the oil under examination is allowed to fall into the crucible. If the temperature is above the ignition point of the sample, combustion, more or less violent, takes place, while below the ignition temperature no explosion or flame is observed. Tests are repeated until the lowest point at which ignition takes place is determined.

FOURIER'S THEOREM

This relates to the expansion of an arbitrary function $f(x)$ in terms of circular functions of a particular type. Consider, in the first instance, the case where $f(x)$ is itself periodic, *i.e.* its value recurs exactly whenever the variable has a given constant increment a, so that

$$f(x+a)=f(x), \quad . \quad . \quad . \quad (1)$$

for all values of x. The simplest example of this relation is afforded by the circular functions $\cos(2s\pi x/a)$ and $\sin(2s\pi x/a)$, where s is any integer. The theorem is that whatever the form of $f(x)$, subject to certain restrictions, it can be approximated to as closely as we may desire by a series of terms of the above type, thus

$$f(x)=\mathrm{A}_0+\mathrm{A}_1\cos\frac{2\pi x}{a}+\mathrm{A}_2\cos\frac{4\pi x}{a}+\ .\ .\ .$$
$$+\mathrm{B}_1\sin\frac{2\pi x}{a}+\mathrm{B}_2\sin\frac{4\pi x}{a}+\ .\ .\ . \quad (2)$$

Assuming for the present the truth of the theorem, the values of the coefficients are found as follows. To find A_0, which is evidently the mean value of the function, we integrate both sides of (2) from $x=0$ to $x=a$. This gives

$$\mathrm{A}_0=\frac{1}{a}\int_0^a f(x)dx. \quad . \quad . \quad . \quad (3)$$

To find A_s we multiply both sides of (2) by $\cos(2s\pi x/a)$ and then integrate. The coefficient of A_r in the result is

$$\int_0^a \cos\frac{2\pi rx}{a}\cos\frac{2s\pi x}{a}dx$$
$$=\tfrac{1}{2}\int_0^a\left\{\cos\frac{2(r+s)\pi x}{a}+\cos\frac{2(r-s)\pi x}{a}\right\}dx.$$

Except in the case of $r=s$ each cosine goes through a complete cycle of its values at least once within the range of integration, and the integral vanishes. When $r=s$ the result is $\tfrac{1}{2}a$. Hence

$$\mathrm{A}_s=\frac{2}{a}\int_0^a f(x)\cos\frac{2s\pi x}{a}dx. \quad . \quad . \quad (4)$$

By a similar process

$$\mathrm{B}_s=\frac{2}{a}\int_0^a f(x)\sin\frac{2s\pi x}{a}dx. \quad . \quad . \quad (5)$$

For an account of various practical methods of computing the coefficients, and of the mechanical integrators which have been devised to supersede the numerical work, see "Harmonic Analysers," Vol. IV.

There is nothing special to the two points $x=0$, $x=a$, which have been taken as the limits of the above integrations. Any two points at an interval of a period will give the same result. In particular, writing l for the half-period, we have

$$f(x)=\mathrm{A}_0+\mathrm{A}_1\cos\frac{\pi x}{l}+\mathrm{A}_2\cos\frac{2\pi x}{l}+\ .\ .\ .$$
$$+\mathrm{B}_1\sin\frac{\pi x}{l}+\mathrm{B}_2\sin\frac{2\pi x}{l}+\ .\ .\ ., \quad (6)$$

where

$$\mathrm{A}_0=\frac{1}{2l}\int_{-l}^{l} f(x)dx, \quad \mathrm{A}_s=\frac{1}{l}\int_{-l}^{l} f(x)\cos\frac{s\pi x}{l}dx, \ (7)$$

and

$$\mathrm{B}_s=\frac{1}{l}\int_{-l}^{l} f(x)\sin\frac{s\pi x}{l}dx. \quad . \quad . \quad (8)$$

This leads to two particular cases of special importance. If $f(x)$ be an *even* function of x, so that

$$f(-x)=f(x), \quad . \quad . \quad . \quad (9)$$

we have

$$f(x)=\tfrac{1}{2}\{f(x)+f(-x)\}$$
$$=\mathrm{A}_0+\mathrm{A}_1\cos\frac{\pi x}{l}+\mathrm{A}_2\cos\frac{2\pi x}{l}+\ .\ .\ ., \quad (10)$$

with

$$\mathrm{A}_0=\frac{1}{l}\int_0^l f(x)dx, \quad \mathrm{A}_s=\frac{2}{l}\int_0^l f(x)\sin\frac{s\pi x}{l}. \quad (11)$$

Again, if $f(x)$ be an *odd* function, so that

$$f(-x)=-f(x), \quad . \quad . \quad (12)$$

we have

$$f(x)=\tfrac{1}{2}\{f(x)-f(-x)\}$$
$$=\mathrm{B}_1\sin\frac{\pi x}{l}+\mathrm{B}_2\sin\frac{2\pi x}{l}+\ .\ .\ ., \quad (13)$$

where

$$\mathrm{B}_s=\frac{2}{l}\int_0^l f(x)\sin\frac{s\pi x}{l}dx. \quad . \quad . \quad (14)$$

In many applications, especially when the variable x is a space co-ordinate, we are concerned only with a limited range of x, say from 0 to l. As instances we have the vibrations of a string, and the flow of heat through a plate. Outside the above limits the function $f(x)$ may not exist, so far as the physical problem is concerned, but we are at liberty to imagine it continued analytically both ways as a periodic function. We are further at liberty to suppose it continued as an odd or as an even function of x, as is illustrated by the annexed figures. It is to be noticed, however, that in the second case the process of continuation introduces discontinuities at $x=0$, $x=l$, unless $f(x)$ vanishes at these points.

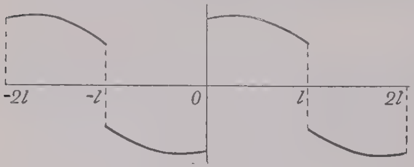

FIG. 1.

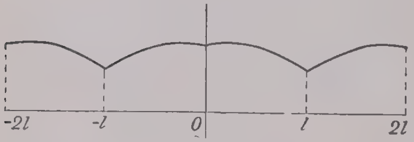

FIG. 2.

Similarly, in the original form (2) of the theorem, if the function is continued with a period a, discontinuities will be introduced at $x=0$, $x=a$, unless $f(0)=f(a)$.

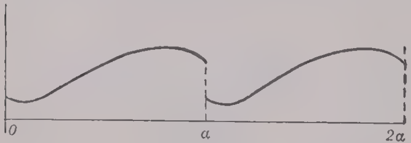

FIG. 3.

A complete statement of the conditions under which the theorem (2) holds is not attempted here. For physical purposes it may be sufficient for the moment to say that the expansion is valid provided $f(x)$ be continuous, and has (within the period) only a finite number of maxima and minima. The mathematical proof, which is necessarily somewhat intricate, must be omitted, but physical arguments of a very convincing kind are easily adduced. Suppose, for example, that x is measured along the circumference of a uniform thin metal ring whose total perimeter is a; and let $f(x)$ denote the initial distribution of temperature. If radiation from the surface be neglected, the theory of conduction of heat indicates that the subsequent process is made up by superposition of the various "normal modes" of approach to a steady state, with arbitrary coefficients, thus

$$\mathrm{A}_0+\mathrm{A}_1 \cos\frac{2\pi x}{a}e^{-\lambda_1 t}+\mathrm{A}_2 \cos\frac{4\pi x}{a}e^{-\lambda_2 t}+\ \ldots$$

$$+\mathrm{B}_1 \sin\frac{2\pi x}{a}e^{-\lambda_1 t}+\mathrm{B}_2 \sin\frac{4\pi x}{a}e^{-\lambda_2 t}+\ \ldots, \quad (15)$$

where

$$\lambda_s=4\pi\kappa s^2/a^2. \quad . \quad . \quad (16)$$

This being granted, the initial distribution $f(x)$ must correspond to $t=0$. Hence $f(x)$ must admit of expansion in the form (2). Arguments of a similar character might be adduced from Acoustics, and other branches of Physics.

The restriction as to continuity, above made, can to a certain extent be dispensed with. Provided the discontinuities are of finite amount, and occur (within the range of a period) only at a finite number of isolated points, the expansion (2) will still hold except at the points of discontinuity. At such a point the value of $f(x)$ is of course ambiguous, but it may be proved that the series on the right-hand side of (2) converges to a definite value which is the arithmetic mean of the values of $f(x)$ immediately to the left and right of the discontinuity. This applies in particular to the discontinuities which may be introduced when a function given over a finite range is continued as a periodic function, in the manner already explained.

Suppose, for instance, that it is required to express in the form (13) the initial temperature of a conducting slab bounded by the planes $x=0$, $x=l$, and, for simplicity, that the initial temperature is everywhere unity. Putting $f(x)=1$ we have

$$\mathrm{B}_s=\frac{2}{l}\int_0^l \sin\frac{s\pi x}{l}dx=\frac{2}{s\pi}(1-\cos s\pi). \quad (17)$$

This is equal to $4/s\pi$ or 0, according as s is odd or even. Thus

$$1=\frac{4}{\pi}\left(\sin\frac{s\pi x}{l}+\tfrac{1}{3}\sin\frac{3s\pi x}{l}\right.$$

$$\left.+\tfrac{1}{5}\sin\frac{5s\pi x}{l}+\ \ldots\right). \quad (18)$$

When in this case $f(x)$ is continued as an odd function there is a sudden change from 1 to -1, or *vice versa*, at $x=0$ and $x=l$. The series has then the value zero, which is the arithmetic mean aforesaid. The figure shows the approximation given by the first three terms of the expansion. It may be added, in leaving this topic, that in the applications to physical problems a mathematical discontinuity (*e.g.* of temperature) is only to be regarded as the idealised expression of a very rapid transition. In practice there is, of course, a limit to

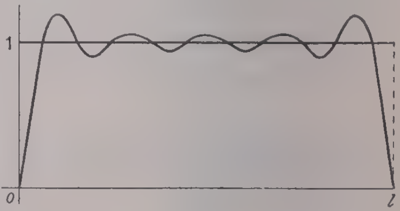

FIG. 4.

the number of the coefficients A_s, B_s which it is convenient to calculate. The rapidity with which the series converges depends on the smoothness or regularity (in a general sense) of the function $f(x)$. It is evident that the coefficients, as determined by (4) or (5), must ultimately diminish without limit as the order s increases, owing to the more and more rapid fluctuations in sign of the circular functions $\cos(2s\pi x/a)$ and $\sin(2s\pi x/a)$, and the consequent more complete cancelling of the positive and negative elements in the integrals. More definite results were given by Stokes. If the function $f(x)$, *as continued*, has only isolated discontinuities, the coefficients ultimately diminish as $1/s$; this is illustrated by (18). If $f(x)$ is everywhere continuous, whilst its derived function $f'(x)$ has isolated discontinuities, the convergence is as $1/s^2$, and so on. The present point has many exemplifications in Acoustics. For instance, the more gradual the initial impulse given to a string, the fainter are the higher harmonics in the resulting note.

The approximate representation of an arbitrary function over a given range by means of functions of a specified type is a problem which naturally admits of solution in various ways. It is of interest to note that Fourier's method is the one which makes the sum of the squares of the errors a minimum. Taking for brevity the sine-series (13), and limiting ourselves, in the first instance, to a finite number of terms, the sum of the squares of the errors is

$$\int_0^l \left\{ f(x) - B_1 \sin\frac{\pi x}{l} - B_2 \sin\frac{2\pi x}{l} - \ . \ . \ . \right. \\ \left. - B_m \sin\frac{m\pi x}{l} \right\}^2 dx. \quad (19)$$

To make this a minimum we must equate the differential coefficients with respect to $B_1, B_2 \ . \ . \ . \ , B_m$ to zero. The typical equation is

$$\int_0^l \left\{ f(x) - B_1 \sin\frac{\pi x}{l} - B_2 \sin\frac{2\pi x}{l} - \ . \ . \ . \right. \\ \left. - B_m \sin\frac{m\pi x}{l} \right\} \sin\frac{s\pi x}{l} dx = 0, \quad (20)$$

whence $$B_s = \frac{2}{l}\int_0^l f(x) \sin\frac{s\pi x}{l} dx, \ . \ . \quad (21)$$

as in (14). Each additional term included in the series necessarily lowers the minimum, and so improves the approximation, as tested by the method of least squares. H. L.

FRICTION

Introduction.—Friction may be broadly defined as the resisting force which is called into existence at the common boundary of two substances in contact when under the action of some external agency one of the substances slides, or tends to slide, over the surface of the other. The direction of the force of friction is tangential to the surface of contact, and so long as there is no motion its magnitude is equal to the component in the direction of motion of the external force tending to produce sliding.

The phenomenon of friction is common to all substances, solid, liquid, or gaseous, which may be in contact with each other and subject to forces tending to cause relative motion, but the laws correlating the magnitude of the frictional forces produced, with the magnitude of the external forces acting and the state of motion produced by them, differ widely with the nature of the substances. For example, the friction between the wheels of a locomotive and the rails, in virtue of which railroad traffic becomes possible, depends on the weight on the wheels and not on the speed of the wheels, whereas the frictional resistance of the water to the motion of a ship floating on it depends on the speed of the ship and is independent of the pressure of the water.

The term friction has also been extended, with certain restrictions, the necessity for which will be explained below, to include the mutual resistance which different parts of the same substance offer to sliding over each other. That this interpretation must, of necessity, be extended to fluids is obvious from the consideration that in the case of the skin friction of a ship referred to above, the particles of the water in contact with the surface of the ship are at rest relatively to it, and the sliding to which the resistance is due takes place in the body of the water itself. The resistance to motion of the ship is, therefore, due to the shearing resistance of the water in which it moves, and for this reason this shearing stress is commonly called the internal friction of the water. In the case of an elastic solid, however, the conditions of relative motion of its particles due to the action of external forces are more complex. For example, suppose a vertical elastic rod is supported rigidly at its upper end and carries at its lower extremity a mass which executes free torsional oscillations about the axis of the rod. During each half-oscillation a certain amount of the work done by the rotating mass is stored up as potential energy in the rod and this is given out again to the mass on the return movement. It is found, however, that the amplitude of the oscillations diminishes much more rapidly than would be due to the resistance of the air in which it swings, and it is concluded that frictional resistances have existed in the material of the rod to bring this about, *i.e.* the rod has a certain amount of internal friction or viscosity. In this particular illustration we have, therefore, a case in which part of the work done against the resistance to distortion is stored up as potential energy of the material and part is converted into heat. That the two phenomena are essentially different will be seen from the fact that in the elastic distortion the resistance is proportional to the relative displacement, whereas in the case of internal friction, or viscosity, the resistance is proportional to the time rate of relative displacement.

The necessity for the restriction of the use of the term friction to those cases in which the work done against the frictional resistance is converted into heat is, therefore, obvious.

From these considerations it will be seen that a more precise definition of friction than that given in the first paragraph would be as follows. The resisting forces brought into existence at the surface separating two substances in contact, or two parts of the same substance, by the action of any external agency tending to produce relative motion at the surface are denominated frictional forces in all cases in which the work done by them is converted into heat.

In previous works on the subject of friction it has been customary to classify all cases of frictional resistance under one or the other of the following two divisions:

(*a*) Friction between solid bodies in contact; the frictional resistance being subject to certain empirical laws.

(*b*) Friction between solids and fluids or between solids separated by a film of fluid; the resistance being determined from the motion and physical characteristics of the fluid.

In recent years, however, it has become more and more recognised that this broad division of the subject cannot be made for the reason that it is almost impossible in practice to obtain contact between solid surfaces without the intervention of a contaminating film of fluid which renders the phenomenon one in which the nature of the resistance is to a greater or less extent dependent on the characteristics of the contaminating film. The modern tendency is, therefore, to regard the frictional resistance of solids in contact and moving relatively to each other as a limiting case of the friction between the solid surfaces separated by a layer of fluid when the thickness of this layer is diminished to such an extent that its motion can no longer be treated by the laws of hydrodynamics, so that the unknown boundary conditions constitute the main characteristics governing the resistance.

For this reason it is proposed in the present article to commence with the treatment of the internal friction of fluids and the manner in which it is affected by the characteristics of the motion, and then to proceed to a discussion of the force acting at a solid bounding surface of a fluid tangential to the direction of the fluid flow, in the first instance when the conditions at the boundary are known, and finally when these conditions are hypothetical.

The detailed classification of the subject-matter of the present article will therefore be as follows:

Division I. Internal Friction, or Viscosity.

Division II. The Nature of the Motion of Fluids over Solid Surfaces and the Characteristics of the Frictional Forces Consequent on the Motion.

Division III. The Determination Theoretically and by Experiment of the Frictional Resistance offered by Solid Surfaces to the Motion of Fluids over them, in all Cases in which the Resistance is determined by the Motion of the Fluid.

Division IV. The Frictional Resistances between Solid Surfaces separated, or Partially separated, by a Film of Fluid of such a Depth that the Fluid does not Conform to the Laws of Hydrodynamics.

Division V. The Frictional Resistance of Clean Solid Surfaces.

Division VI. The Relation between Friction and Heat Transmission.

I. INTERNAL FRICTION, OR VISCOSITY

§ (1) VISCOUS FLUIDS.—In distinguishing between solids and fluids it is customary to define a fluid as a substance which is incapable of sustaining tangential or shearing stress. This definition, however, is only true in the case of actual fluids when they are at rest. When relative motion exists between neighbouring portions of the same fluid, a measurable resistance to the relative motion can be observed and affords a proof that actual fluids are capable of sustaining shearing stresses; the fluid is said to exhibit the property of viscosity or internal friction. It would appear probable, therefore, that some definite relation exists between this shearing stress in fluids and the rate of distortion of the fluids of which it is the characteristic feature. It was assumed by Newton that, for a fluid moving in parallel layers, the shearing stress at any point at which the velocity gradient in a direction perpendicular to the layers was dv/dy, would be simply proportional to the value of the gradient, *i.e.* that the relation between internal friction and the relative motion would be given by

$$f=\mu\frac{dv}{dy},$$

where μ, called the coefficient of viscosity, is a fundamental characteristic of the fluid.

The definition given by Maxwell is as follows:

The coefficient of viscosity of a substance is measured by the tangential force on unit area of either of two horizontal planes at unit distance apart, one of which is fixed while the other moves with the unit of velocity, the space between being filled with the viscous substance.

The interpretation of the coefficient of viscosity of a fluid, according to the kinetic theory of matter, is as follows:

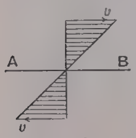

FIG. 1.

Let AB (*Fig.* 1) represent the trace of a plane in the fluid, parallel to the direction of motion, and let there be a definite gradient of velocity at right angles to AB as indicated by the lines parallel to AB representing the magnitude of the velocity of the layers relative to the velocity of AB, so that the molecules immediately above AB are moving faster than those below it. Some of these molecules will cross AB from the upper to the lower side and an equal number will pass upwards to replace them. Thus the layer immediately above AB is continually losing momentum and that below is continually gaining it. The effect is to bring into existence a definite shearing stress on the plane AB which constitutes the viscous drag. The internal friction of fluids consists therefore of a transfer of motion from one layer to the other, but this transfer does not proceed without loss of energy, since the translatory motion of the layers is transformed into heat. This is evident from the consideration that heat motion differs from translatory motion only in the fact that in the former case particles are moving in all possible directions and in the latter in one and the same direction and that a change from uni-directional motion to multi-directional motion cannot fail to take place in a medium which consists of particles which exert actions on each other by the forces of cohesion or collisions.

§ (2) VISCOSITY OF GASES.—In the case of gases in which the molecules are supposed to be outside the sphere of each other's attraction during the greater part of the time considered it is possible by means of the dynamical theory to obtain the value of the coefficient of viscosity in terms of the characteristics of the gas.[1]

We picture the gas as composed of a very large number of molecules, moving with varying velocities in all directions and influencing each other by their collisions. Let us consider a group consisting of N molecules contained in a unit of volume in the form of a cube; then we may suppose, with Joule, that the average velocity at right angles to each face of the cubes is the same, so that if V be the mean resultant velocity and u, v, w the components we have $V^2=u^2+v^2+w^2=3u^2$, for u, v, w are equal.

Thus we may regard the gas as consisting of three groups each containing N molecules and moving with equal velocities $V/\sqrt{3}$ in the three directions at right angles, or as three groups, each containing N/3 molecules, moving with velocity V in each of the three directions in question. In either case the energy of agitation will be the same.

Adopting this latter view it is clear that considering the whole number of molecules N in unit volume of the gas, since one-third of this number will be in motion perpendicular to any two opposite faces of the unit cube containing them, and of these half are moving towards either face and half away from it, therefore the number which will be moving from the upper to the lower side of any one face will be one-sixth of the total. Further, considering all the molecules which pass through this face from the upper to the lower side in unit time, it is evident that these will be limited to the molecules whose distance from the face at the beginning of the time interval was less than the length of the path which they would travel in unit time. Hence all the molecules which cross the face from the upper to the lower side in unit time come from the prism whose base is the face and whose height is measured by the velocity V of the molecules, *i.e.* they all come from a prism of volume V. The number of molecules, therefore, which cross unit area in unit time in this direction is $\frac{1}{6}$NV. It must be remembered also that each of these molecules has only been moving in a direction perpendicular to the face of the unit cube, since its last collision, and that therefore it will only form one of the group during the time which elapses from one collision to another, *i.e.* over the distance known as the molecular free path L, the average distance travelled by a molecule between two collisions.

Now assuming the existence of a velocity gradient perpendicular to the face of the cube whose value is unity, *i.e.* that the velocity of flow at a distance "y" above the unit face is numerically equal to "y" so that according to our definition the friction over the face measures the coefficient of viscosity, we can calculate the friction between the two layers of gas separated by the unit face as follows: The number of particles which pass the face from one side to the other per unit of time is $\frac{1}{6}$NV. These have begun their path towards the face at different depths, but on the average they come from a distance from the face which is equal to the mean free path L, and have described this distance in the unit of time.

---

[1] Jeans, *Kinetic Theory of Gases.*

Their mean forward velocity is therefore given by $V=L$. Therefore each molecule carries with it over the face the momentum mL, where m is its mass, and the total momentum carried over in unit time is $\frac{1}{6}NVmL$.

Simultaneously there pass in the opposite direction across the face $\frac{1}{6}$ NV molecules, each of which comes from an average distance from the face of $-L$ and whose mean forward velocity is given by $V=-L$. The total momentum carried over in this direction is therefore $-\frac{1}{6}NVmL$.

Therefore the layer above the unit face loses in unit time the momentum

$$\tfrac{1}{6}NVmL-(-\tfrac{1}{6}NVmL)$$
$$=\tfrac{1}{3}NVmL,$$

and this, by hypothesis, is the amount of the friction exerted on the face, and is the expression for the coefficient of viscosity. Since Nm is the density (ρ) of the gas we may write

$$\mu=\tfrac{1}{3}\rho VL.$$

If, instead of making the assumption that all the molecules have equal speeds, we assume Maxwell's law for their distribution, it can be shown that a more accurate value of the coefficient of viscosity is given by

$$\mu=0{\cdot}30967\rho\bar{V}L,$$

where $\bar{V}$ is the mean value of the speed derived from Maxwell's law. (See Meyer's *Kinetic Theory of Gases*, Appendix iv. p. 451.)

Substituting in these equations the value obtained by Clausius for the mean free path

$$L=\frac{\frac{3}{4}\lambda^3}{\pi s^2},$$

where s is the radius of the sphere of action of the molecules and λ is the volume occupied by a single molecule, we have

$$\mu=\frac{N\lambda^3 mV}{4\pi s^2},$$

and since $N\lambda^3=1, \quad \mu=\dfrac{mV}{4\pi s^2}.$

In this expression for μ there is no factor which depends on the pressure of the gas, a deduction from the theory which led Maxwell to predict that the viscosity of a gas would be independent of its density, and thus that the oscillations of a pendulum in a gas would be equally damped by gaseous friction, however low the pressure might be.

This conclusion was so much opposed to the general opinion of physicists at the time that the experimental verification of Maxwell's prediction, which took place soon afterwards, was perhaps the most important factor in the acceptance by physicists of the kinetic theory. It has been found, however, that when the pressure of a gas is reduced to extremely small values, the viscosity no longer remains constant. This lower limit has been found by Kundt and Warburg to be in the neighbourhood of one-sixtieth of an atmosphere. As would be expected, there is also an upper pressure limit at which the law no longer holds, since at high pressures the general assumptions of the theory are not approximately correct.

A further deduction from the kinetic theory as originally developed by Maxwell and Clausius was that the viscosity was proportional to the square root of the absolute temperature of the gas. Experimental investigation, however, failed to establish this relation, and it was found that the actual law of variation of μ with T was given by $\mu\propto T^n$ where n ranged from its lowest value of about ·7 for hydrogen to about 1·0 for the less perfect gases. On the assumption that n was equal to unity for all gases Maxwell deduced that the molecules must repel each other with a force inversely proportional to the fifth power of the distance between them. This hypothesis, however, had to be abandoned when it became certain that n was a variable quantity. By a re-examination of the fundamental assumptions on which the kinetic theory was based Sutherland was led to the conclusion that, although the attraction between two molecules of a gas is negligible at their average distance apart, yet, when two molecules are passing quite close to each other the force of attraction can bring about a collision which in its absence would not have taken place.

On this hypothesis Sutherland[1] has deduced from the equation of the orbit of a molecule that the effect of the molecular attraction in producing collisions is to diminish the mean free path L in the ratio: $(1+c/T)$, where c is a constant for the gas. It follows therefore, from the expression $\mu=\frac{1}{3}\rho GL$, that since G varies as $\sqrt{T}$ and L varies inversely as $(1+c/T)$, the value of μ will vary as

$$\frac{\sqrt{T}}{1+c/T}.$$

In an experimental investigation into the viscosity of air (see § (5)), it was found by Grindley and Gibson that this relation held with considerable accuracy between temperatures of 0 and 100°, the maximum deviation of the experimental results from the above law being 1·3 per cent.

§ (3)· **The Experimental Determination of the Values of Coefficients of Viscosity for Fluids.** (i.) *Equations of Motion.*—As the majority of the methods used to measure viscosity depend on a relation between the motion of the fluid and the variations of its pressure from point to point, a brief account of the derivation of the equations of motion of a viscous fluid is here given.

Assuming the truth of the Newtonian hypothesis, the equations of motion of the fluid can be obtained as follows: If we imagine three planes to be drawn through any point P in the fluid perpendicular to the axes of x, y, and z respectively, the three components of the stress per unit area exerted across the first of these planes may be denoted by p_{xx}, p_{xy}, p_{xz} respectively; those of the stress across the plane perpendicular to y by p_{yx}, p_{yy}, p_{yz}; and those of the stress across the plane perpendicular to z by p_{zx}, p_{zy}, p_{zz}.

It follows at once that, considering an

---

[1] "Viscosity of Gases," *Phil. Mag.*, Dec. 1893.

element $\delta x \delta y \delta z$ having its centre at P, and taking moments,

$$p_{yz}=p_{zy},\ p_{zx}=p_{xz},\ p_{xy}=p_{yx}.$$

Also, if p_1, p_2, p_3 be the principal stresses at P, it can be shown (*a*) that[1]

$$p_{xx}+p_{yy}+p_{zz}=p_1+p_2+p_3\,; \qquad . \quad (1)$$

i.e. the arithmetic mean of the normal pressures on any three mutually perpendicular planes through the point P is the same and equal to p (say); and (*b*) that the values of the stresses in terms of p, the coefficient of viscosity μ, and the rates of distortion are given by the expressions

$$\left.\begin{aligned}
p_{xx}&=-p-\tfrac{2}{3}\mu\left(\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}+\frac{\partial w}{\partial z}\right)+2\mu\frac{\partial u}{\partial x}\\
p_{yy}&=-p-\tfrac{2}{3}\mu\left(\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}+\frac{\partial w}{\partial z}\right)+2\mu\frac{\partial v}{\partial y}\\
p_{zz}&=-p-\tfrac{2}{3}\mu\left(\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}+\frac{\partial w}{\partial z}\right)+2\mu\frac{\partial w}{\partial z}\\
p_{yz}&=p_{zy}=\mu\left(\frac{\partial w}{\partial y}+\frac{\partial v}{\partial z}\right)\\
p_{zx}&=p_{xz}=\mu\left(\frac{\partial u}{\partial z}+\frac{\partial w}{\partial x}\right)\\
p_{xy}&=p_{yx}=\mu\left(\frac{\partial v}{\partial x}+\frac{\partial u}{\partial y}\right)
\end{aligned}\right\} . \quad (2)$$

The condition for "laminar motion"—motion, that is, in which the fluid moves in a system of parallel planes, the velocity being in direction everywhere the same, and in magnitude proportional to the distance from some fixed plane of the system—is seen to be

$$u=ay, \quad v=0, \quad w=0,$$

from which it follows that the axis of x being taken in the direction of motion and the velocity being proportional to the distance from the plane zx

$$p_{xx}=p_{yy}=p_{zz}=-p, \quad p_{yz}=0, \quad p_{zx}=0, \quad p_{xy}=\mu a,$$

"a" being the rate of distortion.

The stresses in different fluids under similar conditions of motion will be proportional to the corresponding values of μ, but if we wish to compare their effects in modifying the existing motion we have to take account of the ratio of these stresses to the inertia of the fluid. From this point of view the determining quantity is the ratio μ/ρ, which is denoted by the special symbol ν, called by Maxwell the "kinematic" coefficient of viscosity. The equations of motion are obtained by considering the forces acting on a rectangular element having its centre at P. Thus resolving parallel to x, the difference of the normal pressures is $(\partial p_{xx}/\partial x)\delta x\delta y\delta z$. The tangential tractions on the zx faces amount to $(\partial p_{yz}/\partial y)\delta y\delta x\delta z$, and those on the xy faces are $(\partial p_{zx}/\partial z)\delta z\delta x\delta y$. If therefore X, Y, and Z are the components of the external forces per unit mass, we have

$$\left.\begin{aligned}
\rho\frac{\mathrm{D}u}{\mathrm{D}t}&=\rho\mathrm{X}+\frac{\partial p_{xx}}{\partial x}+\frac{\partial p_{yx}}{\partial y}+\frac{\partial p_{zx}}{\partial z}\\
\rho\frac{\mathrm{D}v}{\mathrm{D}t}&=\rho\mathrm{Y}+\frac{\partial p_{xy}}{\partial x}+\frac{\partial p_{yy}}{\partial y}+\frac{\partial p_{zy}}{\partial z}\\
\frac{\rho\mathrm{D}w}{\mathrm{D}t}&=\rho\mathrm{Z}+\frac{\partial p_{xz}}{\partial x}+\frac{\partial p_{yz}}{\partial y}+\frac{\partial p_{zz}}{\partial z}
\end{aligned}\right\}, \quad . \quad (3)$$

where $\mathrm{D}/\mathrm{D}t$ denotes a differentiation following the motion of the fluid, *i.e.*

$$\frac{\mathrm{D}}{\mathrm{D}t}=\frac{\partial}{\partial t}+u\frac{\partial}{\partial x}+v\frac{\partial}{\partial y}+w\frac{\partial}{\partial z}.$$

Substituting the values of p_{xx}, etc., given above, we have

$$\rho\frac{\mathrm{D}u}{\mathrm{D}t}=\rho\mathrm{X}-\frac{\partial p}{\partial x}+\tfrac{1}{3}\mu\frac{\partial\theta}{\partial x}+\mu\nabla^2 u, \quad . \quad (4)$$

etc. .

where $$\theta=\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}+\frac{\partial w}{\partial z}$$

and $$\nabla^2=\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}+\frac{\partial^2}{\partial z^2}.$$

When the fluid is incompressible, these reduce to

$$\left.\begin{aligned}
\rho\frac{\mathrm{D}u}{\mathrm{D}t}&=\rho\mathrm{X}-\frac{\partial p}{\partial x}+\mu\nabla^2 u\\
\rho\frac{\mathrm{D}v}{\mathrm{D}t}&=\rho\mathrm{Y}-\frac{\partial p}{\partial y}+\mu\nabla^2 v\\
\rho\frac{\mathrm{D}w}{\mathrm{D}t}&=\rho\mathrm{Z}-\frac{\partial p}{\partial z}+\mu\nabla^2 w
\end{aligned}\right\}. \quad . \quad . \quad (5)$$

(ii.) *Flow through a Circular Pipe.*—As an example of the applications of these equations we may take the important case of the steady flow of a liquid through a pipe of uniform circular section.

Taking the axis of z to be coincident with the axis of the pipe, and assuming that the velocity is everywhere parallel to z, and dependent solely on the distance from the axis, we have $w=0$, $v=0$, and therefore from (5)

$$\frac{\partial p}{\partial x}=0, \quad \frac{\partial p}{\partial y}=0, \quad . \quad . \quad . \quad (1)$$

i.e. the mean pressure is uniform over each section of the pipe. Again, from (5) we have

$$\frac{\partial p}{\partial z}=\mu\left(\frac{\partial^2 w}{\partial x^2}+\frac{\partial^2 w}{\partial z^2}\right), \quad . \quad . \quad (2)$$

where p is a function of z. Transforming into polar co-ordinates r and θ

$$\frac{\partial p}{\partial z}=\mu\left\{\frac{\partial^2 w}{\partial r^2}+\frac{1}{r}\frac{\partial w}{\partial r}+\frac{1}{r^2}\frac{\partial^2 w}{\partial\theta^2}\right\}, \quad . \quad (3)$$

and, since by symmetry w is independent of θ, the last term on the right-hand side vanishes.

---

[1] Lamb's *Hydrodynamics* (1916 ed.), p. 569. See also "Elasticity, Theory of," § (6).

Hence the equation may be written

$$\frac{\partial}{\partial r}\left(r\frac{\partial w}{\partial z}\right)=\frac{1}{\mu}\frac{\partial p}{\partial z}r \quad . \quad . \quad . \quad (4)$$

or integrating

$$w=\frac{1}{4\mu}\cdot\frac{\partial p}{\partial z}+\mathrm{A}\log r+\mathrm{B}. \quad . \quad . \quad (5)$$

Since the velocity must be finite at the axis A=0 and, if B be determined on the assumption that $w=0$ at the boundary, *i.e.* there is no slipping at the wall of the pipe ($r=a$ say), we have

$$w=\frac{(a^2-r^2)}{4\mu}\cdot\frac{\partial p}{\partial z}. \quad . \quad . \quad . \quad (6)$$

The flow across any section is therefore

$$\int_0^a w\,.\,2\pi r\partial r=\frac{\pi a^4}{8\mu}\cdot\frac{\partial p}{\partial z}. \quad . \quad . \quad (7)$$

Thus if V be the volume passing in time T so that the flow is V/T, we have

$$\mathrm{V}=\mathrm{T}\frac{\pi a^4}{8\mu}\frac{dp}{dz}.$$

If the fall of pressure along a length l of the tube is uniform and equal to p_1-p_2, this equation may be written

$$\mathrm{V}=\mathrm{T}\frac{\pi a^4}{8\mu}\frac{p_1-p_2}{l}.$$

If, on the other hand, the possibility of a slip at the boundary is not excluded, the most natural assumption to make is that the slipping is resisted by a tangential force proportional to the relative velocity,[1] *i.e.* the boundary condition would be

$$-\mu\frac{\partial w}{\partial r}=\beta w,$$

where β is a slipping coefficient, or

$$w=-\lambda\frac{\partial w}{\partial r}, \quad \text{if } \lambda=\frac{\mu}{\beta}.$$

This determines B in equation above, so that

$$w=\frac{\partial p}{\partial z}\left(\frac{a^2-r^2+2\lambda a}{4\mu}\right).$$

If λ/a is small, this gives sensibly the same law of velocity as in a tube of radius $a+\lambda$ on the hypothesis of no slipping. The corresponding value of the flow is

$$\frac{\pi a^4}{8\mu}\left(1+4\frac{\lambda}{a}\right)\frac{\partial p}{\partial z}.$$

§ (4) EFFECT OF TURBULENCE.—It is clear that any experimental verification of the truth of the law of resistance postulated by Newton will depend upon whether in the relation

$$f=\mu\frac{dv}{dy}$$

a value of μ for any given fluid can be found which has an identical value for all values of the velocity gradient dv/dy. It will be seen later that in those cases of fluid motion in which the motion is turbulent or eddying, the ratio of the shearing stress in the fluid parallel to the mean direction of the flow to the mean velocity gradient perpendicular to this direction is not an absolute constant for the fluid, but depends on the actual values of the velocity of flow and the distribution of the solid boundaries of the flow. In these cases the Newtonian hypothesis breaks down, but its truth under circumstances of streamline flow defined by the condition that the velocity of the fluid at any fixed point is always constant in magnitude and direction has been fully demonstrated. Under these conditions of motion the coefficient μ has been shown to be a physical property of the fluid and is known as the absolute coefficient of viscosity.

§ (5) RESULTS OF EXPERIMENTS. (i.) *Gases.*—Most of the earlier determinations on gases were carried out by the method of noting the damping of the oscillations of a disc in the gas, as in the case of Maxwell's classical experiments.[2] In this method, however, there are considerable mathematical difficulties in determining the motion of the air at the edge of the disc, and in recent work on the subject the method of observing the fall of pressure of the fluid when flowing at a known speed through a channel with parallel walls has been used. An example of this method is seen in the work of Grindley and Gibson on the viscosity of air.[3] The apparatus used consisted of two gas-holders of about 3 cubic feet capacity connected by a length of lead tubing of 0·125 inch diameter, of which part was used as the experimental tube. The ends of the experimental portion are connected to a manometer by which the fall of pressure can be measured. In commencing an experiment one of the gas-holders contains air and the other water, and by admitting water under pressure to the lower part of the gas-holder containing air, the air is forced through the tube at the desired rate. The gas-holders were calibrated so that the volume of air passing through the tube in a given time could be determined. The length of the tube between the vessels, which was about 190 feet, was wound on a central brass cylinder on a helix of $\frac{5}{32}$ pitch and 1 ft. diameter. The cylinder rested on supports in a vessel filled with water and provided with devices for maintaining the temperature at any desired value between 0° C. and 100° C. The experimental part of the tube was about 108 feet long.

By inserting the known values of the flow and value of the pressure gradient in equation (6), § (3), the value of μ was deduced. It was found that in accordance with the results of previous investigators the value of μ was independent of the pressure, and, further, that its variation with temperature closely approximated to the law deduced by Sutherland from theoretical considerations, so that the value could be written

[1] Lamb's *Hydrodynamics* (1916 edition), p. 572.

[2] *Phil. Trans. Roy. Soc.* clvi.

[3] *Proc. Roy. Soc.* A, lxxx. 114.

$$\mu = \frac{K\sqrt{T}}{1 + c/T},$$

where T is the absolute temperature, and, for the case of air,

$$K = 141{\cdot}8 \times 10^{-7},$$
$$c = 102{\cdot}5.$$

For comparison with the results of other observers which are expressed in the form $\mu = a(1 + bt + ct^2)$, the values of the constants a, b, and c for air were found to be $a = 170{\cdot}2 \times 10^{-6}$, $b = 0{\cdot}00329$, $c = 0{\cdot}000007$.

(ii.) *Liquids.*—In forming a physical conception of the viscosity of liquids it is of interest following Maxwell,[1] to regard the phenomenon, not as an example of the diffusion of matter, but as a limiting case of an elastic solid when the material breaks down under shear. Thus in the case of an elastic solid the shearing stress on any plane is proportional to the space rate of displacement of the material parallel to the plane. The viscous drag is therefore related to the velocity in precisely the same way as the elastic shearing stress to the displacement. We may, therefore, look upon a viscous liquid as capable of exerting a certain amount of shearing stress for a short time and then breaking down and the shear recommencing. If we suppose that the rate at which the shearing stress breaks down is proportional to the shear and is equal to $\lambda\theta$, where θ is the shear given by $\theta = dx/dy$, x being the horizontal displacement, the rate at which shear is supplied is $d\theta/dt$, or $d/dy \,.\, dx/dt$, *i.e.* $d/dy \,.\, v$, where v is the velocity of displacement. We have therefore $\lambda\theta = dv/dy$, and since the shearing stress is given by $f = n\theta$ we have $f = n/\lambda \,.\, dv/dx$, or $n/\lambda = \mu$. The quantity $1/\lambda$ is called the time of relaxation of the liquid and measures the time taken by the shear to disappear when no fresh shear is supplied.

§ (6) EARLY EXPERIMENTS. (i.) *Poiseuille's Method.*—The earliest experimenter on the viscosity of liquids was Poiseuille, who carried out a very extensive series of observations on the flow of water through capillary tubes.[2] In these experiments the outlet end of the capillary tube was connected to a reservoir of water, the pressure in which could be regulated to any desired value by means of an air-pump, connected to the upper cover of the reservoir. Provision was also made for regulating the temperature of the water to any desired value. It was, therefore possible, by using capillary tubes of varying bore and length, to obtain a relation between the rate of discharge, the dimensions of the tubes, and the pressure and temperature of the water. The relation as given by Poiseuille was

$$Q = 1836{\cdot}724(1 + 0{\cdot}0336T + 0{\cdot}000221T^2)\frac{PD^4}{L},$$

where Q is the discharge in milligrammes of water per second, P is the pressure difference between the ends of the capillary tube in millimetres of mercury, and D and L are the diameter and length of the tube in millimetres. It will be noticed that this relation agrees exactly with the results of the motion of a viscous fluid through a pipe of circular cross-section, on the assumption that the velocity at the boundary is zero, *i.e.* the time of efflux of a given volume of water is directly as the length of the tube inversely as the fourth power of the diameter and inversely as the difference of pressure at its ends. As an instance of the high order of accuracy obtained in these experiments it may be remarked that the value of μ for $T = 0$, calculated from the above expression, is in close agreement with the most modern determination. It has been pointed out by Lamb that, if any appreciable amount of slipping at the boundary of the pipes used by Poiseuille took place, a deviation from the law of the fourth power of the diameter would become apparent, and the fact that this was not the case excludes the possibility of such an amount of slipping as has been inferred by Helmholtz and Pietrowski from their experiments on the torsional oscillations of metal spheres filled with water. The question is very fully discussed by Whetham,[3] who concluded that no slipping took place.

(ii.) *Temperature Effect.*—It will be seen that the variation of viscosity with temperature is of the opposite sign from that of gases, and it appears to be a characteristic of all liquids that the viscosity diminishes as the temperature rises. In the case of water the change is fairly rapid, as will be seen from the following table, which gives the results of determinations by Hosking.

Temp.	0° C.	10	20	30	40	50	60	70
$\mu =$	·018	·013	·010	·008	·0066	·0055	·0047	·0040

This rate of variation is in very fair agreement with the temperature coefficient unit determined by Poiseuille and given in the formula above.

(iii.) *Corrections.*—The Poiseuille method, on account of the simplicity of the apparatus required and the ease with which the observations can be made, is still much used, but it should be observed that for accurate work two corrections to the results must be applied.

---

[1] "Dynamical Theory of Gases," *Phil. Trans. Royal Society*, clvii.

[2] *Comptes rendus*, 1840–41, tt. xi. xii.

[3] *Phil. Trans. R.S.* A, clxxxi. 559.

In the first place, the difference of pressure between still water on the inlet and outlet sides of the pipe is not an accurate measure of the pressure gradient along the pipe, since some of this pressure difference is required to communicate the kinetic energy of motion to the water. Further, in deriving the equation of flow (§ (3)), it is assumed that the velocity distribution across the pipe has become uniform and that no accelerations parallel to the axis of the pipe are taking place. This condition is not fulfilled near the inlet end of the pipe, as an appreciable length of the pipe from the inlet in the direction of flow is required in which the accelerations die out and the velocity distribution becomes uniform. For these reasons instead of the use of the simple formula derived from equation (7), § (3),

$$\mu = \frac{\pi a^4 \mathrm{T}}{8\mathrm{V}} \cdot \frac{p_1 - p_2}{l},$$

in which T is the time of efflux of the volume V of liquid, $(p_1 - p_2)$ the pressure difference between the inlet and outlet ends of the pipe, and l the length of the pipe, the following formula, in which the corrections explained above are inserted, should be used:

$$\mu = \frac{\pi a^4 \mathrm{T}(p_1 - p_2)}{8\mathrm{V}(l + na)} + \frac{m\rho \mathrm{V}}{8\pi \mathrm{T}(l + na)},$$

where ρ is the density of the liquid under test and n and m are constants. The value of n may be taken as 1·64 in all cases, and provided that the value of the second term in equation is small compared with that of the first, m may be assumed equal to unity. Where high accuracy is required it is necessary that the value of m should be obtained experimentally by a series of viscosity determinations with different rates of flow.

§ (7) MODERN INVESTIGATIONS.—In recent work, however, it has been found that no great difficulty is experienced in making an accurate measure of the pressure gradient along the pipe at a sufficient distance from the inlet, provided that the pipe is made of some substance which can be easily machined. In this method two fine holes are drilled in the walls of the pipe at a known distance apart along the axis, great care being taken to prevent a "burr" being formed in the inner surface of the pipe where the hole passes through the wall. Suitable nipples are screwed into the holes at the outer surface and flexible pipe connections made, one to each side of a sensitive manometer. In this way when the flow is set up an accurate measure of the fall of static pressure of the fluid between the holes is obtained. As it is known that the static pressure is constant across any section of the pipe, the intensity of the surface friction is easily calculated from the formula $\mathrm{R} = pa/2l$, where p is the pressure difference per unit area indicated by the manometer and l is the distance between the holes and a the radius.[1] This method has recently been used at the National Physical Laboratory for the determination of the resistance to flow of thick oils in pipes. As the method of obtaining the pressure gradient in the pipes in these experiments is novel, a brief description of it is given.

The manometer used was one of the Chattock type, the principle of which is that the pressure difference at the two ends of a U-tube is balanced by tilting the tube through a small measured angle so that the "head" due to the difference of level of the fluid in the two vertical arms of the U-tube balances the external pressure difference, and no movement of the fluid through the tube takes place. For the latter purpose a telescope is fixed to the tilting-table, the level of which is always adjusted so that the line of collimation passes through the surface of the manometer fluid, say water or mercury. It is, however, essential for the elimination of unknown forces due to capillarity that the ends of the manometer tube where the surface of the fluid is situated should be cup-shaped as shown in *Fig.* 2, and as the detection of the movement of such a large surface is a matter of some difficulty, the device is adopted of introducing a second liquid, usually oil, which will not mix with the water or mercury, into the horizontal limb of the gauge, and the hair-line of the telescope is focussed on to the meniscus formed by the common surface of the two liquids. This is the usual device adopted for measuring pressure differences due to the flow of gases through pipes when the static pressure of the gas is small. For measuring the pressure drop in pipes conveying liquids and when the static pressure of the liquid is high, the type of manometer illustrated in *Fig.* 2 is more convenient. This consists of a U-tube filled with mercury up to the centre of the lower cups, the space above the mercury being filled with salt water. In order to obtain a sharply defined surface of high sensitivity as an indicator of the movement of the mercury, the right-hand cup is contracted to a small section and a second cup attached to it as shown. The upper end of this second cup is connected to a reservoir containing a transparent oil which will not mix with the salt water. A side connection to the upper cup is connected with the experimental pipe. The gauge is filled so that the separating surface of the oil and water form a meniscus at the extremity of the contracted part of the lower cup, and on this the hair-line of the telescope is focussed. The auxiliary glass-bulb fittings at the sides are introduced for convenience in filling the gauge and making sure that no bubbles of air are left in any part of the connections, and in order to obtain a short-circuiting device by means of which the zero of the gauge can be read off without stopping the flow of liquid in the pipe. For the latter observation the two taps in the experimental pipe connections are shut and the tap in the short connecting pipe opened. By this apparatus the frictional resistance to flow was obtained in the case of thick oils of viscosity ranging up to $20\cdot0 \times 10^{-3}$ in absolute C.G.S. units.

[1] Clearly $\mathrm{R} \times 2\pi a l$ = total frictional force = difference of thrust $= p\pi a^2$.

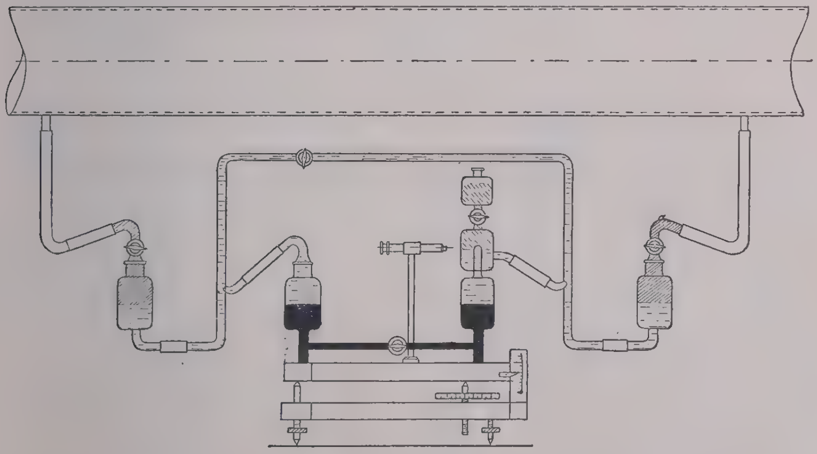

FIG. 2.

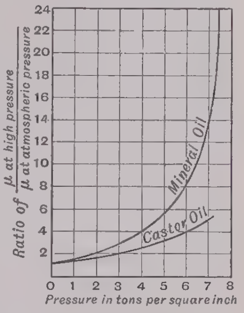

FIG. 3.

§ (8) THE EFFECT OF PRESSURE ON THE VISCOSITY OF LIQUIDS.—In the case of liquids of relatively low viscosity the variation in the value of the coefficient of viscosity with change of pressure is not very marked. The viscosity of water diminishes slightly for pressures of a few atmospheres, and that of benzol and ether increases. Recent researches on the changes of viscosity of certain liquids when the pressure is carried to values as high as 1000 atmospheres have, however, shown enormous increases in viscosity due to high pressures. Thus in the cases of alcohol, carbon bisulphide and ethyl alcohol, Professor O. Faust of Göttingen has found the viscosity of these liquids at pressures of 3000 atmospheres to be more than treble the value at atmospheric pressure. In a recent research carried out at the National Physical Laboratory by Mr. J. H. Hyde,[1] the viscosities of mineral oils at a pressure of 1100 atmospheres were found to have a value exceeding 10 times the value at atmospheric pressure, whereas in the case of a vegetable oil such as rape, the ratio was not higher than 4 to 1. The remarkable character of the rate of rise of viscosity with pressure at the higher pressures will be seen from the curves in *Fig.* 3, which illustrate the results obtained for castor oil and a mineral oil. As this investigation has an important bearing on the constitution of liquids, a short description of the method used at the National Physical Laboratory for measurements of the coefficient of viscosity at high pressures is here given. The apparatus used for these experiments was designed for carrying out the tests by a method suggested by Dr. T. E. Stanton, and a diagrammatic sketch is shown in *Fig.* 4. The instrument consists of a U-tube, the limbs A and B of which are connected together at their lower ends by a large bore tube and at their upper ends by a capillary tube C as shown. The whole is mounted on a frame supported by a knife-edge D, and so arranged that the left-hand side is heavier than the right. The lower half of the circuit is filled with mercury and the upper half with the liquid under experiment. The motion of the frame is governed by the extension of a spring S, to which it is connected through the supporting arm F terminating in a pointer which moves over a finely divided scale. In making an experiment, the tilting frame is set in such a position that the horizontal tubes are level and the scale is adjusted so that the pointer is at zero. A tilt is given to the frame by moving the pointer vertically upwards, the taps T and P being open. The tilt causes a flow in the U-tube, and when this flow has ceased the taps are closed and the frame restored to its original position with the pointer at zero, the tension of the spring being adjusted to support the frame in this position. The head of mercury in the circuit tending to cause flow round it can be calculated from the motion which has been given to the pointer and from the distances DR and AB. If now the tap T be opened, the liquid will flow through the capillary tube from A to B and the mercury from B to A. The spring is so designed that the displacement of the frame due to the flow of mercury from one vertical limb to the other is such that the head of mercury producing the flow remains constant, and it is clear that the fall of the frame as indicated by the movement of the pointer over the scale gives a measure of the volume of liquid which passes from one side to the other. In this way the whole of the data required for the calculation of the coefficient of viscosity are available when the dimensions of the capillary tube are accurately known, and the value of μ is obtained from the formula (see § (3))

---

[1] *Proc. Roy. Soc.* A, xcvii.

$$\mu = \frac{\pi \rho h a^4 T}{8 V l},$$

where ρ is the density of the liquid, h the head of liquid, a the radius of the capillary tube, T the time in passing the volume of liquid V through the tube, and l the length of the tube.

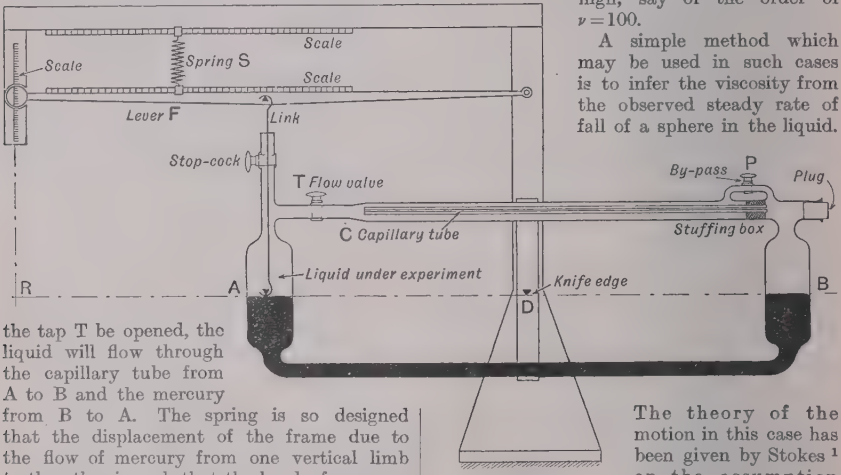

FIG. 4.

It will be seen that the above formula requires a knowledge of the variation in the density of the liquid with pressure before the value of the coefficient of viscosity can be obtained. In the paper by Mr. J. H. Hyde referred to, a simple method is described by means of which the densities of liquids can be obtained up to pressures of 1500 atmospheres. It may be remarked that the construction of the high-pressure viscosity apparatus presented considerable practical difficulty when the pressures used were of the order of 1000 atmospheres, necessitating the use of high-tensile steel for the parts subjected to pressure. For details of these and further numerical data the original paper may be consulted.

§ (9) LIQUIDS OF HIGH VISCOSITY.—The method described above for the estimation of the viscosity of fluids, by observing the known gradient of pressure and the rate of flow of the fluid through a pipe of known dimensions, has obvious practical limitations when the viscosity of the fluid is very high, say of the order of $\nu = 100$.

A simple method which may be used in such cases is to infer the viscosity from the observed steady rate of fall of a sphere in the liquid.

The theory of the motion in this case has been given by Stokes[1] on the assumption that the inertia terms in the equations (5) may be neglected, i.e. that

$$\frac{\partial u}{\partial t} = -\frac{1}{\rho} \cdot \frac{\partial p}{\partial x} + \nu \cdot \nabla^2 u, \text{ etc.}$$

On this assumption the external force acting on the sphere is given by

$$P = 6\pi\mu a U,$$

where a is the radius of the sphere and U the velocity of fall. It has been pointed out by Lord Rayleigh that the assumption on which this solution is based limits the velocity of fall to extremely low values, since the relation will not hold with fair accuracy unless Ua is small compared with ν. The motion at higher speeds than this has been investigated by Williams.[2]

Another method which may be employed for liquids of high viscosity is the oscillating disc method first used by Maxwell. This appears to be well suited for the difficult but practically important case of molten glass.

§ (10) The Viscosity of Solids.—As pointed out in the introduction to this article, the frictional resistance which one part of a solid body offers to the sliding of the other part over it is made up of two distinct phenomena: (1) the elastic distortion of the substance in which the work done is stored up as potential energy in the molecules of the body, and (2) the viscous distortion, the energy of which is converted into heat. It has been remarked by Lord Kelvin[1] that this distinction is not rigidly correct, since even in the absolutely perfect elasticity of volume presented by homogeneous crystals dissipation of energy is an evitable result of every change of volume, because of the accompanying change of temperature and consequent dissipation of heat by conduction and radiation. It is, however, recognised that the loss of energy due to this cause is small compared with the whole loss of energy which occurs in many cases of the vibration of metals, so that the statement above may be taken as sufficiently accurate for most purposes. The usual method of studying the phenomena of the viscosity of metals is by noting the rate of damping of the torsional oscillations of long rods carrying a heavy mass at one end and fixed at the other end. The damping of the oscillations is said to be more rapid in glass than in most of the elastic metals such as copper, iron, silver, aluminium, but on the other hand the damping in the case of zinc and india-rubber is more rapid than in glass. In the experiments described by Lord Kelvin in the paper referred to, it was found, as would be expected, that the loss of energy in a vibration was greater the greater the velocity, but that the variation with speed was not nearly proportional to the velocity of deformation as in the case of fluids. It would appear, therefore, that the damping is not altogether the effect of viscous resistances of the ordinary type which are proportional to the rates of strain.

§ (11) The Internal Friction of Fluids in Turbulent Motion. (i.) *Eddying Motion.*—Before entering upon a discussion of the characteristics of the internal friction of fluids when the general motion is eddying or turbulent, a brief description of the methods of velocity estimation under these conditions is desirable for the reason that a measurement of the mean rate of flow of the fluid through any fixed element of surface taken over an appreciable time is a matter of fundamental importance in the practical determination of the frictional resistance. Since by definition a fluid in turbulent motion consists of a mass of eddies, it might be supposed that any determination of the kind under consideration would be meaningless as defining any physical condition of the fluid, and this is probably true in such cases as those in which eddies, relatively large in size and slow in period, are thrown off from the projecting edges of bodies immersed in fluids moving relatively to them. It has been found, however, that in the majority of cases of fluid motion in which turbulence is known to exist either from the fact that the critical speed[2] has been exceeded, or from the observations on the resistance to flow being greatly in excess of those due to streamline motion, the eddies are apparently of such small dimensions and of such high periodicity that any appreciable variation of the forces produced on an immersed body by the turbulent motion of the fluid over it cannot be detected by ordinary methods. For example, if in a parallel channel through which air is in motion above the critical speed, a small open-mouthed tube be placed with its axis parallel to the axis of the channel and its other end connected to a sensitive manometer as shown in *Fig.* 5, it will be observed that if sufficient precautions are taken to eliminate external disturbances and irregularities of the mechanism causing the flow, the reading of the manometer remains perfectly steady. Further, if the pressure in the tube be accurately measured it will be found that its value exceeds that of the fluid itself by the quantity $\frac{1}{2}\rho v^2$, where ρ is the density of the fluid and v is the mean speed of the fluid which would exist over the area occupied by the mouth of the tube if it were removed. The pressure of the fluid itself is usually called the static pressure, and in the case of a fluid in motion, either streamlike or turbulent in character, the static pressure at any point is the pressure at the boundary of any smooth solid surface containing the point and parallel to the direction of flow at that point. It is evident that the above relation between the dynamical pressure at the mouth of the tube and the static pressure affords a convenient method of determining the value of the mean speed of a fluid at any point in it.

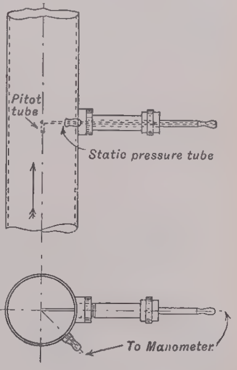

Fig. 5.

(ii.) *The Pitot Tube.*—In the case of the parallel channel, since it is known that the pressure is independent of the radius (see § (3)), all that is necessary is to measure the difference in pressure between the open-mouthed tube facing the current, commonly called a Pitot tube, and that at a hole in the walls of the channel at the same cross-section, and equating this to $\frac{1}{2}\rho v^2$, the velocity can be calculated. In this way the velocity distribution over the cross-section of a parallel channel may be determined and the total flow calculated by graphical methods. Comparison of the total flow so estimated and that given by a discharge meter at the outlet of the channel has shown that the method can be relied upon to a high degree of accuracy. For cases in which the flow does not take place in a channel with parallel walls, it is necessary, for the purpose of obtaining the static pressure, to introduce an artificial boundary as close to the mouth of the Pitot tube as possible. One method of doing this is shown in *Fig.* 6, which is an illustration of the standard instrument used for velocity measurement at the National Physical Laboratory. Careful experiments[1] with an instrument of this type moving in free air have shown that the velocity estimation obtained from it when the pressure differences are measured on a manometer of the Chattock type have a limit of accuracy of one-tenth of one per cent. In the use of the instrument it is, of course, necessary that the density of the fluid at the point considered should be known, and in the case of a compressible fluid where considerable differences of density exist this may involve another experimental determination of some difficulty.

---

[1] *Proc. R.S.*, 1865, xiv. 289.

[2] See § (71), (iii.).

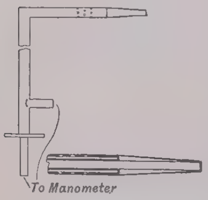

Fig. 6.

The original use of the Pitot tube seems to have been for the purpose of measuring the distribution of velocity in rivers and canals. In this form it consists simply of a glass tube bent through a right angle and held vertically in the current, the height of the column of water inside the tube above the surrounding surface being noted. By this means the use of a static pressure tube is avoided, but it is obvious that the velocity estimations must be of only an approximate nature.

(iii.) *The Critical Velocity.*—It was first shown by Osborne Reynolds that, when a fluid was in motion through a parallel channel, there existed a critical value of the mean speed of flow at which the character of the motion changed from one of steady streams parallel to the axis of the channel to one of turbulence in which the whole of the fluid was broken up into a mass of eddies. The causes of the change in the type of motion will be discussed in greater detail in the subsequent sections of this article, but for the present purpose it is sufficient to remark that the change was found to coincide with a change in the law of frictional resistance to flow through the channel, the streamline motion corresponding to a resistance varying as the first power of the speed, and the turbulent motion corresponding to a resistance varying nearly as the square of the speed. In the latter case, although the mean motion at any point when taken over a sufficient time is parallel to the sides of the channel, it is made up of a succession of motions crossing the channel in different directions. It is evident that in this case if we are to adhere to the definition of the coefficient of viscosity as the ratio of the shearing stress to the rate of distortion, *i.e.* that $f=\mu(dv/dy)$, and, further, if v is taken to express the mean motion taken over a sufficient time, then since f is known to vary as a power of the velocity greater than unity μ must be a function of the velocity and must be held to include the momentum per second parallel to the plane of shear, which is carried by the cross-streams through the plane.[2]

(iv.) *The Two Viscosities.*—If, however, we regard the above relation as expressing the instantaneous value of the intensity of the resistance at a point in the fluid, we must realise that dv/dy is the instantaneous value of the rate of distortion, a quantity which we have no means of measuring directly, and that then μ is independent of the motion and a physical property of the fluid. It appears therefore that, as pointed out by Osborne Reynolds, there are two essentially distinct viscosities in fluids. One is a physical property of the fluid and is a measure of the instantaneous resistance to distortion at a point moving with the fluid, and the other is a mechanical viscosity arising from the molar motion of the fluid and given by the relation $f=\mu'(dv/dy)$, where v is the mean motion at a point taken over a sufficient time, and μ' is a function of v and probably also of the distribution of the solid boundaries of the fluid.

That these characteristics are independent of each other, apart from the fact of the dependence of the existence of the mechanical viscosity on the physical viscosity, is shown by the striking fact that when the motion of a fluid is such that the resistance is as the square of the velocity, the magnitude of the resistance is independent of the character of the fluid in all respects, except that of its density.

---

[2] Reynolds, *Scientific Papers*, ii. 236.

§ (12) MEASUREMENT OF THE MECHANICAL VISCOSITY.—In a research carried out at the National Physical Laboratory in 1911,[1] the characteristics of the mechanical viscosity of a fluid as affected by the speed and the dimensions of the channel in which the flow took place were investigated. The fluid used was air, which was forced through cylindrical pipes at speeds above the critical, and the distribution of mean velocity was determined by means of a Pitot and static pressure-tube device of the kind described above. In order to simplify the investigation it was desirable that the resistance to flow should vary exactly as the square of the velocity of flow, in which case, as mentioned above, the motion would be entirely independent of the physical viscosity of the fluid. This condition was secured by a suitable roughening of the internal surface of the brass pipes used for the experiments.

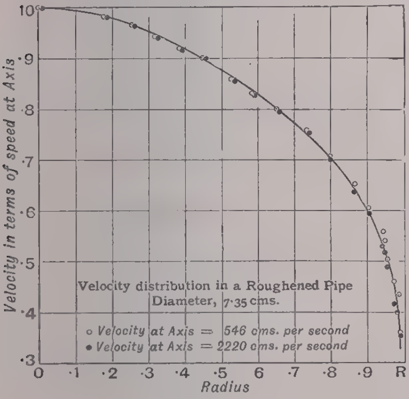

FIG. 7.

The distribution of mean axial speed across the section of the pipe was then measured, and a typical curve of distribution is shown in *Fig.* 7. It will be seen that the distribution of mean axial velocity in the case of the turbulent motion is approximately parabolic from the axis up to a comparatively short distance from the walls, *i.e.* the equation to this part of the velocity curve can be written

$$v = v_c - \mathrm{A}r^2, \quad . \quad . \quad . \quad (1)$$

where v_c is the velocity at the axis, r is the radius at which v is measured, and A is a constant.

It was also found that for any section of the pipe the static pressure of the fluid was constant for all values of the radius, so that for any cylinder of fluid of radius r between any two sections distant l apart the shearing stress on the outer surface would be given by

$$f 2\pi r l = (p_1 - p_2)\pi r^2$$

or

$$f = \frac{(p_1 - p_2)r}{2l}, \quad . \quad . \quad . \quad (2)$$

where $(p_1 - p_2)$ is the fall of static pressure between the two sections, and f the intensity of shearing stress. The shearing stress in the fluid is therefore proportional to the radius.

But from (1) it is seen that

$$\frac{dv}{dr} = -2\mathrm{A}r,$$

so that the relation $f = \mu'(dv/dr)$ becomes $(p_1 - p_2)/2l = -2\mu'\mathrm{A}$.

Hence μ', which is the mechanical viscosity, is constant across the pipe up to within a relatively small distance from the boundary.

The next step in the investigation was to determine the dependence of μ' on the rate of flow through the pipe. By taking a series of distributions of axial velocity at different rates of flow and plotting the values of v/v_c on a radius base, it was found that all the points lay on the same curve, indicating that in equation (1) $v/v_c = 1 - (\mathrm{A}/v_c) \, . \, r^2$ the value of A/v_c was constant, *i.e.* that A was proportional to the speed at the axis, and therefore that the value of dv/dr for any radius was simply proportional to the velocity of flow. It follows that, since the shearing stress is proportional to the square of the speed of flow, μ' must be proportional to the first power of the speed.

Finally, a series of experiments were made with the object of determining the effect of the dimensions of the channels on the mechanical viscosity. For this purpose two pipes of radii a_1, a_2 were prepared, in which the surface roughnesses were geometrically similar, so that the intensity of the surface frictions was exactly proportional to the squares of the speeds of flow. On determining the velocity distributions in these pipes, and plotting the values of v/v_c on a base of r/a, where "a" is the outside radius of the pipe, it was found that all the points fell on the same curve, whose equation was

$$\frac{v}{v_c} = 1 - k \, . \, \frac{r^2}{a^2},$$

where k was a constant.

Now, if f_{s1}, f_{s2} are the values of the *surface* frictions in the two pipes, and f_1, f_2 the values of the internal fluid friction at corresponding radii r_1 and r_2,

$$\frac{f_{s1}}{f_{s2}} = \frac{{v_{c1}}^2}{{v_{c2}}^2}, \quad \text{and} \quad \frac{f_1}{f_{s1}} = \frac{r_1}{a_1} \quad \frac{f_2}{f_{s2}} = \frac{r_2}{a_2},$$

we have therefore

$$\frac{f_1}{f_2} = \frac{{v_{c1}}^2 r_1 a_2}{{v_{c2}}^2 a_1 r_2} = \frac{{\mu_1}'(dv/dr)_1}{{\mu_2}'(dv/dr)_2} = \frac{{\mu_1}' 2 v_{c1} r_1}{{a_1}^2} \cdot \frac{{a_2}^2}{{\mu_2}' 2 v_{c2} r_2}$$

or

$$\frac{{\mu_1}'}{{\mu_2}'} = \frac{v_{c1} \, . \, a_1}{v_{c2} a_2},$$

---

[1] Stanton, *Proc. Roy. Soc.* A, lxxxv.

i.e. the ratio of the mechanical viscosities in the two pipes is proportional to the product of the speed of flow and the diameter of the pipe. It appears therefore that the coefficient of mechanical viscosity for flow in parallel channels in which the friction varies as the square of the speed may be written $\mu' = kvd$, where v is the speed of flow, d is the linear dimension of the channel, and k a constant depending on the nature of the fluid used in the experiments.

Since the dimensions of μ' are [M/LT] it is evident that the dimensions of k are M/L^3, *i.e.* that k is proportional to the density of the fluid used, as would be expected from the statement in paragraph (10).

§ (13) EDDY VISCOSITY.—The characteristics of the coefficient of eddy viscosity have also been investigated by Mr. G. I. Taylor in connection with atmospheric phenomena.[1]

Considering the interchange of momentum between consecutive horizontal layers of air in a steady wind due to the movement of the eddies in it, let U_z and V_z be the average horizontal components of wind velocity at a height z parallel to perpendicular co-ordinates x and y, and u', v', w' the components of eddy velocity, so that the three components of velocity are $U_z + u'$, $V_z + v'$, and w', then the rate at which x-momentum is transmitted across any horizontal area is

$$\iint \rho(U_z + u')w' dxdy. \quad . \quad . \quad (1)$$

Mr. Taylor then proceeds to consider a particular case of disturbed motion, supposing the fluid incompressible, and the motion to take place in two dimensions x and z.

If originally the fluid is flowing parallel to the axis of x with velocity U_z, then after disturbance the rate at which momentum leaves a layer of thickness δz is

$$\left[\frac{\partial}{\partial z}\iint \rho(U_z + u')w' dxdy\right]\delta z = I\delta z. \quad . \quad (2)$$

But since U_z is constant over the plane xy and there is no resultant flow across a horizontal plane

$$\iint \rho U_z w' dxdy = 0,$$

and therefore

$$I = \rho\frac{\partial}{\partial z}\iint u'w' dxdy = \rho\iint\left(u'\frac{\partial w'}{\partial z} + w'\frac{\partial u'}{\partial z}\right)dxdy. \quad (3)$$

Further, since the motion is confined to two dimensions $\partial(U_z + u')/\partial z - \partial w'/\partial x =$ twice the vorticity at the point x, y, z, and since every portion of the fluid retains its vorticity throughout the motion, this must be equal to twice the vorticity which the fluid at the point x, y, z had before the disturbance set in. This is equal to the value of dU_z/dz at the height z_0 of the layer from which the fluid at the point x, y, z originated, and therefore

$$\frac{dU_z}{dz} + \frac{\partial u'}{\partial z} - \frac{\partial w'}{\partial x} = \left[\frac{dU_z}{dz}\right]_{z_0}. \quad . \quad (4)$$

From this relation, together with the equation of continuity,

$$\frac{\partial u'}{\partial x} + \frac{\partial w'}{\partial z} = 0, \quad . \quad . \quad . \quad (5)$$

equation (3) becomes

$$I = \rho\iint\left(-u'\frac{\partial u'}{\partial x} + w'\frac{\partial w'}{\partial x} + w'\left[\frac{dU_z}{dz}\right]_{z_0} - w'\frac{dU_z}{dz}\right)dxdy$$

$$= \rho\iint\frac{\partial(w'^2 - u'^2)}{\partial x}dxdy + \rho\iint w'\left(\left[\frac{dU_z}{dz}\right]_{z_0} - \frac{dU_z}{dz}\right)dxdy. \quad (6)$$

The first term of this expression vanishes when a large area is considered, but the second term does not vanish.

Expanding $[dU_z/d_z]_{z_0}$ in powers of $(z_0 - z)$ we have

$$\left[\frac{dU_z}{dz}\right]_{z_0} = \frac{dU_z}{dz} + (z_0 - z)\frac{d^2U_z}{dz^2} + \ldots,$$

and therefore

$$I = \rho\iint w'\left[(z_0 - z)\frac{d^2U_z}{dz^2} + \frac{(z_0 - z)^2}{2}\frac{d^3U_z}{dz^3} + \ldots\right]dxdy, \quad (7)$$

and if $(z_0 - z)$ be of such a magnitude that the change in dU_z/dz in that distance is small compared with dU_z/dz itself,

$$I = \rho\frac{d^2U_z}{dz^2}\iint w'(z_0 - z)dxdy, \quad . \quad (8)$$

and the rate at which the x-momentum leaves a layer of thickness dz is

$$\rho\frac{\partial^2 U_2}{\partial z^2}\delta z\iint w'(z_0 - z)dxdy. \quad . \quad (9)$$

The effect of the disturbance is therefore to reduce the x-momentum of a horizontal layer of thickness dz at the rate $\rho(\partial^2U_z/\partial z^2)\delta z \times$ (average value of $w'(z_0 - z)$ per unit area). The same effect would be produced on a layer of thickness dz by a viscosity equal to $\rho \times$ (average value of $w'(z_0 - z)$) if the motion had not been disturbed.

According to Mr. Taylor's theory, therefore, when we wish to consider the disturbed motion of layers of air we can take account of the eddies by introducing a coefficient of eddy viscosity equal to $\rho \times$ average value of $w'(z_0 - z)$, and supposing that the motion is steady

---

[1] *Phil. Trans. Roy. Soc.* A, ccxv. 11.

$(z_0 - z)$ is the height through which the air has moved since the last mixture took place.

The average value of $w'(z_0 - z)$ can be expressed in the form $\frac{1}{2}(\overline{wd})$, where d is the average height through which an eddy moves before mixing with its surroundings and w' roughly represents the average vertical velocity in places where w' is positive.

The movement of the air on the earth's surface as affected by the eddy viscosity may be investigated as follows.

As before, assuming the air incompressible, the equations of motion (see p. 345) may be written

$$\left.\begin{aligned}\frac{Du}{Dt} &= X - \frac{1}{\rho}\frac{\partial p}{\partial x} + \frac{\mu'}{\rho}\nabla^2 u\\ \frac{Dv}{Dt} &= Y - \frac{1}{\rho}\frac{\partial p}{\partial y} + \frac{\mu'}{\rho}\nabla^2 v\\ \frac{Dw}{Dt} &= Z - \frac{1}{\rho}\frac{\partial p}{\partial z} + \frac{\mu'}{\rho}\nabla^2 w\end{aligned}\right\} \quad . \quad . \quad (1)$$

with the usual notation.

Assume a constant pressure gradient G acting in the direction of y. The remaining forces are gravity and those due to the earth's rotation.

Hence
$$\left.\begin{aligned}X &= -2\omega v \sin\lambda\\ Y &= 2\omega u \sin\lambda\\ Z &= -g\end{aligned}\right\}, \quad . \quad . \quad . \quad (2)$$

where ω is the angular velocity of the earth's rotation and λ is the latitude, and

$$p = k - g\rho z + Gy, \quad \text{where } k = \text{constant}.$$

Assuming the motion to be horizontal, equations (1) become

$$0 = -2\omega v \sin\lambda + \frac{\mu'}{\rho}\cdot\frac{d^2u}{dz^2}, \quad . \quad . \quad . \quad (3)$$

$$0 = -2\omega u \sin\lambda - \frac{G}{\rho} + \frac{\mu'}{\rho}\cdot\frac{d^2v}{dz^2}. \quad . \quad (4)$$

Eliminating u we have

$$\frac{d^4v}{dz^4} + 4B^4v = 0, \quad \text{where } 2B^2 = \frac{2\omega\rho\sin\lambda}{\mu'}, \quad (5)$$

or $$v = A_2e^{-Bz}\sin Bz + A_4e^{-Bz}\cos Bz, \quad (6)$$

or substituting in (4)

$$u = A_2e^{-Bz}\cos Bz - A_4e^{-Bz}\sin Bz + \frac{G}{2\mu'B^2}. \quad (7)$$

At great heights, therefore, $v = 0$ and

$$u = \frac{G}{2\mu'B^2} = \frac{G}{2\omega\rho\sin\lambda}, \quad . \quad . \quad . \quad (8)$$

i.e. u is independent of μ' and is the value of the velocity calculated from the pressure distribution, and is called the gradient velocity.

The values of A_2 and A_4 are found as follows:

Assuming that at the surface

$$\frac{du/dz}{dv/dz} = \frac{u}{v},$$

this becomes by substitution from the above relations

$$-\left(\frac{A_2 + A_4}{A_2 - A_4}\right) = \frac{A_2 + (G/2\mu'B^2)}{A_4} = \frac{A_2 + Q_G}{A_4}, \quad (9)$$

where Q_G is the gradient velocity.

Again, if the wind at the surface be deviated through an angle α from the gradient wind in such a way that if one stands facing the surface wind the gradient wind will be coming from the right if α be positive. Then

$$\tan\alpha = -\left(\frac{v}{u}\right)_{z=0} = \frac{A_4}{A_2 + Q_G},$$

and we have

$$\left.\begin{aligned}A_2 &= \frac{-\tan\alpha(1 + \tan\alpha)}{1 + \tan^2\alpha}Q_G\\ A_4 &= \frac{-\tan\alpha(1 - \tan\alpha)}{1 + \tan^2\alpha}\,.\,Q_G\end{aligned}\right\} \quad . \quad . \quad (10)$$

Now the surface wind

$$\begin{aligned}Q_s &= \sqrt{(u^2 + v^2)_{z=0}}\\ &= \sqrt{A_4^2 + (A_2 + Q_G)^2}\\ &= \frac{Q_G}{1 + \tan^2\alpha}\sqrt{\tan^2\alpha(1 - \tan\alpha)^2 + (1 - \tan\alpha)^2}\end{aligned}$$

or $$Q_s = Q_G(\cos\alpha - \sin\alpha). \quad . \quad (11)$$

This relation has been verified by direct observations made by means of pilot balloons on Salisbury Plain by Mr. G. M. B. Dobson.

Again, if H_1 be the height at which the direction of the wind coincides with that of the gradient wind, putting $v = 0$ we have

$$A_2 \sin BH_1 + A_4 \cos BH_1 = 0$$

or $$\tan BH_1 = -\frac{A_4}{A_2},$$

and substituting for A_2 and A_4

$$\tan BH_1 = \frac{1 - \tan\alpha}{1 + \tan\alpha} = \tan\left(\alpha - \frac{\pi}{4}\right). \quad (12)$$

Since α is positive and less than $\pi/4$, the smallest positive value of H_1 is given by $BH_1 = 3\pi/4 + \alpha$.

The height H_2 at which the wind velocity first becomes equal to the gradient velocity is given by $u^2 + v^2 = Q_G{}^2$, or

$$l^{-BH_2} = \frac{(1 + \tan\alpha)\cos BH_2 - (1 - \tan\alpha)\sin BH_2}{\tan\alpha}. \quad (13)$$

The relation between BH_2, BH_1, H_1/H_2, and α are given in the following table:

$\alpha°$.	BH_2.	BH_1.	$\frac{H_1}{H_2}$.
0	·78	2·35	3·0
10	·91	2·53	2·8
20	1·04	2·70	2·6
30	1·20	2·88	2·4
45	1·44	3·15	2·2

Mr. Dobson gives 800 metres/300 metres $= 2·66$ as the observed value of H_1/H_2 for

$\alpha=20°$, which is in very close agreement with the above calculation.

Further, assuming a value for α of 20°, we have from the above table $BH_1=2{\cdot}7$, and substituting in the relation

$$B=\sqrt{\frac{\omega\rho\sin\lambda}{\mu'}},$$

$$\frac{\mu'}{\rho}=H_1^2\frac{\omega\sin\alpha}{2{\cdot}7^2} \quad . \quad . \quad . \quad . \quad (14)$$

Putting $\omega=0{\cdot}000073$ and $\lambda=50°$ N., we have for the South of England

$$\frac{\mu'}{\rho}=H_1^2\times0{\cdot}77\times10^{-5}.$$

Taking the values of H_1 from Mr. Dobson's paper, we obtain the following table:

Wind.	H_1 in Metres.	$\frac{\mu'}{\rho}$.
Strong . . .	900	62×10^3
Moderate . .	800	50×10^3
Light . . .	600	28×10^3

II. The Nature of the Motion of Fluids over Solid Surfaces tangential to the Direction of Flow and the Characteristics of the Frictional Forces consequent on the Motion

§ (14) Resistance to Motion over a Solid Boundary.—The relations between the resistance encountered by a solid body moving through a fluid in which it is completely immersed, or by a fluid in moving over a fixed solid surface, can be broadly divided into two classes. The resistance is either proportional simply to the relative speed of surface and fluid, or it is proportional to a power of the relative speed which is in the neighbourhood of 2.

(i.) *The Critical Velocity, Osborne Reynolds' Law.*—It is found that these two classes of resistance correspond to two definite states of internal motion of the fluid. When the elements of the fluid follow one another along lines of motion which lead in the most direct manner to their destination, the resistance is proportional to the relative velocity simply. When the particles of the fluid eddy about in sinuous paths the most indirect possible, *i.e.* the fluid is in turbulent motion, the resistance varies nearly as the square of the speed. The transparency of most fluids renders it difficult to determine when a fluid is in steady or turbulent motion. Thus in the case of water passing through a glass tube it is quite impossible by visual examination of the flow to determine which of the two states of motion is taking place. A simple method of demonstrating the nature of the motion of fluids and of the manner in which one state of motion will pass into the other was devised by Osborne Reynolds in 1883.[1] In these experiments a straight tube of glass 5 feet long and provided with a trumpet mouthpiece was placed in a water tank 6 feet long, 18 inches deep, and 18 inches broad in the manner shown in *Fig.* 8, and provided with a stopcock to regulate the rate of flow of the water through it. A small reservoir of coloured water was placed above the tank with an outlet into the tank in such a position that a stream of coloured water could be delivered at a very slow speed a few inches in front of the trumpet mouthpiece, with the result that a streak of the colour could be drawn into the pipe when flow through it took place. The flow of colour was regulated by a clip on the india-rubber pipe connection. It was found that when the cock was slightly opened and a streak of colour allowed to enter the pipe with the water, no mixture of the two fluids took place, the streak exhibiting itself as a thin band parallel to the axis of the pipe. As the discharge cock was gradually opened further it was observed that for some definite value of the velocity of flow, which was always the same for the same temperature of the water, the whole of the colour band extending downstream from a point at some distance from the mouthpiece would suddenly break up and mix with the surrounding water, so that this part of the tube became full of a mass of coloured water. By further increasing the rate of flow the point at which the breakdown occurred moved back towards the mouthpiece, but it was not found possible by increasing the flow to the greatest extent possible to cause the break-up of the stream to take place at the mouthpiece. The significance of this effect will be referred to later.

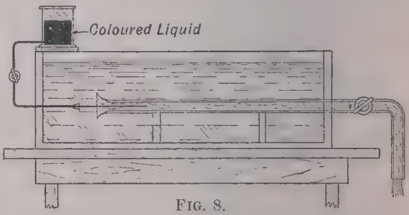

Fig. 8.

As regards the conditions which determined the break-up of the steady motion, it was observed by Reynolds, from an examination of the equations of motion of the fluid, that if the motion be supposed to depend on a single velocity parameter U, say the mean velocity along the tube, and on a single linear parameter c, say the radius of the tube, then the accelerations would be expressed in terms of 2 types; in one of which U^2/c^2 is a factor and in the other $\mu U/\rho c^4$ is a factor. The relative values of these terms depend on the value of the ratio $c\rho U/\mu$, and it would appear, therefore, that if the eddies were due to one particular cause the birth of the eddies would coincide with some particular value of this ratio.

---

[1] *Phil. Trans. Roy. Soc.*, 1883.

To test the accuracy of this conclusion, a large number of observations were made in the apparatus shown in *Fig.* 8 to determine the value of the velocity at which the steady motion broke down in pipes of different diameters.

For the purpose of obtaining the effect of a variation in the value of μ, the temperature of the water in the tank was varied between the values 5° C. and 22° C.

The results of the experiments fully corroborated the conclusions drawn from the equations of motion, the law of the critical point being given by the equation $v_c d\rho/\mu = 300$, where v_c is the critical velocity of flow, *i.e.* the discharge per unit of time divided by the area of the pipe; d is the diameter of the pipe, and μ and ρ the viscosity and density of the fluid, all measured in some self-consistent system of units.

(ii.) *Effect of the Boundary.*—It was noticed, however, that the critical velocity was much higher than had been expected in pipes of the sizes used, since resistances varying as the square of the velocity had been found at much smaller velocities than those at which the eddies appeared in the tank experiment. Further, it was observed that the critical velocity was very sensitive to disturbance of the water before entering the tubes, and it was only by the greatest care as to the uniformity of temperature of the tank and stillness of the water that consistent results were obtained. This showed that the steady motion was unstable for large disturbances long before the critical velocity was reached. As it appeared probable that the cause of this phenomenon was dependent on the boundary condition, the following experiment to show the effect on the motion of an elimination of the solid boundaries was devised. A glass tube 5 feet long and 1·2 inch in diameter, having its ends slightly bent up as shown in *Fig.* 9, was half filled with bisulphide of carbon and then filled up with water and both ends corked. The bisulphide was chosen as being a limpid liquid but little heavier than water and completely insoluble, so that the surface between the two liquids could be clearly distinguished. When the tube was horizontal the surface of separation extended along the axis of the tube. On one end of the tube being slightly raised the water would flow to the upper end and the bisulphide to the other, causing opposite currents along the upper and lower halves of the tube. It was found that when one end of the tube was raised quickly by a certain definite amount, waves showed themselves at the surface of separation which presented the appearance of wind waves. Further, it was noticed that after the expiration of some days a skin formed slowly between the bisulphide and the water, and that when this was formed a repetition of the tilt did not result in the formation of the waves but in the production of eddies, below and above the surface of separation. It would appear, therefore, that there is a critical velocity independent of the boundary action, and that the introduction of a boundary condition alters materially the nature of the motion. This conclusion was confirmed by observing the effect of the wind on a surface of water calmed by oil drops. It was noticed that as the sheet of oil on the surface of the water drifted before the wind, there was distinct evidence of eddies in the water below the oil at some distance from the windward edge, but that without oil there was no indication of eddies, thus indicating that the boundary condition introduced by the oil was the cause of the eddies. There appeared, therefore, to be no doubt that the break-down of the steady motion in the straight pipes was due to eddies thrown off from the solid boundary, and that, consequently, eddies produced by any other cause such as a disturbance in the water would also tend to bring about the same result. Further, it follows that there must be another critical velocity which would be the velocity at which previously existing eddies would die out and the motion become steady. It was decided by Reynolds to test this conclusion by allowing water in a high state of disturbance to enter a tube and observing the motion at a distance from the inlet considered sufficient for the eddies to have died out if at all.

FIG. 9.

Obviously the colour band method was useless for the purpose of settling this question, as the effect of adding colour to a mass of water in turbulent motion was to render the whole of it uniform in colour. It was decided finally to investigate the changes in frictional resistance with speed, as it was thought that the speed at which the law of resistance changed from that of the square to that of the first power of the speed might be sufficiently well marked to define a critical speed. For this purpose lead tubes of about 16 feet in length and a half-inch and a quarter-inch diameter were connected to a supply of water in such a way that the water entered the tubes in a high state of turbulence. The last 5 feet of the tube was connected to a manometer by small pipes leading from two holes, one at each extremity of the experimental length. The water flowing from the tubes was passed through a special meter, so that all the data for calculating the speed of flow and the frictional resistance were available. It was found that the critical velocity at which the motion changed from one type to another was very clearly marked, both by the violent disturbance of the water in the manometer when the critical velocity was reached, and also by the marked change of slope of the curve of resistance of which the ordinates and abscissae were the frictional resistance and the speed of the water.

As was anticipated, the value of the critical speed thus found was considerably lower than that obtained by the method of colour bands, thus indicating that the critical speed in the latter case had a fictitious value. From the friction experiments it was found that the real critical speed was given by the relation

$$\frac{v_c d\rho}{\mu}=2000.$$

(iii.) *Reynolds' Index Law.*—Reynolds' method of presenting the results of the experiments was by means of plotting not the observed values of the resistance and speed, but the logarithms of these numbers. It was found that when this process was carried out for any particular pipe the resulting curve consisted of two straight branches, the lower one corresponding to observations below the critical being inclined at 45° and the upper one at a slope to the axis of pressure of n to 1. These curves are shown in *Fig.* 10 for the case of the two lead pipes used.

It was evident, therefore, that the law of resistance for speeds about the critical was not, as had been supposed, of the form

$$R=Av^2+Bv,$$

but of the form $R=Cv^n$.

It will be seen later that this relation, known as the index law of resistance, is only approximate, but over the range covered by Reynolds' experiments its accuracy is fairly high.

A general law of resistance for pipes of all dimensions and rates of flow was obtained by Reynolds as follows. From the logarithmic plotting it appeared that $R/R_c=(v/v_c)^n$ where R_c and R are the frictional resistances per unit area at the critical velocity and above it. But since by Reynolds' discovery the value of v_c is always given by $v_c d\rho/\mu=k$, and R_c from the streamline theory is known to be equal to $4\mu v_c/d$, we have, by substitution,

$$\frac{R\rho d^2}{4\mu^2 k}=\left(\frac{vd\rho}{k\mu}\right)^n,$$

a relation which, according as $n=1$ or a value in the neighbourhood of 2 depending on the nature of the surface of the pipe, expresses the law of resistance for all sizes of pipe and conditions of flow of the fluid. The experiments of Reynolds on which these conclusions are based were carried out in smooth lead pipes of 1·27 and 0·62 cm. diameter, and through a speed range of from 3 to 706 cm. per second for the 1·27 cm. pipe, and from 7 to 469 cm. per second for the 0·62 cm. pipe. Further, a careful examination of Darcy's very extensive experiments on water flowing in pipes ranging from 1·2 cm. to 50 cm. in diameter did not show any systematic deviation whatever from the general relation laid down, and with very few exceptions the agreement with the Reynolds formula was within 2 or 3 per cent.

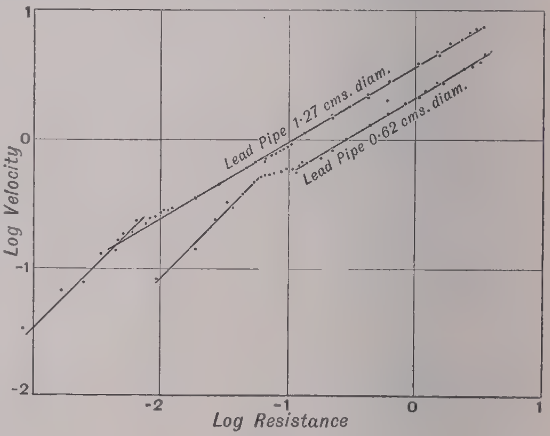

FIG. 10.

III. The Determination by Theory and Experiment of the Frictional Resistance of Surfaces to the Motion of Fluids over Them

§ (15) Resistance to Motion of a Solid.—The analytical investigation of the resistance encountered by a solid moving through a fluid is one of considerable difficulty. In the early study of the problem, in order to simplify the treatment, the fluid was assumed frictionless. As this method led to the conclusion that the resistance was *nil*, in order to obtain results more in agreement with the known facts it was assumed that a surface of discontinuity existed in the fluid whose boundaries consisted partly of fixed plane walls and partly of surfaces of constant pressure. In this way the resistance of a plane lamina in a fluid, inclined to the direction of flow, was obtained by Lord Rayleigh[1] in the form $R=\rho AV^2(\pi \sin \alpha/4+\pi \sin \alpha)$, where V is the velocity of flow and α the angle which the lamina makes with the direction of flow. In this expression the variation of the resistance with the square of the speed has been verified by experiment, but in practice the value of the numerical factor is modified by the existence of a "suction" at the rear of the lamina, which renders the calculated value too small. Broadly stated, the position as regards the possibility of solving problems in fluid resistance by the aid of mathematical analysis is that cases in which the motion of the fluid is "steady"—*i.e.* streamline in character—are amenable to mathematical treatment, but that cases of turbulent motion are intractable, because no analytical method of treating the motion of a fluid which consists of a mass of eddies has yet been evolved. Since in practically all cases of importance the motion in the neighbourhood of the solid surface is turbulent in character, our knowledge of the resistance to the motion of solid bodies through fluids is largely empirical.

§ (16) PRINCIPLE OF DYNAMICAL SIMILARITY.[2] — Considerable progress has, however, been made in the prediction of the resistances of such large bodies as ships and aircraft by the carrying out of experiments on scale models of these bodies in accordance with the principles of dynamical similarity. Thus it has been shown by Lord Rayleigh[3] that the relation obtained by Reynolds for the case of the flow of water in parallel channels is only a particular case of a general law of the resistance of bodies of geometrically similar shape immersed in fluids moving relatively to them, under the assumption that this resistance depends only on the linear dimensions of the body and on the velocity, density, and kinematic viscosity of the fluid. It is further assumed that the geometrical similarity extends to those surface irregularities which constitute roughness. If this be the case, the expression for the resistance may be written

$$R=kV^a l^b \rho^c \mu^d, \quad . \quad . \quad . \quad (1)$$

where R is the resistance per unit area of the body, l is the linear dimension of the body, V is the velocity, ρ the density, and μ the viscosity of the fluid, k being a dimensionless constant.

Now the dimensions of R are $[M/LT^2]$, and the dimensions of the right-hand side of equation (1) are $(L/T)^a(L)^b(M/L^3)^c(M/LT)^d$, and by the principle of dynamical similarity these must be identical, *i.e.* the indices of the respective units must be the same. Equating these we have

$$\left.\begin{aligned} c+d&=1 \\ a+d&-2 \\ a+b-3c-d&=-1 \end{aligned}\right\}, \quad . \quad . \quad (2)$$

or $$c=1-d, \quad b=-d, \quad a=2-d,$$

so that $$R=k\rho V^2\left(\frac{\mu}{\rho Vl}\right)^a,$$

or generally $$R=\rho V^2 F\left(\frac{Vl}{\nu}\right), \quad . \quad . \quad . \quad (3)$$

where F is a function of the one variable (Vl/ν), ν being the kinematic viscosity of the fluid.

It should be observed that the demonstration of the truth of this relation is a matter for experimental investigation, as it is quite possible that some characteristic of the fluid or of its motion may have been overlooked in the initial assumptions, such as, for instance, the elasticity of the fluid. Comparing this relation with the experimentally determined relation of Osborne Reynolds (§ (14), (iii.)), which may be put in the form

$$\frac{R}{\rho V^2}=4k^{1-n}\left(\frac{\nu}{Vd}\right)^{2-n},$$

we see that when $n=1$, *i.e.* when the flow is streamline in character,

$$\frac{R}{\rho V^2}=\frac{4\nu}{Vd},$$

i.e. $$F\left(\frac{Vd}{\nu}\right)=\frac{4\nu}{Vd},$$

and that when $n=1\cdot75$ as in the case of the turbulent flow of water through smooth pipes,

$$F\left(\frac{Vd}{\nu}\right)=4k^{-\cdot75}\left(\frac{\nu}{Vd}\right)^{\cdot25}.$$

A somewhat more general treatment of the problem of the conditions for similarity of motion in fluids was given in 1873 by Helmholtz,[4] of which the following sketch may be of interest. Considering two fluids of densities ρ_1, ρ_2, and kinematic viscosities ν_1, ν_2, the conditions under which the motions of the two fluids are similar are determined thus. Taking the equation of motion of the first fluid as

$$-\frac{1}{\rho_1}\frac{dp}{dx}=\frac{du}{dt}+u\frac{du}{dx}+v\frac{du}{dy}+w\frac{du}{dz} -\nu_1\left\{\frac{d^2u}{dx^2}+\frac{d^2u}{dy^2}+\frac{d^2u}{dz^2}\right\}, \quad (1)$$

and two similar equations, and writing

$$\nu_2=q\nu_1, \quad \rho_2=r\rho_1,$$

then in order that these equations may be transformed into the equations for the second fluid

$$-\frac{1}{\rho_2}\frac{dP}{dX}=\frac{dU}{dT}+U\frac{dU}{dX}+V\frac{dU}{dY}+W\frac{dU}{dZ} -\nu_2\left\{\frac{d^2U}{dX^2}+\frac{d^2U}{dY^2}+\frac{d^2U}{dZ^2}\right\}, \quad (2)$$

---

[1] Rayleigh, *Scientific Papers*, i. 291.

[2] See article "Dynamical Similarity."

[3] *Philosophical Magazine*, 1899, xlviii. 321.

[4] *Wissenschaftliche Abhandlungen*, i. 158.

under the given conditions of similarity

$$U=nu,\quad V=nv,\quad W=nw,$$

it will be seen that multiplying (1) by n^3/q the required transformation is effected if the changes in the scales of length, time, and pressure are

$$X=\frac{q}{n}x,\quad T=\frac{q}{n^2}t,\quad P=n^2rp. \qquad . \quad . \quad (3)$$

It follows, therefore, from the linear scale relation, that if l, L are corresponding dimensions of two tubes in which fluids of densities ρ_1, ρ_2, and kinematic viscosities ν_1, ν_2, are flowing in order that the two motions may be similar, $L=(\nu_2 vl/\nu_1 V)$, *i.e.* VL/ν, must have the same value for each. Again, from the pressure scale relation it follows that for similar motion the value of $P/\rho V^2$ is the same for each fluid. The investigation of Helmholtz leads, therefore, to the same condition for similarity of motion as that deduced from the dimension method of Lord Rayleigh. It has been pointed out by Sir George Greenhill that the interpretation of Proposition 32, book ii., in Newton's *Principia* leads to the same conditions.

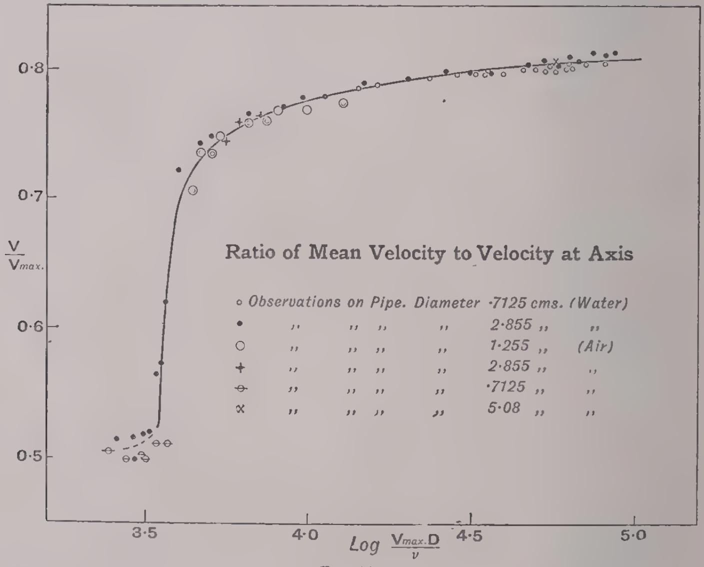

FIG. 11.

§ (17) EXPERIMENTAL VERIFICATION OF THE RAYLEIGH FORMULA.—An extensive series of investigations were carried out at the National Physical Laboratory[1] during the years 1910–1915 to test the accuracy of the assumptions on which the Rayleigh resistance formula is based. These experiments consisted of determinations of the intensity of the surface friction of fluids moving over geometrically similar solid surfaces, so as to include the widest range in the velocities of flow, the linear dimensions of the surfaces, and the nature of the fluids used as could be obtained.

The most convenient method of securing these conditions, both as regards range in the value of the above characteristics and accuracy in the measurements of the velocity of flow of the fluid and the frictional forces consequent upon it, was obviously that previously adopted by Reynolds, consisting in experiments on the flow through parallel pipes of circular cross-section.

Adopting this method of working, a very complete series of experiments were carried out with air, water, and thick oils as the fluids and with velocities of flow ranging from 30 to 6000 cm. per second. For accurate comparison, as pointed out by Lord Rayleigh, the surfaces of the tubes should have been precisely geometrically similar as regards surface roughness, but as this condition could not be fulfilled the experiments were all made on commercially smooth-drawn brass tubes. From the general agreement of the results obtained with different pipes it was not apparent that slight irregularities in this respect had any marked effect on the resistance. The velocity of flow was in all cases taken to be the mean velocity across the section of the pipe. In the case of the pipes of small diameter this was most conveniently estimated by passing the whole of the discharge through a meter and measuring the rate over a given time. This method of procedure was not possible for the large pipes, and in these cases the value of the velocity at the axis of the pipe was measured by means of a Pitot tube and then multiplied by the ratio of the mean speed to the maximum speed. As this ratio was not constant for different speeds and dimensions of pipe, it was necessary to carry out a special investigation on the law of its variation. This was done for the large pipes by fitting the Pitot tube with a micrometer head so that it could be traversed across the pipe, and a series of observations made of the velocity at different distances from the axis. The value of the ratio was then found by plotting and mechanical integration in the usual way.

---

[1] *Phil. Trans. Roy. Soc.* A, ccxiv.

The values of the ratio and its variation with the value of $V_{\max.}d/\nu$ are shown in *Fig.* 11, where $V_{\max.}$ is the velocity at the axis. It will be seen that for low values of $V_{\max.}d/\nu$ the variation is considerable, but that when $V_{\max.}d/\nu$ exceeds 100,000 it becomes small.

In all cases the value of the surface friction was calculated from the pressure drop along the pipe between two sections sufficiently far removed from the inlet of the pipe for the velocity distribution across the pipe to have become uniform. The value of the pressure drop was, in the great majority of cases,

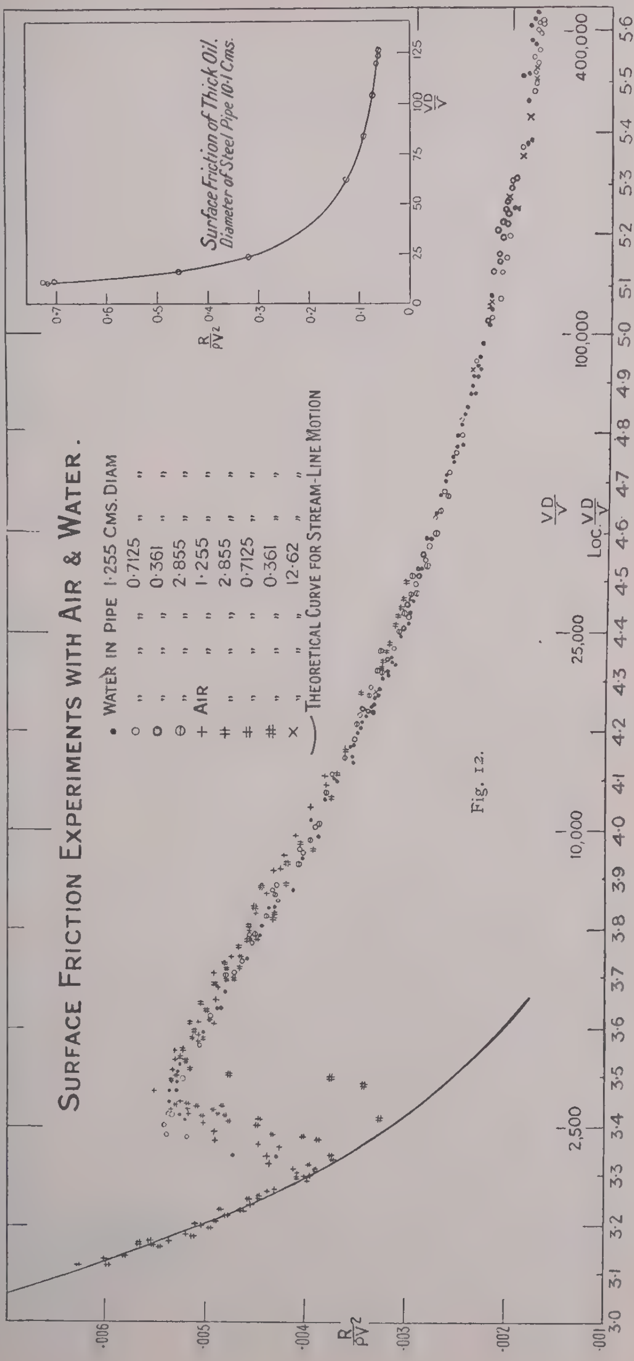

Fig. 12.

measured by connecting two holes in the wall of the pipe, one at each section, with a tilting manometer of the Chattock type, by means of which pressure differences as low as one-thousandth of an inch of water can be accurately measured. For the experiments with water flowing through small pipes at speeds from 5000 to 6000 cm. per second, where the pressure drop to be measured was of the order of 50 lbs. per sq. in., specially calibrated Bourdon gauges were employed. These tests gave the highest value of vd/ν obtained in the experiments—430,000—and the frictional resistance was as high as 18 grammes per square centimetre. The whole of the results are shown plotted in *Fig.* 12, in which the ordinates are the values of $R/\rho v^2$, and the abscissae the corresponding values of vd/ν, where R is the surface friction per unit area, ρ the density of the fluid, and v the mean velocity of flow. It will be seen that the curve consists of two branches connected by a narrow vertical band over which the points are somewhat irregularly spread. This band indicates the region of the flow between the break-down of the steady motion and the establishment of complete turbulence. The left-hand branch, corresponding with speeds below the critical value, is in very good agreement with the critical curve obtained from the hydrodynamical formula for steady flow,

$$R = \frac{8\mu v}{d}.$$

For values of the speed of flow above the critical it will be seen that the inclination of the curve to the horizontal becomes gradually less as the value of vd/ν increases, indicating that the law of resistance tends to become one in which the friction varies as the square of the velocity, and therefore independent of the dimensions of the channel and the temperature of the fluid. Throughout the whole of the range covered by the experiments above the critical speed, *i.e.* from $(vd/\nu) = 2500$ to $(vd/\nu) = 470{,}000$, with the exception of a few individual determinations due possibly to errors of observation, the variation of $R/\rho v^2$ for either fluid in any of the five pipes from its mean value does not exceed 2·0 per cent, so that the accuracy of the assumptions in the derivation of the Rayleigh law of resistance is fully demonstrated.

There remained the comparison on the same basis of the results of previous experimenters on the flow of fluids in pipes with those obtained at the National Physical Laboratory. These included the very elaborate investigations of Darcy[1] on the water mains of Paris, a very complete series of tests on the flow of water through drawn brass tubes by Saph and Schoder,[2] and the results of researches by Brix[3] and Stockalper[4] on the flow of air through lead and iron tubes.

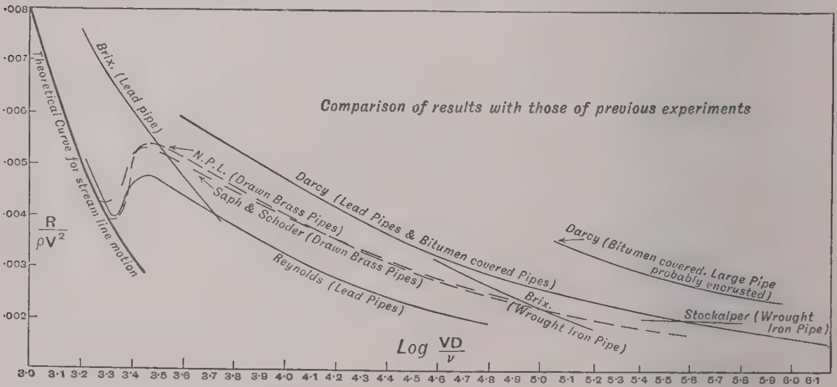

FIG. 13.

Unfortunately in some of these observations the temperature had not been recorded, so that the values of ν could not be calculated with accuracy.

The reduced results were plotted in the same manner as in *Fig.* 12, and the mean curves through them are shown in *Fig.* 13, in which the curve for the National Physical Laboratory experiments is also indicated. In the case of Darcy's experiments the curve for the largest pipe is distinct from that of the others, presumably indicating greater roughness of the internal surfaces, but the general characteristics of the curves are what would be expected, For Reynolds' experiments on two smooth lead pipes a mean line has been drawn which indicates a lower resistance than that found in the National Physical Laboratory experiments, but the agreement is quite satisfactory as regards the character of the curve and the position of the critical point. The most satisfactory comparison, however, is possible with Saph and Schoder's results, since the nature of the surfaces in the two researches was probably identical. It will be seen that the two curves are nearly coincident throughout the whole range of the experiments, and indicate a very satisfactory agreement between the results of the two researches. For the comparison in the case of air flow the amount of experimental data available was not large, and there are some discrepancies which are difficult to account for. These, however, are confined to one series of observations on a small pipe and may be due to an inaccuracy in the determination of its diameter. For the larger pipes the agreement is fair.

[1] *Comptes rendus*, xxxviii.

[2] *Proc. Am. Soc. Civ. Eng.*, 1903, li. 253.

[3] *Phil. Mag.*, 1909, xvii. 395.

[4] *Revue Univ. des Mines*, vii. 257.

It has been shown by Dr. C. H. Lees[1] that the relation between $R/\rho v^2$ and vd/ν indicated by the curve in *Fig.* 12 may be expressed algebraically in the form

$$\left(\frac{R}{\rho v^2}-0{\cdot}0009\right)\left(\frac{vd}{\nu}\right)^{0\cdot35}=0{\cdot}0765$$

or

$$R=\rho\left[0{\cdot}0765\left(\frac{\nu}{vd}\right)^{0\cdot35}v^{1\cdot65}+0{\cdot}0009v^2\right].$$

It may be remarked from the final expression for R written above, that the frictional resistance will for all velocities be approximately proportional to a power of the velocity between the 1·65th and the 2nd, and that as the speed and diameter increase or the kinematic viscosity decreases the law of variation of the friction will approximate more and more closely to that of the square of the speed. This is in agreement with the experimental results obtained in the 1·26-cm. pipe referred to above. It is shown by Lees that if for any reason a single power formula for the frictional resistance is desired the most accurate value of n in the formula

$$R=Cv^n$$

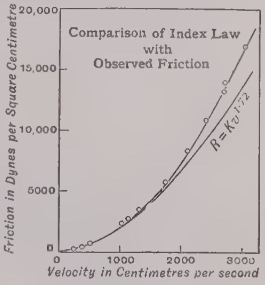
is given by

$$n=2-29{\cdot}7\Big/\left\{85+\left(\frac{vd}{\nu}\right)^{0\cdot35}\right\}.$$

It is also evident that as the resistance becomes more and more proportional to the square of the speed, due to increase of the diameter or velocity, the effect of change of temperature becomes less important. Thus it has been observed by Maw for water that when the resistance varies as the 1·8th power of the speed it decreases 0·6 per cent per degree centigrade, and when the resistance varies as the 1·9th power it only decreases 0·25 per cent per degree.

§ (18) THE ACCURACY OF THE INDEX LAW.—The determination in these experiments of the frictional resistance of a 1·255-cm. pipe when the velocity ranged from 22 cm. per second, corresponding to the first commencement of eddying motion, to 3150 cm. per second, made possible a check, within these limits, of the accuracy of the well-known index law of resistance due to Reynolds and Froude.

The results for the 1·255-cm. pipe were taken, and according to Reynolds' method the logarithms of the friction and velocity from $v=40$ to $v=100$ cm. per second were carefully plotted. The points so obtained were found to be on a straight line whose slope was 1·72 to 1. Assuming a law of resistance $R=Cv^n$ where n had this value, C was determined from the low speed observations used for the evaluation of n, and a series of values of R were calculated up to a speed of 3200 cm. per second. Plotting these calculated values and those actually obtained in the experiments, the two curves in *Fig.* 14 were obtained, from which it will be seen that by the use of the index law the resistance is underestimated by 5 per cent at 1000 cm. per second, by 8·5 per cent at 2000 cm. per second, and by 15 per cent at 3000 cm. per second.



Flow of Water in Pipe
1·255 Centimetres Diameter

FIG. 14.

In order to show the manner of variation of n throughout the whole range of velocities obtained, the values of n were taken out by the Reynolds method at four different stages and were found to be:

Velocity per sec. (cm.) . .	58	258	900	2250
Value of n from plotting .	1·72	1·77	1·82	1·92

Similar results, showing a gradual increase in the value of n as the velocity of flow increased, were obtained by the reduction of the observations for the 0·712 and 1·255 cm. pipes, and it was, therefore, fully demonstrated that an index law for surface friction cannot be devised which will express the facts with high accuracy, except over a comparatively small range in the value of vd/ν. The importance of a realisation of this fact when predicting the skin friction of large bodies moving in fluids from observations on small-scale models of them in the same fluid will be obvious.

§ (19) THE EXPERIMENTAL DETERMINATION OF THE FRICTIONAL RESISTANCE OF THIN PLATES. (i.) *Froude's Experiments.*—As previously mentioned (§ (16)), the results on the frictional resistance to the flow of fluids in pipes, plotted in *Fig.* 12, are only applicable to cases in which the velocity of the fluid at a given distance from the boundary is constant over the whole length considered. They are, therefore, not applicable to the prediction of the frictional resistance of any surface which includes that part of it over which the particles of fluid are being gradually retarded—*i.e.* the part in the neighbourhood of the leading edge of the surface such as, for example, the immersed surface of a ship. For the prediction of the skin friction of ships special experiments are necessary, and a large series of very important observations was carried out by Mr. William Froude in 1872–74.[1] These experiments were made in a water tank 278 feet long, 36 feet wide at the top, the depth of the water being 8 feet 9 inches. The boards of which the frictional resistance was determined were about $\frac{3}{16}$-inch thick, 19 inches deep, the top edge being $1\frac{1}{2}$ inches below the surface. The length varied from 1 foot 6 inches to 50 feet.

---

[1] *Proc. R.S.*, 1914, A, xci.

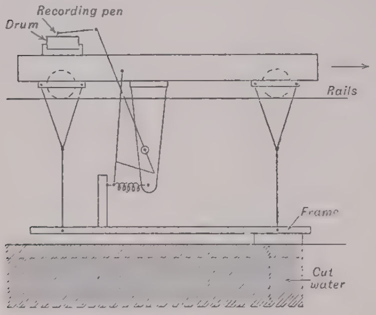


FIG. 15.

The experimental apparatus (*Fig.* 15) consisted of a carriage running on rails fixed to the walls of the tank and capable of being drawn along at a uniform rate. A parallel motion suspended from the carriage carries the board, which is provided with a lead keel and a cut-water. The frictional resistance of the board is taken by the spring shown, the extension of which is magnified and transmitted to a recording drum on which a line is drawn whose distance from the base is proportional to the resistance. The drum is connected by gearing to the carriage-wheels so that the abscissa of the pencil trace is proportional to the distance moved through, and from a second record of time intervals on the paper made by means of an electric clock, the data for calculating the variation of resistance with speed are available.

In this way a series of resistance-velocity curves (*Fig.* 16) was obtained for each length of board, and from these a set of resistance length curves (*Fig.* 17) for given speeds could be deduced. In the first set of experiments the latter curves did not pass through the origin, but above it, showing that the resistance was not zero for zero length. This was found to be due to the bluntness of the bow and stern of the board. On shaping these to knife-edges it was found that the curves passed through the origin. It was found, however, that the curves were not straight but at all speeds were concave to the base line, indicating that the resistance did not vary as the length but at a less rate. This result is due to the fact that the portions of the surface down-stream from the leading edge are in contact with water whose motion relative to them is less than in the neighbourhood of the leading edge, and the frictional resistance of these portions is, therefore, less than that of the other portions nearer the edge.

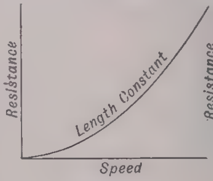

FIG. 16.

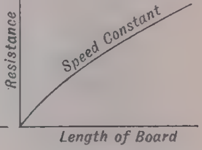

FIG. 17.

It was found that for a given plank the resistance varied as v^n where n was constant for the particular plank, but in different planks depended on the length and quality of the surface. The value of n is found by the Reynolds method of logarithmic plotting previously described. Very approximately the results could be expressed by the formula $R = fSv^n$, where S is the area of the immersed

surface and v is the speed in feet per second. The value of f was found to depend on

(1) The quality of the surface.
(2) The length of the surface.
(3) The temperature of the water.
(4) The density of the water.

The values of n and f deduced from the curves are given in Table I.

§ (20) ESTIMATION OF THE FRICTION OF PLATES FROM THE CHANGES IN MOMENTUM OF THE FLUID PASSING OVER THEM.—The experimental determination of the frictional resistance of the surfaces of thin plates immersed in a fluid by means of a direct measurement of the amount of the tangential force experienced by the plate itself, as in the case of Froude's experiments, is attended with considerable difficulties which render any accurate investigation of the *variation* of the intensity of the resistance almost impossible. These are due to the smallness of the force to be measured, the difficulty of obtaining a thin plate of the required rigidity, and the uncertainty of the large corrections which have to be made in taking account of the resistances of the supporting spindles. For this reason considerable attention has been given to the possibility of an estimation of the frictional resistances from the changes in the characteristics of the fluid which are the necessary effects of the forces exerted, *i.e.* to the changes of momentum of its molecules. One experimental method of this nature has already been discussed in some detail in describing the common device for measuring the frictional resistance of the surface of a parallel channel from the fall of pressure of the fluid between two given points in its axis. The essential feature of this method, however, is that it is only the changes in molecular momentum, or pressure, which are measured, and that the molar momentum of the fluid entering and leaving the two sections is the same. This method is, therefore, inapplicable, as has been previously mentioned, to any case in which the accelerations of the fluid due to the first impingement of the streams against the solid body have not died out, and is, consequently, valueless for predictions of the frictional resistance of air or water craft.

An extension of the method to take into account the changes in molar momentum has recently been attempted in an investigation of the frictional resistance of thin plates in a current of air at the National Physical Laboratory, and, as the results appear to be promising, a brief description of the manner in which the problem has been attacked and the results obtained will be given.

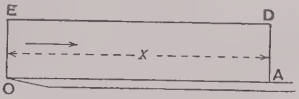

FIG. 18.

In *Fig.* 18 let O be the leading edge of the plate, OA the length whose frictional resistance is to be determined, OE and AD the traces of planes through O and A perpendicular to the direction of flow of the air, and ED the trace of a plane parallel to the plate and at such a distance from it that the flow along ED is unaffected by the presence of the plate. Let V_0 be the velocity of the air impinging on the edge of the plate and supposed uniform over OE, and let V be the velocity of the air in any layer of thickness dz parallel to the plate and distant x from O, *i.e.* in the section AD. Then, considering the changes of momentum in the layer of unit width perpendicular to the plane of the paper passing though the section AD, we have

Change in molecular momentum $=(p-p_0)dz$ where p is the pressure at AD.

Change in molar momentum $=$ (mass passing through the extremity of the layer in AD) $(V_0-V)=\{\rho V(V_0-V)\}dz$.

Therefore the total change of momentum in the layer is

$$\{p_0-p+\rho VV_0-\rho V^2\}dz, \quad . \quad . \quad (1)$$

so that if R is the mean frictional resistance per unit area and we consider a strip of the plate of unit width perpendicular to the plane of the paper and x is the distance OA, we have for the frictional resistance of strip

$$xR=\int_{AD}\{p_0-p+\rho VV_0-\rho V^2\}dz. \quad . \quad (2)$$

Hence if the values of p_0, p, and V_0V for the various layers are known the value of the frictional resistance can be determined by graphical integration. Now p and p_0 are the static pressures of the fluid, and a separate determination of their values or even of their difference is a matter of some experimental difficulty. The expression (1) can, however, be thrown into a form suitable for experimental evaluation if written as follows:

$$xR=\int_{AD}\left\{(p_0+\tfrac{1}{2}\rho V_0^2)-(p+\tfrac{1}{2}\rho V^2)-\frac{\rho}{2}(V_0-V)^2\right\}dz. \quad (3)$$

Here the expression $(p+\frac{1}{2}\rho V^2)$ is the total head of the fluid and is the actual pressure which is maintained in a Pitot tube facing a current of fluid. The determination of the skin friction is therefore seen to involve the measurement of the difference in pressure of two Pitot tubes, one placed in the section OE and the other at various points in AD successively, together with the variation of the velocity with distance from the surface at the section AD. As the third term in (2) is relatively small, the accuracy required in the determination of V is not high.

In the practical application of the above formula, it should be noted that one essential condition is that the reduction in the value of the total head $(p+\frac{1}{2}\rho V^2)$ of the air passing the plate should be entirely due to the frictional resistance of the plate and not affected by the presence of the walls of the wind channel in which the plate is suspended. In all experimental determinations, therefore, the plate should be removed and a measurement made of the fall, if any, in the value of the total head, by noting the difference in the pressures of the two Pitot tubes. If any difference is found to exist, this must be used as a correction to the subsequent readings when the plate is in position.

In the experiments at the National Physical Laboratory a pair of fine Pitot tubes were attached to the arm of a rocking-lever in such a position that their axes were in the same straight line parallel to the axis of the plate. The rocking-lever was operated by a micrometer screw so that the distance of the Pitot tube axis could be set to any desired position. The position of the leading tube was 2 inches in front of the leading edge of the plate and that of the back tube 2 inches behind the back edge of the plate.

Readings of the pressure differences in the tubes and the difference in pressure between the back tube and the static pressure of the fluid at the back tube were taken at successive intervals of ·025 inch from the surface of the plate up to the distance at which the differences in pressure were negligible, *i.e.* the total pressure head of the air flowing past the plate was unaffected by the presence of the plate. The differences in the values of the total heads and of $\frac{1}{2}\rho(V_0-V)^2$ were then plotted on a distance base and the areas of the resulting curves determined by a planimeter. The values of the above integrals multiplied by the width of the plate b are given in Table II., in which are also tabulated the measured resistances of the plate when attached to a sensitive balance arm and weighed directly.

TABLE II

Wind Speed. Ft.-sec.	(1). $b\int_{AD}\{(p_0+\frac{1}{2}\rho V_0^2)-(p+\frac{1}{2}\rho V^2)\}dz$ in Dynes.	(2). $b\int\frac{\rho}{2}(V_0-V)^2dz$ in Dynes.	(1), (2). Dynes.	Measured Resistance of Plate by Direct Weighing.
30	1390	90	1300	1160
50	3980	310	3670	3470

It will be seen that the results given by the method described are probably in good agreement with the results of direct weighings, when consideration is taken into account of the falling off in resistance at the long edges of the plate.

A research on the distribution of the intensity of skin friction is in progress at the National Physical Laboratory. The results obtained show that the "wake" effect in skin friction is much smaller than has recently been supposed, and in this respect tend to agreement with the older experiments of W. Froude.

§ (21) EFFECT OF CURVATURE OF SURFACES ON FRICTIONAL RESISTANCE.—It may be remarked that the experiments of which the results are plotted in *Fig.* 12 were all made on straight lengths of pipe, and that there is some evidence that curvature of the streams in the direction of flow has a marked effect both on the value of the critical velocity and the law of resistance with speed after the critical velocity has been exceeded. This effect was apparently found in Grindley and Gibson's experiments on a long length of pipe 0·32 cm. internal diameter which was coiled round a drum of 36 cm. diameter. In these experiments the critical velocity was found to be as low as 60 cm. per second, corresponding to a value of vd/ν of about 130. For velocities between 60 and 1200 cm. per second the law of frictional resistance was of the form

$$R=Cv^{1\cdot25}.$$

It may be remarked that even at the highest speed attained in these experiments the Reynolds criterion $vd/\nu=2000$ was not attained, so that it is quite possible that in the event of observations at still higher speeds being made the results would have agreed with that part of the curve of *Fig.* 12 above the critical.

It is possible, of course, that the true value of the critical speed found in these experiments might be due to other causes than the curvature of the pipe, but in view of the accuracy in the reduction of the value of the coefficient of viscosity for air from the observations there is a strong probability that such was the real cause of the effect noted.

An interesting series of experiments illustrating the effect of curvature of parallel boundaries have been made by Mr. A. Mallock.[1] In these experiments the fluid was placed in the annular space between two concentric cylinders, one of which revolved, the other being stationary. The frictional resistance of the surface was measured by measuring the moment on the stationary cylinder which could be either the inner or the outer one.

Three distinct sets of conditions were tried, *i.e.* (1) outer cylinder revolving, inner cylinder stationary; (2) inner cylinder revolving, outer cylinder stationary; (3) repetition of series (1) with an annulus of different width.

The arrangement of the apparatus for the tests on series (1) is shown in *Fig.* 19.

The inner cylinder A is suspended by a torsion wire attached by a gimbal ring to the shaft B, which carries a divided circle read by a telescope T. E is the outer cylinder carried on the shaft F, which is driven by a motor provided with a speed regulator. A is filled with water and E is water jacketed, the temperatures of both being observed and the temperature of the fluid in the annulus taken as the mean of these. The cylinder A has its floor about half an inch from the lower edge of the wall, and the space so formed is filled with air. Further, by means of a ring of the same diameter as A fixed to the floor of the outer cylinder, and by filling the annular space between the ring and cylinder with mercury, there is comparatively no drag on the water in the annulus due to the bottom of the outer cylinder.

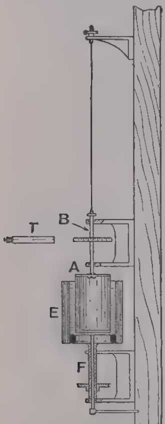

FIG. 19.

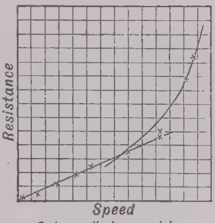
In the case of the first series of experiments, with the outer cylinder revolving and the inner one stationary, the results were similar to those obtained in straight pipes, *i.e.* the friction was proportional to the speed up to a certain critical velocity, at which the motion broke down and steady readings of the friction were impossible to obtain, the conditions becoming steady again at higher values of the speed. This is shown in *Fig.* 20. The results, however, differed fundamentally from those obtained in straight pipes in that

(*a*) The critical velocity was not proportional to the value of the coefficient of viscosity, *i.e.* its value did not conform to the theoretical condition $v_c l/\nu$ constant.

Thus, comparing the results obtained with water at 50° C. and 0° C., the viscosity of water at 50° C. is only one-third of its value at 0° C., and it would be supposed therefore that the critical velocity at 50° would be one-third of its value at 0°. It was found, however, that instability began at the former temperature at a speed only 11 or 12 per cent less than at the latter.

(*b*) It was found that at speeds above the critical the frictional resistance varied as a power of the speed of the order of 2·4, whereas in Reynolds' and Froude's experiments with flat boards and pipes the exponent was about 1·8.



Outer cylinder revolving
Inner ,, fixed

FIG. 20.

Values of the coefficient of viscosity deduced from the low-speed experiments in series (1) were found to be consistently higher than the true values. The experiments of series (3), in which the width of the annulus was only half an inch, gave values of μ, which were nearer to the true value. Previous experiments by Mr. Mallock, by the same method but in which the distance was only about $\frac{1}{8}$ in., gave values of μ closely approximating to the true value, so that there is no doubt that the discrepancy is due to the thickness of the annulus. The results are shown in *Fig.* 21.

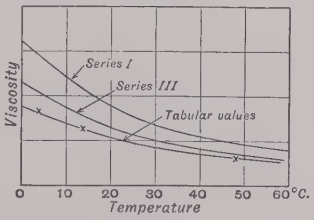


FIG. 21.

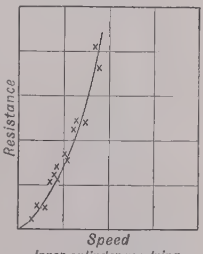
In the experiments with the inner cylinder revolving and the outer cylinder fixed, the motion was essentially unstable at all speeds, and no value of the coefficient of viscosity could be deduced. The results from this method are shown in *Fig.* 22, and indicate that the conditions of flow approximate more closely to the eddying flow of fluid



Inner cylinder revolving
Outer ,, fixed

[1] *Phil. Trans. Roy. Soc.*, 1896, p. 14.

in straight pipes in that the friction varies as a power of the speed of about 1·8, and the measured value of the resistance per unit area at 10 feet per second was roughly that obtained by Mr. Froude in his experiments on planks.

§ (22) Possibility of an Increase in Resistance caused by a Reduction in Viscosity.—In the practical application of the results of the experiments embodied in the curve of *Fig.* 12, it must be remembered that there was one important condition which was fulfilled in every case, which was that the observations were not taken until the distribution of speed across the section of the pipes had become uniform, *i.e.* all accelerations parallel to the axis of the pipes had ceased. It was found by trial that this condition was not fulfilled until a distance along the pipe from the inlet of about 100 diameters was attained. The results of the experiments are therefore not applicable to the prediction of the intensity of surface friction of the part of the tube in the neighbourhood of the inlet, when the layers of fluid in the neighbourhood of the surface are gradually reduced in speed owing to the frictional drag of the surface.

Further, although it might be expected that, in the case of solid surfaces of shapes other than those of parallel channels, the phases of flow would correspond with those observed in pipes, *i.e.* there would be a phase of streamline flow in which the resistance would vary as the first power of the relative speed, a critical velocity at which this form of flow would break down and a subsequent condition of turbulent motion in which the resistance would vary approximately as the square of the speed, it cannot be assumed that the form of the resistance curve will be similar to that of *Fig.* 12. For example, throughout the whole range of the turbulent motion covered in *Fig.* 12 the value of $R/\rho v^2$ falls continuously as vd/ν increases. Suppose this increase is due to an increase in v from v_1 to v_2, ν remaining constant. Then it is clear that R_2/R_1 increases at a less rate than $(v_2/v_1)^2$, or $R_2/R_1=(v_2/v_1)^n$, where n is less than 2. Suppose, on the other hand, that the increase in vd/ν takes place by a reduction in the value of ν from ν_1 to ν_2, v remaining constant. Then evidently R_2 is less than R_1 and we conclude that throughout the whole range of turbulence covered in *Fig.* 12 a reduction in viscosity is accompanied by a reduction in frictional resistance. Very conclusive evidence has, however, been found that in some cases of the resistances of bodies immersed in fluids the value of $R/\rho v^2$ increases with increase of vd/ν. It is evident that, in such cases, since the increase in vd/ν may take place by a reduction in the value of ν, v remaining constant, and therefore R_2 being numerically greater than R_1, a reduction in viscosity will be accompanied by an *increase* in the frictional resistance. Further, since in such cases $R_2/R_1=(v_2/v_1)^n$, where n is greater than 2, the criterion of such an effect will be a resistance varying as a power of the speed greater than 2. The following are some examples.

(*a*) *Friction in Smooth Pipes.*—As was mentioned in the description of Reynolds' experiments, it is usually found that over the region intermediate between turbulent and steady motion the friction conditions are so unsteady that consistent readings at any given speed are impossible. In some observations with a small pipe of $\frac{1}{8}$ in. diameter, at the National Physical Laboratory in 1913, it was found, however, that the change from streamline to eddy motion took place very gradually, and that it was possible to obtain a series of consistent readings of friction and speed over the range of speed between the two conditions of motion. The results are plotted in *Fig.* 23, in which the ordinates are the losses of head in feet of water over the fixed length of pipe under observation and the abscissae are the corresponding values of the discharge in gallons per second, *i.e.* the curve shows the variation of the surface friction with the speed of flow. In the lower curve is shown the value of n in the relation $R=kv^n$ obtained from the upper curve, in the ordinary manner by logarithmic plotting. It will be seen that at very small values of the velocity the friction is proportional to the speed, and that at high speeds it varies nearly as the square of the speed. Between these points indicated by AB and CD in *Fig.* 23 is the section BC representing the flow at intermediate stages of

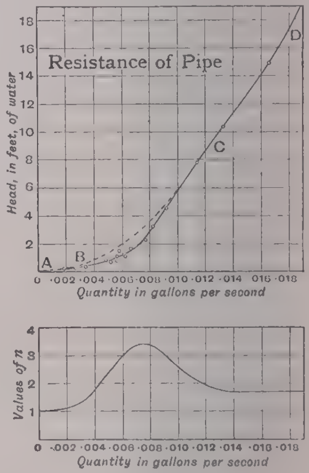

Fig. 23.

turbulence, where, as shown by the lower curve, the resistance varies as a power of the speed which may be as high as 3·5. This evidence confirms the general reliability of the portion of the curve in *Fig.* 12 in the neighbourhood of the critical point.

(*b*) *The Resistance of Spheres.*—At very small velocities the total resistance of a sphere is given by Stokes' formula,

$$\frac{R}{\rho v^2 l^2}=3\pi\frac{\nu}{vl},$$

where l is the diameter of the sphere and v its velocity relative to the fluid at a great distance away from it. Experiments at higher values of vl/ν have been made by M. Eiffel[1] in a wind-channel and by Mr. Shakespeare[2] by dropping weighted spheres down a tower and observing the terminal velocity. Mr. Shakespeare states that over the range of his experiments the resistance increases more rapidly than the square of the speed and more rapidly than the square of the diameter. The experimental results are shown plotted in *Fig.* 24, which, it will be seen, bears a marked resemblance to that for resistance in pipes with the exception that the part corresponding with values of n greater than 2 occupies a greater proportion of the whole experimental range. The part of the curve JK (*Fig.* 24) corresponds with the centre portion of *Fig.* 12.

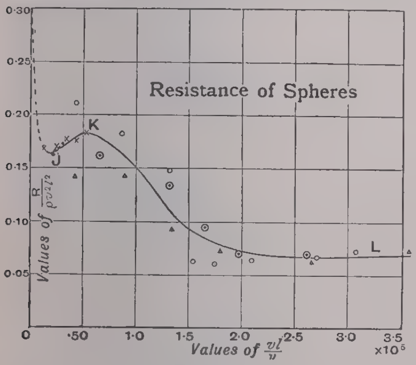

FIG. 24.

(*c*) *The Resistance of Cylinders.*—This subject has received considerable attention owing to the importance of a knowledge of the resistance of wires in aircraft rigging. A very full account of the experiments will be found in the *Report of the Advisory Committee for Aeronautics*, 1912–13, p. 126, and in *Fig.* 25 the mean curve of the results is reproduced. It will be seen that that part of the curve over which $R/\rho v^2 l^2$ increases with the value of vl/ν, thus indicating a diminution of resistance with increase of viscosity, is now a large fraction of the whole curve, and constitutes perhaps the most important evidence of the effect.

It would appear, therefore, that the existence of particular states of flow in fluids, in which an increase in viscosity is accompanied by a reduction in resistance, has been fully demonstrated. The precise explanation of the phenomenon is not clear, but there is a strong probability that the increase in viscosity has the effect of reducing partial and already existing turbulence, and thus procuring a reversion to the conditions of streamline flow.

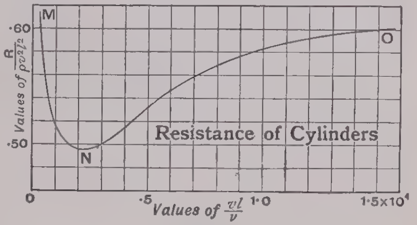

FIG. 25.

§ (23) DIRECT MEASUREMENT OF FRICTIONAL RESISTANCE FROM VELOCITY SLOPE AT THE BOUNDARY.—From the preceding discussion of the practical methods which can be used for the measurement of skin friction in turbulent motion, it will be seen that any accurate determination of the intensity of skin friction on a small area of a surface over which the variation is considerable is a matter of considerable difficulty if not altogether impossible. Up to the present, success in the measurement of skin friction has only been attained in those cases in which the accelerations of the fluid in the direction of flow have died out, such as the flow of fluids in long pipes. Unfortunately the problems of skin friction, which are of the greatest importance in practice, such as the determination of the frictional resistance of ships and aircraft, are those in which the velocity of the fluid is continually changing, and it does not appear that the solution of these problems can be hoped for unless the conditions at the boundary of a fluid in turbulent motion are known, and several attempts to investigate these conditions have recently been made. Such advances as have been made in the knowledge of the boundary conditions of a fluid in turbulent motion have been obtained, as would be expected, from a study of the conditions of flow in parallel pipes. In such flow it is generally accepted that when the speed is below the critical, the layer of fluid in contact with the boundary is at rest relative to it, as any slipping of finite amount would be detected in a variation from the Poiseuille law of the relationship between the diameter of a pipe and the time of efflux of a given volume of fluid. At speeds above the critical, observations near the walls have shown that the mean velocity falls rapidly as the solid bounding surface is approached, and it has been suggested that at the walls there may exist a thin layer in which the flow is laminar in character, in which case, if there is no slipping, the frictional resistance would be determined from the slope of the velocity curve in the surface layer and the coefficient of viscosity of the fluid. Several attempts have been made at the National Physical Laboratory to obtain evidence as to the truth of this assumption, and a series of experiments were carried out in 1920,[1] the results of which afford strong evidence that such a layer exists. The method adopted was to set up a condition of turbulent fluid motion over a surface of which the frictional resistance could be accurately determined and to measure, by means of a very fine Pitot tube, the velocity of the fluid at a point as near the wall as possible. The difficulties of using a Pitot tube under such conditions were: (*a*) that the pressure indications of the Pitot tube might be considerably affected by an interference in the flow in the neighbourhood of the boundary due to the presence of the tube itself; and (*b*) that when such a tube was placed in a current of fluid in which the variation of velocity across the mouth of the tube was very great (amounting in the extreme cases when the tube touched the walls to several hundred per cent of the mean speed), it was by no means certain that the value of the speed deduced from the pressure in the Pitot tube would be the actual speed at the geometrical centre of the tube. The Pitot tube, which was finally adopted for the work, was one of which the external dimensions at the orifice were 0·1 × 0·8 mm. and the internal dimensions 0·05 × 0·75 mm. This was set up in a pipe of 0·714 cm. diameter, through which a current of air was passed by means of a centrifugal fan, and observations of the Pitot tube pressure were taken over as wide a range in the mean rate of flow through the pipe as possible. At the same time the corresponding slopes of the static pressure gradient down the pipe were accurately determined. From the latter measurements the values of the surface friction of the walls for different rates of flow were calculated. The Pitot tube observations were then repeated for other distances of the tube from the walls. For each distance a curve of speed variation with surface friction was plotted, and from these curves it was possible to scale off, for any given value of the surface friction, the speeds corresponding to the different distances of the Pitot tube from the walls and so plot a curve showing the variation of speed with position of Pitot tube. These curves are shown in *Fig.* 26. In the same figure are shown in dotted lines the velocity slopes which would exist at the boundary if the flow were laminar. These are calculated from the known frictional resistances and the values of the coefficient of viscosity for air.

---

[1] *La Résistance de l'Air.*
[2] *Brit. Ass. Rep.*, 1913.

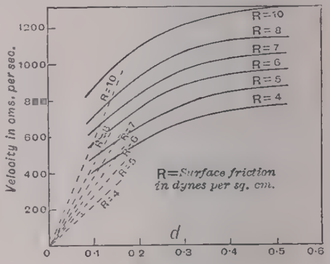

FIG. 26.

To show the relation between surface friction and the speed at a point near the wall, the corresponding observations were reduced by the Reynolds method of logarithmic plotting previously described, as shown in *Fig.* 27. These plottings show that the relation between surface friction and speed at a point is of the same form as for surface friction and mean flow, *i.e.* $R = Cv^n$, but that the value of n diminishes as the boundary is approached until when the geometrical centre of the Pitot tube is ·075 mm. from the wall the value of n is 1·16. It would appear, therefore, that at this distance the eddy motion has nearly disappeared.

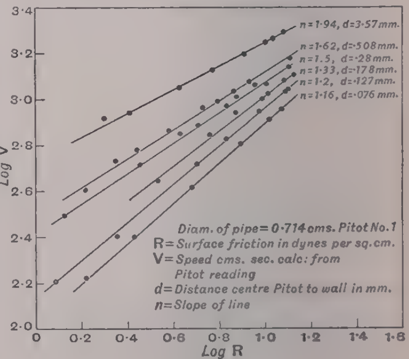

FIG. 27.

On examining the curves in *Fig.* 26, and assuming the errors mentioned under (*a*) and (*b*) above are negligible, the following characteristics will be noted.

---

[1] *Proc. Roy. Soc.* A, xcvii. 413.

(*c*) The slopes of the tangents to the velocity curves at distances of ·075 mm. and above from the walls are very much smaller than would be the case if the flow were laminar at these distances from the wall.

(*d*) The speeds calculated from the observations at a distance of ·075 mm. and less from the walls are appreciably higher than would exist in laminar flow with the measured surface friction. For example, with a frictional resistance of 10 dynes per sq. cm. the calculated speed at ·075 cm. from the walls was 795 cm. per second. In laminar flow with this value of the surface friction the speed would be 443 cm. per second.

It appeared, therefore, that if in these experiments it could be assumed that the speed indicated by the Pitot tube was the speed of the fluid at its geometrical centre the streamline motion, if it existed, was confined to a region of less than ·05 mm. from the boundary, and, further, the observations were not inconsistent with a finite amount of slip at the boundary. It was evident, therefore, that the proof of the existence or otherwise of streamline motion at the boundary would involve a much closer exploration of this region than had hitherto been possible. As any further reduction in the cross dimensions of the Pitot tube would have rendered it unworkable, a modification of the shape of the tube was considered, and it was decided to try experiments with a tube in which its boundary adjacent to the wall of the pipe was removed and its place taken by the wall of the pipe itself. This modification is shown in *Fig.* 28. As the space occupied by this tube was considerably less than in the four-walled one, it was decided to fit a Pitot tube of this form to a pipe of 0·25 cm. diameter. The reason for choosing such a small pipe was that the critical velocity in it would be so high that it would be possible to take a series of observations at about 0·1 mm. from the wall at speeds of flow below the critical, in which cases the actual distribution of velocity across the tube was known to be parabolic, and compare these values with those deduced from the Pitot tube readings. In this way the relation between the geometrical centre of the Pitot tube and its effective centre could be determined, and the possibilities of error pointed out in (*a*) and (*b*) above would be avoided.

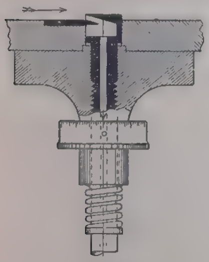

FIG. 28.

A series of tests were accordingly made at a given value of the mean rate of flow below the critical, and at different distances of the geometrical centre of the modified Pitot tube from the wall. From the equation of the distribution of velocity in streamline flow $v=v_c(1-r^2/a^2)$ the values of r were calculated for each value of v calculated from the observations.

Points were then plotted whose ordinates were the values of $(a-r)$ and whose abscissae were the corresponding distances of the geometrical centre of the Pitot tube from the wall.

This process was repeated for different values of the mean flow all below the critical value, and the mean curve through all the plotted points was taken to be the calibration curve for the Pitot tube. This curve is shown in *Fig.* 29. It will be seen that for openings of the Pitot tube of the order of 0·3 mm. the assumption that the calculated speed is that which exists at the geometrical centre of the orifice is not greatly in error, but that when the opening is of the order of 0·075 mm. the interference with the flow is so considerable that the calculated speed is that which exists at the edge of the Pitot tube further from the wall.

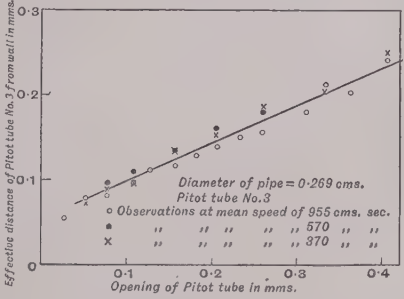

FIG. 29.

A series of observations were then made all at a speed above the critical and with the centre of the tube at different distances from the wall. The speeds calculated from these observations are shown plotted in two methods in *Fig.* 30. On the left-hand side of the figure the abscissae of the points are the distances of the centre of the Pitot tube from the wall, and on the right-hand side the abscissae are the "effective distances" as scaled off from the calibration curve of *Fig.* 29. Assuming that this calibration curve can be applied to conditions of flow above the critical, which seems reasonable in view of the fact that the amount of turbulence at the distances in question must from the evidence of *Fig.* 27 be very small, the curves on the right of *Fig.* 30 show the velocity distribution near the wall when the readings of the Pitot tube are corrected for interference.

It will be seen that the effect of the correction for interference is that at distances of the order of 0·05 from the wall the slopes of the velocity curves approximate fairly closely to the values which would exist in laminar flow. Further, there is no indication of the existence of any slip at the boundary. The conclusion was, therefore, that very definite evidence had been found of the existence at the boundary of a fluid in turbulent flow, of a finite layer of fluid in laminar motion and having zero velocity at the boundary. This evidence was supported by similar observations made on a large pipe of 12·7 cm. diameter, and very large rates of flow, and, although a rigid demonstration was out of the question, there seemed no reason to doubt that in turbulent motion the boundary condition is given by

$$\mathrm{L}t_{x=0}=\mu\frac{dv}{dx}=\mathrm{R}.$$

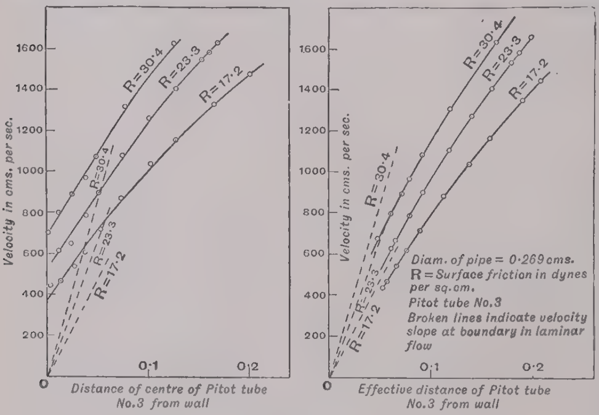

FIG. 30.

§ (24) THE PREDICTION OF THE RESISTANCE OF BODIES MOVING IN FLUIDS, FROM EXPERIMENTS ON SCALE MODELS OF THEM. (i.) *General Considerations.*—From the expression for the resistance of a body moving in a fluid at speeds below the velocity of sound in the fluid $R_1=\rho_1 v_1^2 l_1^2 F(v_1 l_1/\nu_1)$, it is obvious that the resistance of a body S_1 of given shape moving in a fluid of density and kinematic viscosity ρ_1, ν_1 at a speed v_1 may be predicted from the measured resistance of a scale model of the body S_2 moving in a fluid of density and kinematic viscosity ρ_2, ν_2 at a speed v_2, provided that l_2, ν_2, and v_2 are all chosen so that

$$\frac{v_2 l_2}{\nu_2}=\frac{v_1 l_1}{\nu_1},$$

for then

$$R_1=\frac{\rho_1 v_1^2 l_1^2}{\rho_2 v_2^2 l_2^2}R_2,$$

and, since all the terms on the right-hand side are supposed known, R_1 is determinable. If, therefore, the linear dimensions of S_1 are such that no experiment for the purposes of estimating its resistance can be made upon it, the comparison made above opens up a possibility of predicting this resistance from an experiment on a small scale model of it in a laboratory.

In practice the use of this method is limited by the fact that the necessary conditions to be fulfilled in the model test are nearly always impossible to realise. For example, if it is required to predict the resistance of an airship 200 feet long at 60 feet per second and a model of the ship to a scale of $\frac{1}{10}$ is available for the experiments, then supposing the test to be made in air, we have $\nu_1=\nu_2$, $l_1=10l_2$, and therefore $v_2=10v_1=600$ feet per second, a condition which could not be realised in a laboratory experiment. Suppose, however, the *model* experiment be made in water. Then we have $\nu_1=13\nu_2$, $l_1=10l_2$, and since $v_1 l_1/\nu_1=v_2 l_2/\nu_2$, we have $v_2=46$ feet per second. This condition, again, is one which could hardly be realised in water tanks with submerged models, but it will be clear that the possibilities of a prediction are greatly increased. If we could obtain a fluid whose kinematic viscosity was only 1 per cent of that of air, the model test could be made at a speed of 6 feet per second and the prediction could probably be made.

Unfortunately no such fluid is available, so that a direct solution of the problem is not to be hoped for. The importance of scale model tests, however, is not thereby negatived, since a study of the variation in the value of $R/\rho v^2$ over the range in which scale model tests are possible often renders invaluable help in the prediction of the manner in which it will probably vary outside this range. This will be seen from a study of the curves of variation of $R/\rho v^2$ with vl/ν in *Figs.* 12, 24, and 25. In each of these cases it will be seen that for high values of vl/ν, which are those of practical importance, the curve appears to be tending to a definite limiting value, which may be used, with probably fair accuracy, as a basis of prediction in design.

(ii.) *Ship Resistance.*[1]—One of the most important applications of model experiments is the prediction of the resistance of ships, since it is of fundamental importance to know at what speed a ship of given lines will be propelled by engines of a given horse-power, and also to have some reliable means of estimating the benefit which may be derived from a change of lines. The problem of the prediction of ship's resistance is, however, complicated by the fact that a considerable proportion of the total resistance of a ship may be due to the formation of waves on the surface of the sea and that this component cannot be estimated by the application of the law of comparison $vl/\nu = \text{constant}$. A law of comparison for both friction and wave-making may be derived by the ordinary dimensional reasoning, remembering that, in addition to the velocity, density, and viscosity of the fluid, and the linear dimensions of the solid, the acceleration of gravity must also be taken into account, *i.e.* we have

---

[1] See "Ship Resistance," § (4).

$$R = kl^a\rho^b v^c \nu^d g^e \quad . \quad . \quad . \quad (1)$$

or the dimensional equation

$$\left[\frac{ML}{T^2}\right] = \left(L\right)^a \left(\frac{M}{L_3}\right)^b \left(\frac{L}{T}\right)^c \left(\frac{L^2}{T}\right)^d \cdot \left(\frac{L}{T^2}\right)^e, \quad (2)$$

from which

$$\left.\begin{aligned} b &= 1 \\ c + d + 2e &= 2 \\ a - 3b + c + 2d + e &= 1 \end{aligned}\right\} \quad . \quad . \quad . \quad (3)$$

or $\quad b = 1, \quad a = 2 - d + e, \quad c = 2 - d - 2e,$

from which

$$\begin{aligned} R &= kl^{2-d+e}\rho v^{2-d-2e}\nu^d g^e \\ &= k\rho v^2 l^2 \left(\frac{gl}{v^2}\right)^e \left(\frac{\nu}{vl}\right)^d \end{aligned}$$

or

$$R = \rho v^2 l^2 F\left(\frac{gl}{v^2}, \frac{vl}{\nu}\right). \quad . \quad . \quad . \quad (4)$$

In order, therefore, that the total resistance of a ship may be accurately predicted from the measured resistance of a scale model of it, the following relations must hold:

$$\left.\begin{aligned} \frac{vl}{\nu} &= \frac{VL}{N} \\ \frac{v^2}{lg} &= \frac{V^2}{Lg} \end{aligned}\right\}, \quad . \quad . \quad . \quad (5)$$

where the capital letters refer to the ship and the fluid in which it is immersed and the small letters to the model and the fluid in which it is towed. The condition is therefore $N/\nu = VL/vl = (L/l)^{\frac{3}{2}}$.

Assuming $L/l = 25$, it would be essential, for the condition to be fulfilled, that the model should be towed in a fluid whose kinematic viscosity is less than 1 per cent of that of sea-water, which, of course, cannot be realised. For this reason the method adopted in practice is to separate the wave-making resistance from the frictional resistance in the following manner. It is clear from equation (4) that if friction be neglected the wave-making resistance of a ship is given by

$$R_w = \rho v^2 l^2 F\left(\frac{gl}{v^2}\right).$$

If, therefore, we determine the wave-making resistance r_w of a scale model of a ship under the condition that the quantity gl/v^2 is the same for the ship and the model, we have

$$\frac{R_w}{r_w} = \frac{V^2L^2}{v^2l^2} = \frac{L^3}{l^3}, \quad . \quad . \quad . \quad (6)$$

i.e. the wave-making resistances of ship and model are in the ratio of the respective displacements. The procedure adopted is to carry out a test in a water-tank of a scale model of the ship at a speed given by $v^2/l = V^2/L$ and determine its total resistance r. By means of tables of frictional resistances based on Froude's tests on the frictional resistance of thin planks the value of the frictional resistance r_f of the model at a speed v is calculated and we then have $r_w = r - r_f$. The wave-making resistance of the full-sized ship is then given by equation (6)

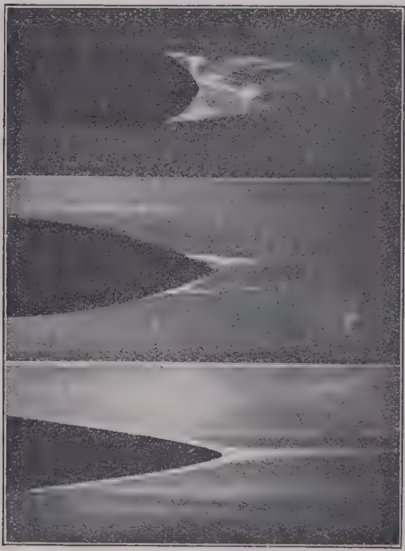
$$R_w = r_w\left(\frac{L}{l}\right)^3.$$

The frictional resistance of the ship is then calculated from the available data and its value R_f is added to R_w to make up the total resistance of the ship.

The objection to the use of data obtained from experiments on thin plates, for the calculation of the skin friction of ships, will be obvious from the consideration that the distributions of the fluid motion in the two cases are widely different. This is particularly marked in the case of the ship's stern owing to the marked tendency of the streams after passing the midship section to separate from the lines of the ship, leaving a wake of eddies at the stern moving at comparatively low speed. This effect is well brought out in the photographs shown in *Fig.* 31. These photographs represent the flow of water round small model balloons of varying fineness of tail. In order to render visible the flow in the region of the tail the model was given a thin coating of colour which would gradually dissolve away as the water flowed past and by the extent of its admixture with the water streams would give an indication of the motion. It will be seen that in each case there is a dead water region at the tail, the extent of which increases with the bluntness of the tail, and since it also increases with the speed of flow, it is probable that the region will be large even in the case of a fine-tailed balloon of normal size and at normal speed. Corresponding effects will take place in the case of a ship unless the lines are particularly fine.

§ (25) THE ESTIMATION OF THE FRICTION OF THE TIDES.—From the curve of *Fig.* 12

it will be seen that for very high values of vl/ν the value of $R/\rho v^2$ tends to a definite limit whose value is not far removed from ·002. It would appear from this that in the case of rivers and canals an approximate estimate of the frictional resistance to flow may be made by assuming that the frictional resistance of the bottom is equal to $\cdot 002\ \rho v^2$. An interesting calculation has recently been made by Mr. G. I. Taylor[1] which indicates that this value may also be applied to the frictional resistance caused by the movement of the tides over the bottom of the sea. Assuming the frictional resistance per unit area to be given by $k\rho v^2$, the energy dissipated per square centimetre per second is $k\rho v^3$. Now the tidal stream at any time t after it has attained its maximum velocity may be taken roughly as $v = V \cos 2\pi t/T$, where V is the maximum tidal stream and T is the semidiurnal tidal period of 12 hrs. 25 mins. The average rate of dissipation of energy over each square centimetre is, therefore, equal to the mean value of $k\rho V^3 \cos^3 2\pi t/T$. Applying this to the case of the Irish Sea, taking $V = 2\frac{1}{4}$ knots, Mr. Taylor finds that the mean rate of dissipation of energy is $k \times 650{,}000$ ergs per sq. cm. per second. By an independent calculation of the rate at which energy flows into the Irish Sea, Mr. Taylor shows that it is possible to find the approximate value of k. Taking the southern entrance to the Irish Sea between Arklow and Bardsey Island, from the known data of the depth of the channel, strength of the current, and range of tide in mid-channel, the mean rate at which energy is transmitted across this section is $6 \cdot 4 \times 10^{17}$ ergs per second. The flow through the North Channel is shown to be negligible compared with this value. In order to arrive at the loss of energy by frictional drag it is necessary to subtract the work done against the moon's attraction by the water. This is estimated by Mr. Taylor to be 110 ergs per sq. cm. per second. Taking the area of the Irish Sea to be $3 \cdot 9 \times 10^{14}$ sq. cm. the energy transmitted is 1640 ergs per sq. cm. per second, and subtracting the 110 due to the work done against the moon's attraction, we have 1530 ergs per sq. cm. per second. Equating this to the above value obtained from the frictional resistance $650{,}000\,k$, we have $k = 0024$. This is in good agreement with the limiting values of k given by the curves of *Fig.* 12.



⟶ Direction of Flow.

FIG. 31.

§ (26) THE FRICTION OF THE WIND ON THE EARTH'S SURFACE.—Assuming that the skin friction of the wind on unit area of the earth's surface can be expressed in the form $F = k\rho Q_s^2$ where Q_s is the velocity of the wind near the surface of the ground, the value of k has been calculated by Mr. G. I. Taylor[2] from his theory of eddy motion and certain meteorological data obtained at Salisbury Plain. Referring to the sketch of this theory given in § (13) above, it will be seen that if F_x and F_y are the components of the friction of the wind along axes parallel and perpendicular to straight isobars and u and v the components of the wind parallel to these axes, then

$$F_x = \int_0^\infty \mu' \frac{d^2u}{dz^2} dz = \mu' \left[\frac{du}{dz}\right]_{z=0}$$

$$\text{and } F_y = \mu' \left[\frac{dv}{dz}\right]_{z=0}, \qquad (1)$$

where μ' is the coefficient of eddy viscosity. The total skin friction is evidently

$$F = \sqrt{F_x^2 + F_y^2}.$$

Now from the equations of § (13) it follows that

$$\left.\begin{aligned} \left[\frac{du}{dz}\right]_{z=0} &= \frac{2\tan\alpha}{1+\tan^2\alpha} \cdot Q_G \frac{\frac{3}{4}\pi+\alpha}{H_1} \\ \left[\frac{dv}{dz}\right]_{z=0} &= \frac{2\tan^2\alpha}{1+\tan^2\alpha} \cdot Q_G \frac{\frac{3}{4}\pi+\alpha}{H_1} \end{aligned}\right\}, \qquad (2)$$

and hence

$$F = 2\mu\, Q_G \sin\alpha \frac{\frac{3}{4}\pi+\alpha}{H_1}, \quad . \quad . \quad (3)$$

so that if, following the ordinary convention, we write $F = k\rho Q_s^2$ we have

$$k = \frac{F}{\rho Q_S^2} = \frac{2\mu}{\rho} \sin\alpha \,.\, \frac{\frac{3}{4}\pi+\alpha}{H_1} \cdot \frac{Q_G}{Q_S^2}, \quad . \quad (4)$$

[1] "Tidal Friction in the Irish Sea," *Phil. Trans. Royal Society*, ccxx. 1.

[2] "Skin Friction of the Wind on the Earth's Surface," *Proc. R.S.* A, D, cxxxvii. 196.

From the data furnished by Mr. Dobson's experiments on Salisbury Plain :

Wind.	$\frac{\mu'}{\rho}$	a.	H_1. Metres.	Q_G.	Q_S.	k.
Strong .	62×10^3	20°	900	1560	950	0·0022
Moderate	50×10^3	$21\frac{1}{2}$°	800	910	590	0·0032
Light .	28×10^3	13°	600	460	330	0·0023

It will be seen, therefore, from reference to the curve in *Fig.* 12 that the limiting value of the ratio $R/\rho v^2$ obtained in laboratory experiments on pipes when the velocity or the linear dimension is large, may also be applied with fair accuracy to the calculation of the skin friction of the wind on the earth's surface.

§ (27) THE FRICTIONAL RESISTANCE OF SURFACES SEPARATED BY A THIN LAYER OF FLUID. (i.) *Cylindrical Surfaces, Tower's Experiments.* — It was discovered by Mr. Beauchamp Tower in 1883 in the course of some experiments made for the Institution of Mechanical Engineers,[1] that in the case of a lubricated bearing resting on a revolving shaft, the surfaces of the shaft and bearing were completely separated by a thin film of oil under pressure, and that the component of the total fluid pressure in the direction of the load was numerically equal to the load.

Tower's apparatus consisted of a half-bearing of brass resting on a shaft 4 in. in diameter, the lower part of the journal being always immersed in oil. Arrangements were made to measure the frictional resistance of the bearing, the speed of the shaft, and the temperature of the oils for various conditions of loading. Further, by inserting pressure holes at various points in the surface of the bearing and connecting these to a manometer it was possible to obtain the distribution of the fluid pressure over the whole surface of the bearing. A typical series of results are given in Table III.

* The definition of the coefficient of friction as tabulated above is—Coefficient of friction multiplied by the total load = moment of friction divided by the radius of the journal.

From an examination of the results it can be shown that the frictional resistance as given by the product of the coefficient of friction and the load was fairly independent of the load and was nearly proportional to the velocity and, further, that it varied considerably with the temperature of the oil film.

(ii.) *Osborne Reynolds' Theory.*—After the publication of the results of these experiments the matter was taken up by Osborne Reynolds, who realised that the film might be thick enough for the unknown boundary condition to disappear, in which case the equations of hydrodynamics could be applied to the motion. As the result of a somewhat intricate investigation,[2] he obtained an approximate solution of the problem of the half-bearing, the results indicating that it was essential for the maintenance of the film that there should be a difference between the radius of the bearing and that of the journal, the two surfaces having a given eccentricity depending on the load, conditions of running and the nature of the lubricant. It was further shown by the theory that this position of nearest approach was not in the line of action of the load, but that the relative position of the two surfaces would be somewhat as shown in *Fig.* 32, the position of nearest approach being on what was termed by Mr. Tower the "off" side of the line of load, *i.e.* the side of recession of the journal surface from the line of load as distinguished from the "on" side or side of approach.

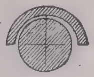

FIG. 32.

Thus, starting from the condition of no load, the distribution of the vertical and horizontal components of the pressure of the oil film would be as indicated by the curves in *Fig.* 33. In this case the position of nearest approach HG is vertically above the centre of the journal, the pressure of the film relative to the pressure at this position being positive on the on side and negative on the off side, and the distribution being such that the total vertical component is zero and the total horizontal component equal to the horizontal component of the friction.

---

[1] *Proc. Inst. Mechanical Engineers*, 1883–84.

[2] *Phil. Trans. Roy. Soc.*, 1886, Part I.

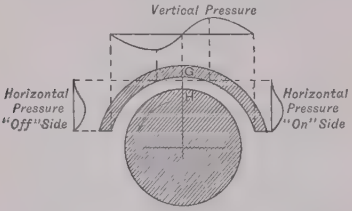

FIG. 33.

On applying a vertical load it is essential for equilibrium that the positive vertical component of the oil pressure should exceed the negative component by the amount of the load imposed, and consequently the bearing tilts over into the position shown in *Fig.* 34, in which the resultant of the vertical pressure of the oil and the friction of the bearing surface exactly balances the load. As the load increases it appears from the theory that the position of nearest approach moves up to the left extremity of the bearing and that on further increasing the load it moves back again towards the central position. Further, when the load is in such a position that the least separating distance HG is almost half the difference in radii of bearing and journal the angular position of HG is about 40° to the off side of the centre line. At this position the pressure on the oil film is everywhere greater than at A and B, the extremities of the bearing and the effect of any additional increase in the load is to produce a negative pressure at A which in practice will produce rupture of the oil film.

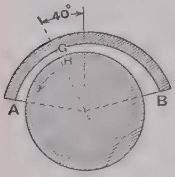

FIG. 34.

It is fairly obvious, therefore, that this condition is the one which obtained in Mr. Tower's experiments at the instant when "seizing" occurred, and may be regarded as determining the maximum load on the bearing. It was possible, therefore, to obtain a check on the accuracy of the theory by calculating the distribution of pressure from the equations when the distance of nearest approach of the surfaces was half the difference of the radii, and comparing this theoretical distribution with the one actually observed by Mr. Tower. This comparison has been carried out in *Fig.* 35, the full curves indicating the theoretical distribution of pressure on an angle base and the crosses the observations. It will be seen that the agreement is very satisfactory.

The mathematical theory of friction under the conditions obtaining when plane or cylindrical surfaces supplied with a lubricant move relatively to each other has also been developed by Sommerfeld, Michell, and Harrison. As the treatment of the problem of the cylindrical bearing by Harrison is simpler than that of Osborne Reynolds, owing to the fact that he has assumed that the bearing is a complete cylinder instead of a half-cylinder and leads in the case of two dimensions to an exact solution, a brief account of the analysis is given here.[1]

(iii.) *Harrison's Theory.*—In forming the equations of motion of the film the effect of gravity and of the inertia of the fluid can be neglected compared with the internal stresses arising from the shearing of the liquid. Also, on account of the thinness of the film, its curvature can be neglected so that the same equations hold whether the surfaces are plane or cylindrical. In the equations x is measured along the moving surface in the direction of motion, y being normal to this surface. The motion is steady and assumed two dimensional.

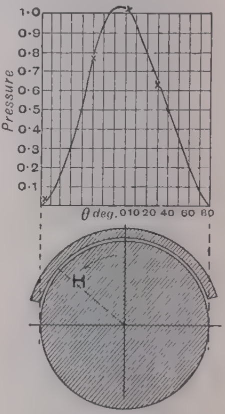

FIG. 35.

If u, v be the component velocities at any point in the liquid, p the pressure, the equations of motion are (see p. 345)

$$\frac{\partial p}{\partial x}=\mu\nabla^2 u, \quad . \quad . \quad . \quad . \tag{1}$$

$$\frac{\partial p}{\partial y}=\mu\nabla^2 v, \quad . \quad . \quad . \quad . \tag{2}$$

where μ is the coefficient of viscosity, and the equation of continuity is

$$\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}=0. \quad . \quad . \quad . \quad . \tag{3}$$

The boundary conditions are

$$\left.\begin{array}{ll} u=\mathrm{U},\ v=0, & \text{where } y=0 \\ u=0,\ v=0, & \text{where } y=h \end{array}\right\}, \tag{4}$$

---

[1] *Transactions, Cambridge Philosophical Society,* xxii. No. 3, p. 39.

where h is the variable distance between the surfaces and is a function of x. Since the surfaces are nearly parallel, v will be small compared with u and the rate of variation of u in the direction of x will be small compared with its rate of variation in the direction of y.

Accordingly equations (1) and (2) become

$$\frac{\partial p}{\partial x} = \mu \frac{d^2u}{dy^2}, \quad . \quad . \quad . \quad (5)$$

$$\frac{\partial p}{\partial y} = 0. \quad . \quad . \quad . \quad . \quad (6)$$

From (6) it is seen that p is independent of y and (5) is then integrable, giving

$$u = \tfrac{1}{2}\mu \frac{\partial p}{\partial x} y(y-h) + \mathrm{U}\left(\frac{h-y}{h}\right). \quad . \quad (7)$$

Now from (3)

$$\int_0^h \frac{\partial u}{\partial x}\partial y = -\Big[v\Big]_0^h = 0,$$

therefore, substituting the value of $\partial u/\partial x$ from (7) and integrating, we have

$$\frac{\partial}{\partial x}\left(h^3 \frac{\partial p}{\partial x}\right) = 6\mu \mathrm{U}\frac{\partial h}{\partial x},$$

or

$$h^3 \frac{\partial p}{\partial x} = 6\mu \mathrm{U}(h - h_1), \quad . \quad . \quad (8)$$

where h_1 is the value of h for which $\partial p/\partial x = 0$.

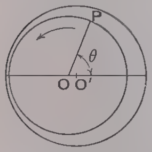

FIG. 36.

Let *Fig.* 36 represent a section through the shaft journal, and let O be the centre of the journal of radius a and O′ the centre of the bearing, $a+\eta$ its radius, and let $\mathrm{OO'} = c\eta$ where $c < 1$.

Then the value of h can be written $h = \eta(1 + c\cos\theta)$ where θ is the angle POO′.

Hence, writing $x = a\theta$, $h_1 = \eta(1 + c\cos\theta_1)$, we have

$$\frac{dp}{d\theta} = \frac{6\mu \mathrm{U}ac(\cos\theta - \cos\theta_1)}{\eta^2(1 + c\cos\theta)^3}, \quad . \quad . \quad (9)$$

from which

$$p = \mathrm{C} + \frac{6\mu \mathrm{U}a}{(1-c^2)^2\eta^2}\Bigg[\frac{c\sin\theta}{(1+\cos\theta)^2}\Big\{-(1-c^2)(1+c\cos\theta) + \tfrac{1}{2}(1+c\cos\theta_1)(1-c^2+3(1+c\cos\theta))\Big\} + (1-c^2)^{-\frac{1}{2}}\{2(1-c^2) - (1+c\cos\theta_1)(2+c^2)\}\tan^{-1}\left\{\sqrt{\frac{1-c}{1+c}}\tan\frac{\theta}{2}\right\}.\Bigg] \quad (10)$$

Now p can only have one value for any given value of θ, and therefore the coefficient of $\tan^{-1}\{\sqrt{(1-c)}/(1+c)\tan(\theta/2)\}$ in the above equation must be zero, *i.e.*

$$3c + (2 + c^2)\cos\theta_1 = 0. \quad . \quad . \quad (11)$$

This equation determines the points at which $(dp/d\theta) = 0$, and substituting this value of θ_1 in equation (10), we have

$$p = \mathrm{C} + \frac{6\mu \mathrm{U}ac\sin\theta(2 + c\cos\theta)}{\eta^2(2+c^2)(1+c\cos\theta)^2}. \quad . \quad (12)$$

It will be seen from this that the positions of maximum and minimum pressure are equidistant from the point of nearest approach, and the one value rises above the value of the pressure at that point by as much as the other value falls below it. The distribution of the pressure for values of C of 0·1, ·3, and ·5 is shown in *Fig.* 37. The total vertical force on the journal due to the pressure acts downwards through O and is given by

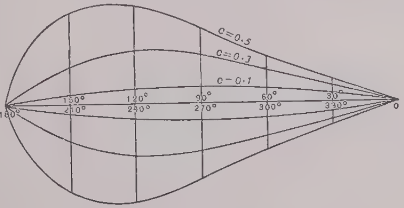

FIG. 37.

$$\mathrm{R} = \int_0^{2\pi} p\sin\theta a d\theta = \frac{12\pi\mu \mathrm{U}a^2c}{\eta^2(2+c^2)(1-c^2)^{\frac{1}{2}}}. \quad (13)$$

The total force due to the viscous drag on the surface of the journal must by symmetry act through O′ and is given by

$$\mathrm{S} = \int_0^{2\pi} f\sin\theta a d\theta.$$

Now

$$f = -\mu\left(\frac{\partial u}{dy}\right)_{y=0} = \left[\mu\frac{\mathrm{U}}{h} + \tfrac{1}{2}h\frac{\partial p}{\partial x}\right]_{y=0} \text{ by (7)}$$

$$= \frac{\mu \mathrm{U}}{\eta}\left[\frac{4}{1+c\cos\theta} - \frac{6(1-c^2)}{(2+c^2)(1+c\cos\theta)^2}\right],$$

or

$$\mathrm{S} = \frac{4\pi\mu \mathrm{U}a}{\eta c}\left[2 - \frac{4-c^2}{(2+c^2)(1-c^2)^{\frac{1}{2}}}\right]. \quad (14)$$

Again the couple exerted on the journal is

$$\mathrm{M} = \int_0^{2\pi} fa^2 d\theta = \frac{4\pi\mu \mathrm{U}a^2(1+2c^2)}{\eta(2+c^2)(1-c^2)^{\frac{1}{2}}}. \quad (15)$$

Now if f' be the viscous drag on the surface of the *bearing*

$$f' = -\mu\left(\frac{du}{\partial y}\right)_{y=h} = \mu\left[\frac{\mathrm{U}}{h} - \tfrac{1}{2}h\frac{\partial p}{\partial x}\right].$$

Hence on the bearing the corresponding forces and couples are R′ acting upwards through O′ and equal to R

$$\mathrm{S'} = \frac{4\pi\mu \mathrm{U}a}{\eta c}\left[1 - \frac{2(1-c^2)^{\frac{1}{2}}}{2+c^2}\right], \quad . \quad (16)$$

$$\mathrm{M'} = \frac{4\pi\mu \mathrm{U}a^2(1-c^2)^{\frac{1}{2}}}{\eta(2+c^2)}. \quad . \quad . \quad (17)$$

Now S and S′ are not equal and opposite, but being of a smaller order than R and R′ may be neglected. In fact it has been shown by Sommerfeld that a closer approximation would establish their identity. The inequality of M and M′ is, however, an essential characteristic of the equality of the force systems (R, M), (R′, M′), R acting at O and R′ at O′. Taking different values of c the ratio of M to M′ is

$c=0$	·1	·4	·6	·9
M/M′ 1	1·03	1·51	2·69	13·8

The coefficient of friction for the journal is given by

$$\lambda=\frac{\mathrm{M}}{\mathrm{R}a}=\frac{\eta(1+2c^2)}{3ac},$$

and that for the bearing λ′ by

$$\lambda'=\frac{\mathrm{M}'}{\mathrm{R}'a}=\frac{\eta(1-c^2)}{3ac}.$$

An appreciation of these facts is of value in the practical determination of the coefficients of friction of bearings in laboratory experiments, for if, as is almost universally the practice, the friction on the bearing is determined it is evident that the actual coefficient of the journal is considerably greater than the value so determined unless the speed be sufficiently great to make c comparatively small.

The fact that the frictional resistance of a journal running at constant speed increases slightly as the load is increased may be illustrated by calculating the values of M and R from equations (13) and (15) for given values of c and assumed values of μ, U, a, and η and plotting the results. This has been done in *Fig.* 38 for a bearing and journal in which

$\mathrm{U}=500$ cm. per sec.,
$a=2{\cdot}5$ cm.,
$\eta={\cdot}005$ cm.,
$\mu-1$,

the calculated values of R and M being as follows:

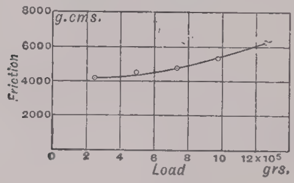

FIG. 38.

c.	R in Grammes.	M in Gramme Cm.
·1	240,200	4084
·2	480,900	4325
·3	722,300	4735
·4	961,500	5319
·5	1,232,500	6164

It will be seen that by increasing the load in the ratio of 5 to 1 the friction is increased by 47 per cent.

The variation in the amount of the frictional resistance as the speed is increased, the load remaining constant, may be shown by calculating the values of U and M from equations (13) and (15) for different values of c, R being constant.

This has been done for the same bearing, journal, and lubricant as in the previous example, taking the value of R as 1,232,500 grammes when $c={\cdot}5$.

The calculated values of U and M are as follows:

c.	U Cm. p.s.	M Gramme Cm.
·5	500	6,164
·4	637	6,660
·3	855	7,970
·2	1285	10,900
·1	2085	16,720

The results are shown in *Fig.* 39, in which the ordinates are the values of M and the abscissae those of U. It will be seen that at the low speeds an increase in the speed of about 30 per cent only results in an increase in the frictional resistance of about 8 per cent, but at the high speeds the friction is practically proportional to the speed.

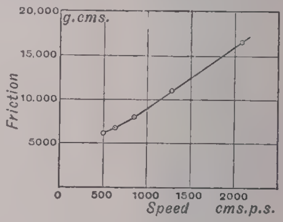

FIG. 39.

It should be noted that the above deductions from Harrison's theory—the ratio of the couple on the journal to that on the bearing and the variations of friction with load and speed—are based on the assumption of a film of lubricant which is continuous round the journal and in which the pressure distribution is symmetrical about a horizontal section through the axis, as in *Fig.* 37. No experimental investigation of the pressure distribution in a lubricated bush appears to have been made, but from some preliminary observations at the National Physical Laboratory it would appear that such a symmetrical distribution is not commonly obtained in practice.

§ (28) FRICTIONAL RESISTANCE OF FLAT INCLINED SURFACES. (i.) *Michell's Theory.*—The hydrodynamical theory of the pressure distribution between two flat inclined surfaces separated by a film of fluid has been worked out by Michell,[1] who has obtained a complete solution in three dimensions for a slide block of finite length and width. The results obtained have recently been applied with great success to the design of thrust blocks of marine engines, and an outline of the analysis may be given here. Let the plane rectangle ABCD in *Fig.* 40 represent the lower surface of a rectangular slide block moving with velocity U over the plane xOz, the space between the planes being filled with a liquid of viscosity μ. U is taken as positive in the direction xO, and the planes AC, xOz are assumed to intersect in the line Oz and the planes AC, xOy the line AB. The width of the block AD is taken as π. Let h = distance between the planes at the point x, y and let $\theta = xOB$, the angle between the planes. Put

---

[1] *Zeitschrift für Mathematick*, 1905, lii

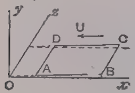

FIG. 40.

$$c=\sin\theta, \quad OA=a, \quad OB=b, \quad h=cx.$$

The boundary conditions are, if p = pressure of liquid at x, y,

$p=0$ when $x=a$ or $x=b$ for all values of z.
$p=0$ when $z=0$ or $z=\pi$ for all values of x.

Then, precisely as in the case of the complete cylindrical bearing (see p. 377), it follows that between the planes AC and xOz, p as a function of x and z must satisfy the equation

$$U\frac{\partial h}{\partial x}=\frac{\partial}{\partial x}\left(\frac{h^3}{6\mu}\cdot\frac{\partial p}{\partial x}\right)+\frac{\partial}{\partial z}\left(\frac{h^3}{6\mu}\cdot\frac{\partial p}{\partial z}\right)$$

or
$$\frac{\partial^2 p}{\partial x^2}+\frac{3}{x}\cdot\frac{\partial p}{\partial x}+\frac{\partial^2 p}{\partial z^2}-\frac{6\mu U}{c^2x^3}=0. \quad . \quad (1)$$

Assuming a solution of the form

$$p=p_1+p_2+p_3+\ .\ .\ .\ p_m,$$

where
$$p_m=\frac{w_m \sin mz}{mx} \quad . \quad . \quad . \quad (2)$$

and w_m is a function of x only, we have

$$p=\Sigma\frac{w_m \sin mz}{mx}.$$

Writing $mx=\zeta$, $24\mu U/\pi c^2=k$, and equation (1) as

$$\frac{\partial^2 p}{\partial x^2}+\frac{3}{x}\cdot\frac{\partial p}{\partial x}+\frac{\partial^2 p}{\partial z^2}-\frac{6\mu U}{c^2x^3}\cdot\frac{4}{\pi}\left\{\sin z+\frac{\sin 3z}{3}+\ .\ .\ .\ \frac{\sin mz}{m}\right\}=0,$$

the sum of the series of sines being $\pi/4$ for all values of z between o and π, we have

$$\left.\begin{aligned}\frac{\partial p}{\partial x}&=m\frac{\partial p}{\partial \zeta}=m\Sigma\left\{\frac{1}{\zeta}\cdot\frac{\partial w_m}{\partial \zeta}-\frac{w_m}{\zeta^2}\right\}\sin mz\\ \frac{\partial^2 p}{\partial x^2}&=m^2\frac{\partial^2 p}{\partial \zeta^2}=m^2\Sigma\left\{\frac{1}{\zeta}\cdot\frac{\partial^2 w_m}{\partial \zeta^2}-\frac{2}{\zeta^2}\cdot\frac{\partial w_m}{\partial \zeta}+\frac{2w_m}{\zeta^3}\right\}\sin mz\\ \frac{\partial^2 p}{\partial z^2}&=-\Sigma\frac{m^2 w_m}{\zeta}\sin mz\end{aligned}\right\}, \quad (3)$$

the differentiation of the series term by term with respect to z being permissible because $p=0$ when $z=0$, and $z=\pi$.

The coefficient of $\sin mz$ in equations (3) now becomes

$$\frac{m^2}{\zeta}\left\{\frac{\partial^2 w_m}{\partial \zeta^2}+\frac{1}{\zeta}\cdot\frac{\partial w_m}{\partial \zeta}-\left(1+\frac{1}{\zeta^2}\right)w_m-\frac{k}{\zeta^2}\right\}, \quad (4)$$

and since every such coefficient must vanish,

$$\frac{\partial^2 w_m}{\partial \zeta^2}+\frac{1}{\zeta}\cdot\frac{\partial w_m}{\partial \zeta}-\left(1+\frac{1}{\zeta^2}\right)w_m-\frac{k}{\zeta^2}=0. \quad (5)$$

The complete solution of (4) is seen to be

$$w_m=A_mI_1(\zeta)+B_mK_1(\zeta)-k\left(1+\frac{\zeta^2}{3}+\frac{\zeta^4}{5\,.\,3^2}+\frac{\zeta^6}{7\,.\,5^2\,.\,3^2}+\ .\ .\ .\right) \quad (6)$$

or

$$w_m=A'_mI_1(\zeta)+B'_mK_1(\zeta)-k(\zeta^{-2}+3\zeta^{-4}+5\,.\,3^2\zeta^{-6}+7\,.\,5^2\,.\,3^2\zeta^{-8}+\ .\ .\ .\ ),$$

where $I_1(\zeta)$ and $K_1(\zeta)$ are the Bessel functions of ζ. Hence the value of p_m will be

$$p_m=\frac{\sin mz}{mx}\left\{A_mI_1(mx)+B_mK_1(mx)-\frac{24\mu U}{\pi c^2}\left(1+\frac{(mx)^2}{3}+\frac{(mx)^4}{5\,.\,3^2}\ .\ .\ .\right)\right\} \quad (7)$$

or

$$p_m=\frac{\sin mz}{mx}\left\{A'_mI_1(mx)+B'_mK_1(mx)-\frac{24\mu U}{(mx)^2\pi c^2}(1+3(mx)^{-2}+5\,.\,3^2(mx)^{-4}\ .\ .\ .\ )\right\},$$

or writing for convenience

$$L_1(mx)=\frac{4}{\pi}\,\frac{1}{mx}\left(1+\frac{(mx)^2}{3}+\frac{(mx)^4}{5\,.\,3^2}+\ .\ .\ .\right)$$

$$L_2(mx)=\frac{4}{\pi}\,\frac{1}{(mx)^3}\left(1+3(mx)^{-2}+5\,.\,3^2(mx)^{-4}.\ .\ .\right),$$

we have
$$C=\frac{6\mu U}{c^2},$$

$$p_m=\sin mz\left\{A_m\frac{I_1(mx)}{mx}+B_m\frac{K_1(mx)}{mx}-CL_1(mx)\right\} \quad (8)$$

or

$$p_m=\sin mz\left\{A'_m\frac{I_1(mx)}{mx}+B'_m\frac{K_1(mx)}{mx}-CL_2(mx)\right\},$$

the first form being suited for calculation when mx is small, the second when mx is large.

The coefficients are determined from the condition that p_m vanishes when $x=a$ or b for all values of z.

The intensity of pressure at any point x, y having been determined, the total pressure

$$P=\int_0^\pi\int_a^b p\,dx\,dz \quad . \quad . \quad . \quad (9)$$

may be found by arithmetical or graphical summation. The friction per unit area at any point x, o, z, precisely as in equations on p. 377, is given by

$$f = -\mu\left(\frac{\partial u}{\partial y}\right)_{y=0} = \mu\frac{\mathrm{U}}{h} - \frac{h}{2}\cdot\frac{\partial p}{\partial x}, \quad . \quad (10)$$

where U is the velocity of the fluid in the direction of x at x, y, z.

The resistance of the whole block is therefore given by

$$\int_0^\pi\int_a^b\left(\mu\frac{\mathrm{U}}{h} - \frac{\partial p}{\partial x}\cdot\frac{h}{2}\right)dxdz$$

$$= \pi\int_a^b \mu\frac{\mathrm{U}}{cx}dx - \int_0^\pi\int_a^b\frac{\partial p}{\partial x}\cdot\frac{cx}{2}dxdz$$

$$= \pi\int_a^b \mu\frac{\mathrm{U}}{cx}dx - \frac{c}{2}\int_0^\pi\left\{(p_b - p_a) - \int_a^b pdx\right\}dz$$

$$= \frac{\pi\mu\mathrm{U}}{c}\log\frac{b}{a} + \frac{c}{2}\cdot\mathrm{P}. \quad . \quad . \quad . \quad . \quad (11)$$

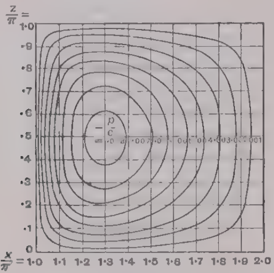

FIG. 41.

(ii.) *The Results of the Application of the Theory to Special Cases. Case I. Square Block—length of side* $=\pi$, $b=2a$.—The distribution of pressure over the block is shown in *Fig.* 41, in which the lines of equal values of p/C, *i.e.* equal values of $pc^2/6\mu\mathrm{U}$, are shown. For tables of the values of the Bessel functions required and the method of obtaining the values of the coefficients, reference may be made to the original paper. The mean pressure is found by arithmetical summation to be $\bar{p} = (\mathrm{P}/\pi^2) = -\cdot 0213(\mu\mathrm{U}/c^2)$, and the position of the resultant pressure is $\cdot 42\pi$ from the rear end of the block. The nominal coefficient of friction

$$= -\frac{\mathrm{F}}{\mathrm{P}} = 10{\cdot}83c.$$

Case II. Slide Block of Width equal to one-third of its Length, $b=2a$, as before.—The distribution of pressure is shown in *Fig.* 42, the mean pressure is given by

$$\bar{p} = \frac{\mathrm{P}}{3\pi^2} = -\cdot 00155\frac{\mu\mathrm{U}}{c^2},$$

and the position of the resultant pressure is at ·39 of the length of the block from the rear end.

The coefficient of friction is $143c$, or thirteen times greater than in the case of the square block.

Case III. Slide Block of Infinite Width.—Assuming $b=2a$ as before, the mean pressure is $\bar{p} = -\cdot 0506\,(\mu\mathrm{U}/c^2)$, the resultant pressure acts at 1·433 of the length of the block from its rear end, and the coefficient of friction is 4·86 C, or less than half of that of the square block.

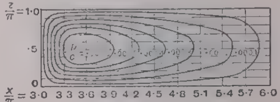

FIG. 42.

The distribution of pressure along the middle line $z=\pi/2$ in this case compared with that for the square and rectangular blocks is shown in *Fig.* 43, in which the influence of the transverse flow in reducing the pressure at the side is clearly brought out.

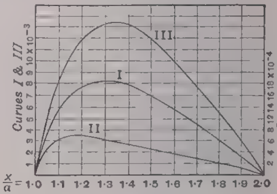

FIG. 43.

The practical application of the essential conditions to secure perfect lubrication between two flat surfaces, indicated by the theory, has led to very great improvements in the design of the thrust blocks of marine engines. Previously collar-thrust bearings of the type shown in *Fig.* 44 were in use. These consisted of collars forming part of the shaft in contact with thrust washers sliding in grooves in the thrust block and transmitting the thrust of the propeller to it. Oil was admitted to the surfaces in contact through radial grooves cut in the thrust washers, but as the two surfaces were coplanar it is evident that no separating oil film could be formed, with the result that the maximum pressure which could be used without seizing was of the order of 60 lbs. per sq. inch. The size and cost of the thrust blocks of large marine engines were therefore very great. The first thrust bearing in which the theoretical condition of an inclination of the surfaces was fulfilled was made by Mr. A. G. M. Michell in

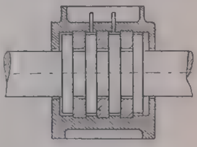

FIG. 44.

Australia in 1905, and since that time the development of this type has been very rapid. *Fig.* 45 shows a bearing on this principle designed by Mr. Newbigin for Messrs. Bellis & Morcom of Birmingham for a steam turbine. In this A is the collar on the shaft, B are the segmental rubbing blocks, the backs of which are cut away to allow of them tipping through the necessary angle to the plane of rotation. C are spacing blocks between which the loose rubbing blocks are fitted. D is the case holding the spacing and rubbing blocks together. E is a washer, concave on one face and flat on the other, to provide means of automatic adjustment. F is the cross-piece with a convex face on to which the washer fits and having holes through which bolts pass to transfer the thrust to the frame of the turbine. The oil is supplied through a hole in the centre of the shaft S. This bearing was tested under a total load of 1500 lbs. or 500 lbs. per sq. inch at a speed of 1750 revolutions per minute, under which conditions it ran continuously at a temperature of 124° F. Owing to the smallness of the angle of inclination of the surfaces it is not practicable to have them fixed, and the blocks are pivoted about an axis passing through the line of action of the resultant of the oil pressure and the friction. In this way the block automatically sets itself to the correct inclination. Designed in this way thrust-bearings have been constructed which have run continuously with a pressure as high as 3000 lbs. per square inch.

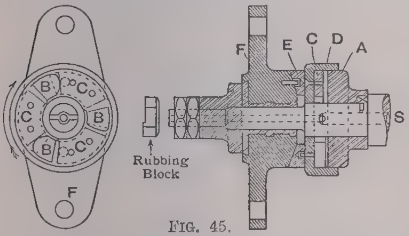

FIG. 45.

IV. THE FRICTIONAL RESISTANCE OF SOLID SURFACES SEPARATED, OR PARTIALLY SEPARATED, BY A FILM OF FLUID OF SUCH SMALL DIMENSIONS LATERALLY THAT THE RESISTANCE IS NO LONGER DUE TO THE SHEARING STRESS IN THE FLUID ALONE

§ (29) OILINESS.[1] (i.) *Lubrication.*—In the cases of the frictional resistance of surfaces separated by a film of fluid whose motion can be predicted from the equations of hydrodynamics, such as those discussed earlier in this article, it is, of course, obvious that the resistance is entirely independent of the nature of the surfaces and dependent on the characteristics of the fluid, so that it may be assumed that, in the case of two bearings and journals of identical dimensions and speed and loaded in such a manner that the relative position of journal and bearing is the same for each, but supplied with different lubricants, the frictional resistances are proportional to the coefficients of viscosity of the two lubricants used. It has long been known, however, by practical engineers that trouble in running machinery caused by hot bearings can be cured by the use of certain oils whose viscosity was of the same order as that of the oil used in the hot bearing. Thus in the case of the heating up of the crank-pins of gas-engines lubricated by mineral oil it is common practice to substitute castor oil for the mineral oil, with the result that the friction diminishes to its normal value and smooth running results. Now the value of μ for castor oil does not differ appreciably from that of a good lubricating mineral oil, so it is evident that the former possesses some lubricating property apart from its viscosity. Although considerable attention has been devoted to the study of this property of good lubricants, no definite relation has yet been found between it and the other physical properties of the oil, and the property itself is somewhat vaguely referred to as "oiliness." There seems, however, to be no doubt that the determining factor of oiliness is the chemical composition of the lubricant and that those oils which contain a large proportion of unsaturated hydrocarbons are the best lubricants. An explanation of the relative superiority as regards lubricating value of animal and vegetable oils over mineral oils is suggested by Langmuir's theory of adsorption. According to this theory, the fact that animal and vegetable oils spread upon water whereas mineral oils do not is due to the presence of an active group in the molecule in the former case and its absence in the latter.[2] The soluble glycerine ester end of the rod-like molecule tends to dissolve in the water, but the insoluble hydrocarbon end refuses to do so, with the result that the molecule stands on end and the surface of the water is covered with a layer of closely packed molecules of the animal or vegetable oil.[3] On the other hand, the mineral oils with hydrocarbon groups at each end of the molecule are inert, and spreading does not take place. Similarly, when a liquid whose molecules contain active groups is in contact with a solid surface adsorption takes place and the molecules orient themselves into the surface layer of the solid in the same manner. We may therefore regard the lubrication of surfaces in apparent contact as being in the extreme case a condition in which the surfaces are separated by a layer of oil one molecule thick, resembling a piece of velvet firmly glued to the metal with the pile outwards. Two such velvet-clad surfaces will presumably be able to glide over each other with little friction, and that lubricant will be the most efficient in which this spreading action over the metallic surfaces is the most complete. It is evident that the action here presumed will depend on the chemical composition of the surface of the bearing, and this affords an explanation of the well-known fact that in cases of lubrication in which, owing to the circumstances of the motion and loading, perfect or "film" lubrication cannot take place, the frictional resistance depends on the nature of the metallic surface, with the result that "anti-friction metals," as they are called, are much used. Mr. Archbutt has recently found that under the same conditions of speed and nature of lubricant the lining of a bronze bearing with white metal enabled double the load to be carried.

(ii.) *Relation between the Lubricant and the Surface—Deeley's Experiments.*—The lubrication of surfaces under the conditions mentioned above and the determination of the coefficients of friction between surfaces of different metals in contact when lubricated with various oils have been investigated by Mr. R. M. Deeley, who has constructed a special machine for the purpose. In this machine (*Fig.* 46) three steel pegs each $\frac{5}{32}$ inch in diameter symmetrically placed in a circle of 7 cm. diameter rest on the flat surface of a disc of metal which can be slowly rotated. These pegs are carried by an upper disc which can be loaded as desired and which actuates a spindle to which a spiral spring and recording index are attached. When the lower disc is rotated the upper disc is carried with it by means of the frictional resistance between the surfaces of the peg and the lower disc, the index recording the value of the torque, until slipping occurs. A pawl and ratchet are attached to the gear to prevent the index from moving back along the scale when slipping takes place. The movable disc on which the pegs rest lies in a circular dish which can be filled with oil. The mechanical details of the machine will be clear from *Fig.* 46. In order to obtain clean surfaces of the disc and pegs these were ground under water with flour of carborundum. They were then polished with fine wet emery cloth, rubbed well in water with a cork to remove as much emery as possible, dried with clean blotting-paper, and finally heated to get rid of all traces of moisture. As soon as the surface was dry it was wetted with the lubricant to be tested, placed in the machine, and the static friction coefficient determined in the manner described above.

As illustrations of the effect of the nature of the metals in contact and of the lubricant employed, the following results of experiments made by Mr. Deeley may be quoted. The pegs were made of mild steel. One of the discs used was of cast iron and the other was a lead-iron alloy of the following composition:

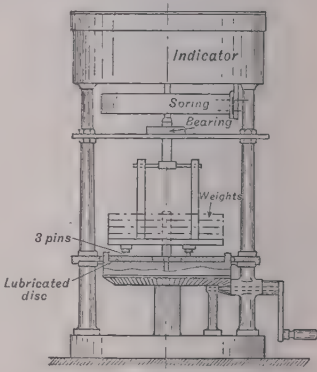

FIG. 46.

Copper	85·88
Tin	5·71
Lead	4·00
Zinc	4·19
Iron	0·10
Nickel	0·12
	100·00

The static coefficient of friction is taken as the mean frictional resistance of the peg divided by the load, and the efficiency of the lubrication is taken as 100 − (static coefficient × 100). Table I. gives the results obtained.

From the results it will be seen that the efficiency of lubrication of mild steel on cast iron is higher than for mild steel on the alloy for all the lubricants tested, but that the amount of the difference varies with the nature of the oil tested, the advantage of the cast iron varying from 0·5 per cent in the case of a mineral oil used for clocks to 12 per cent in the case of a mineral oil used for typewriters. Rape and olive oils give the best results and the mineral oils the worst.

It is of interest to note that those oils which according to the experiments have the lowest coefficient of friction are those which are generally acknowledged by engineers to be the best lubricants.

The general conclusions which Mr. Deeley[1] draws from his experiments are as follows:

---

[1] *Phys. Soc. Proc.*, 1919, discussion on Lubrication.

“‘Oiliness’ appears to be an effect produced by the lubricant upon the metallic surfaces with which it is in contact rather than a property depending on any particular physical property of the lubricant. It would appear that the unsaturated molecules of the lubricant enter into a firm physico-chemical union with the metallic surfaces, thus forming a friction surface which is a compound of oil and metal. This solid surface would also appear in the case of metallic surfaces to be much more than one molecule thick, the oil either penetrating some little distance into the metal and altering its physical properties or as a result of abrasion forming a paste of metal plus oil between surfaces covered by oil layers one molecule thick.”

§ (30) THE N.P.L. GEAR EFFICIENCY EXPERIMENTS. (i.) *Lanchester's Apparatus.*—A series of experiments on lubrication, in which the contact of the sliding surfaces and the distribution of the lubricant was probably of the nature of that presumed in the foregoing discussion, has recently been carried out at the National Physical Laboratory. These experiments consisted of tests of the efficiency of transmission of power through a worm-gear when using different kinds of oils, and were carried out for the Lubricants and Lubrication Inquiry Committee of the Department of Scientific and Industrial Research. The testing machine was specially designed by Mr. F. W. Lanchester for the accurate measurement of the efficiency of power transmission through a worm-gear. A sketch of the machine is given in *Fig.* 47 and an enlarged view showing a section of the gear-box and the oil circu-

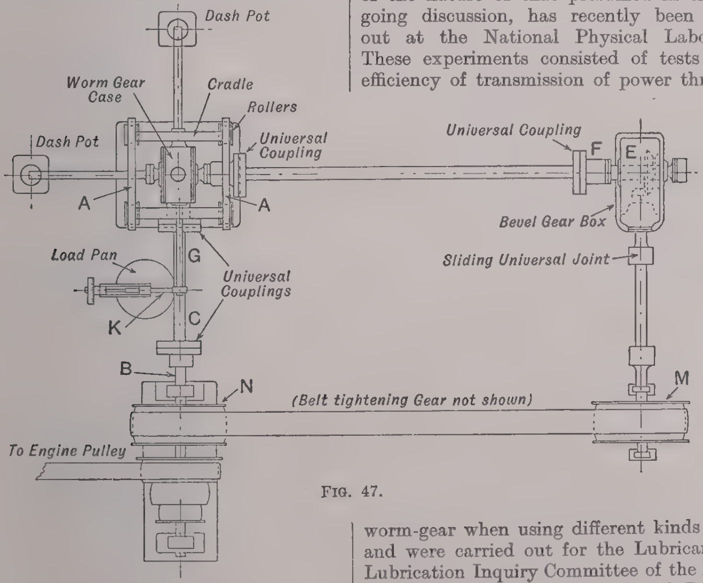

FIG. 47.

lating system in *Fig.* 48. It will be seen from *Fig.* 47 that the gear-box is supported in a cradle A in such a manner that it has freedom of motion through a small angle about two axes at right angles. The worm is driven by the shaft B through the intermediate shaft C, the latter being provided with universal couplings at each end. In the same manner the worm-wheel shaft is connected to the bevel box E, through the shaft D, and the universal couplings F, F. The load is supported by a bracket K fixed to the arm G, the axis of this arm being parallel to and in the same vertical plane as the worm-shaft axis. The load is not fixed directly to the bracket but is carried by a slider, and by means of a screw and nut device the distance of the load from the axis of the arm can be varied. The bracket is permanently fixed to the arm and thus the moment of the load about the worm-wheel axis is equal to the load multiplied by the length of the arm and is always the same for the same load. The moment about the worm-shaft, however, can be adjusted by means of the screw-gear, there being a scale on the bracket giving the distance of the centre line of the load from the axis of the arm. It will be seen, therefore, that if the efficiency of the gear is 100 per cent and the gear ratio 3 to 1 so that the speed of the worm is three times the speed of the worm-wheel, the torque on the worm-shaft will be one-third of that on the worm-wheel shaft, and therefore the distance of the load from the worm axis will be one-third of its distance from the wheel axis. As the efficiency of the gear is less than 100 per cent, it will be necessary to move the load farther from the worm axis in order to balance the gear-box. The calculated distance of the load from the worm axis, assuming 100 per cent efficiency, divided by the distance of the load to obtain a balance of the gear-box is the efficiency of the gear. The drive is taken through the bevel-box to the belt pulley M, the latter being of such a diameter that it tends to drive the pulley N keyed to the driving shaft B at from 3 to 5 per cent higher speed than it is actually making. In this way, by the frictional slipping of the belt over the surface of the pulley keyed to the shaft B, all the power transmitted through the gear, with the exception of that lost in friction of the bevel-gear and shaft-journals, is returned to the driving-shaft. The system constitutes, therefore, a power circuit, and all that is necessary to be supplied

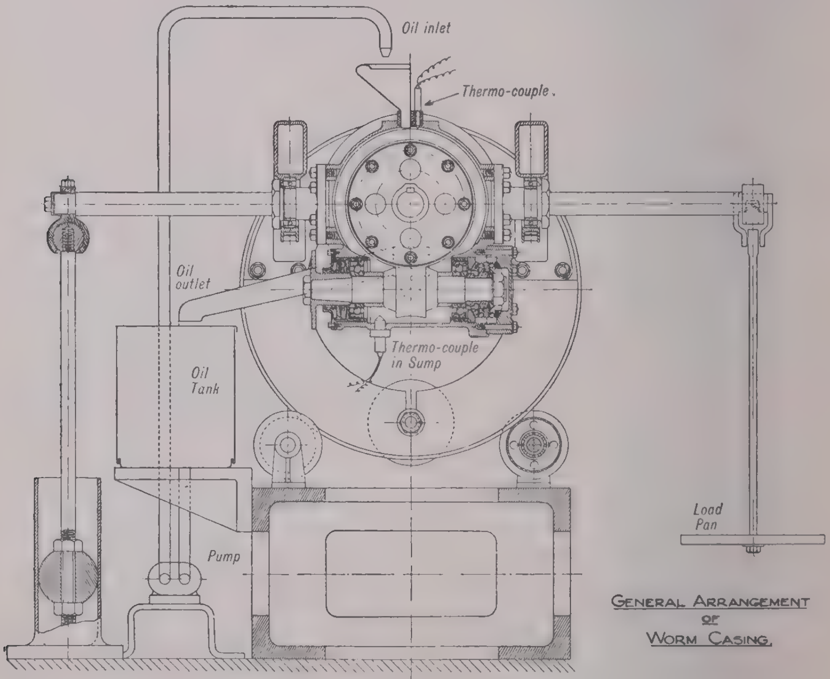

FIG. 48.

from outside sources is the total loss due to the friction of the whole machine. This loss is supplied by a belt drive to the cone pulley P from a 15-h.p. petrol motor. It is arranged that the tension in the belt connecting the pulleys M and N can be adjusted over a wide range, an increase in the belt tension causing an increase in the pressure between the teeth of the worm and worm-wheel, and therefore an increase in the torque. In the machine described the pressure between the teeth could be increased to a value corresponding with a transmission of 100 h.p.

Fig. 48 shows in detail the method of supporting the gear-box. It is held by means of the ball-bearing CC in the cradle A, which can itself rotate through a small angle by rolling in the ball-bearing rollers B and B.

The lubricant contained in the tank shown in *Fig.* 48 is fed into the top of the gear-box by means of a rotary pump, and leaves by means of the pipe K, the hole in the side of the box being about on a level with the top of the worm. The temperature of the oil entering and leaving the gear is taken by thermocouples. It was estimated that in the experiments the absolute accuracy of the efficiency obtained was within 0·2 and 0·3 per cent of the true value, and the agreement of the readings was within 0·1 per cent. A difference corresponding to 0·1 per cent in the efficiency could easily be detected when the apparatus was running smoothly. The gears tested were of the Hindley type, cut by the Daimler Company on Mr. Lanchester's principle, by means of which a high efficiency of transmission is secured even under extremely heavy loading of the lubricated surfaces. In the tests to be described the mean pressure on the surface ranged from 1½ to 2 tons per square inch, and efficiencies of 97 per cent were obtained.

A brief description of the results obtained with various lubricants may be given.

In carrying out the tests it was found that starting with the lubricant at the normal temperature of the room the heat developed in friction at the surfaces of the worm and wheel was such that the temperature of the oil in the receiver gradually increased, thus enabling a consecutive series of observations to be carried out at gradually reduced values of the viscosity.

(ii.) *Experimental Results.* — A complete series of efficiency tests at temperatures of the lubricant ranging from 15° C. to 75° C. were carried out on the following samples of oil:

Mineral	FFF Cylinder. Bayonne. Victory Red.
Animal	Trotter (a substitute for lard oil).
Vegetable . . .	Rape. Castor.
Fish	Sperm.

The more important physical properties of these oils will be seen from the following tables giving the results of determinations made at the National Physical Laboratory:

TABLE II

DENSITY AND VISCOSITY AT 20° C.

	Viscosity / Density	Density.	Viscosity.
Castor . .	7·8	·95	7·5
Rape . .	·99	·91	·90
Trotter . .	·98	·91	·89
Sperm . .	·38	·88	·34
FFF Cylinder	22·1	·89	19·6
Bayonne. .	1·8	·90	1·6
Victory Red.	12·9	·941	12·2

TABLE III

FFF Cylinder	500	36·7	·476
Bayonne. .	375	36·1	·460
Victory Red	274	38·5	·423

(iii.) *The Critical Temperature.*—In the case of all the mineral oils tested it was found that when a certain temperature of the oil had been reached, called the "critical temperature," the running of the gear became decidedly unsteady, and a marked increase in the rate of fall of efficiency with temperature was observed. Experiments beyond the critical temperature were continued until it was considered that the test could not be carried further without injuring the gear. In the case of animal and vegetable oils, no critical stage was reached at temperatures below 75° C., beyond which the tests were not carried.

(iv.) *Conclusions.*—The general nature of the results at a mean pressure on the teeth of $1\frac{1}{2}$ ton per square inch are indicated by the curves in *Fig.* 49, of which the ordinates are the values of the efficiency of transmission and the abscissae the values of the temperature of the lubricant.

It will be seen that at atmospheric temperature the efficiencies of the four fixed oils are appreciably higher than those of the mineral oils, but that in all cases the efficiency is remarkably high, varying from 93·5 for the FFF Cylinder to 95·5 for the fixed oils. When the temperature exceeds 30° the extreme range in the efficiency is not so large as at 20°, and this relative performance is maintained up to about 47° C., at which the critical point of the Bayonne oil is reached and its efficiency falls rapidly. The critical point of the Victory Red oil is not so well defined, but would appear to be approximately 50° C. The performance of the FFF Cylinder, however, remains remarkably constant up to a temperature of 17° C., when a very rapid break in the behaviour of the oil was noted, and the efficiency fell, as in the case of the other mineral oils. The behaviour of the Sperm oil was somewhat abnormal, as the efficiency appeared to form continuously from 20° to 60° and then remained steady. There was, however, no sign of a critical point having been reached. There can be no doubt that the relative superiority of the fixed oils is due to the absence, within the range of temperature obtained, of a critical point. The fact that the critical points of two of the mineral oils were reached at a temperature of 50° C. would have an important bearing on their practical value as lubricants, since such temperatures are not uncommon in internal combustion engines and turbine lubrication.

In *Fig.* 50 are exhibited the results of the same series of tests plotted on a base of absolute viscosity of the lubricant instead of temperature. It will be seen that throughout there is no indication that the frictional resistance of the gears is even approximately proportional to the viscosity of the lubricant employed, as would be the case if the surfaces were separated by a film of oil of measurable thickness. This conclusion is strikingly verified in the comparison of the results for Castor and Trotter oils. At 40° C. the viscosity of Castor oil is approximately six times that of Trotter, but in the tests at this temperature the frictional resistances were approximately the same. As regards the effect of pressure, it was found that there was an appreciable increase (2 per cent) in efficiency obtained by raising the pressure from 1·5 to 2·0 tons per square inch, and further there was an increase of 1 per cent in the efficiency by raising the speed of the worm-shaft from 500 to 1500 r.p.m.

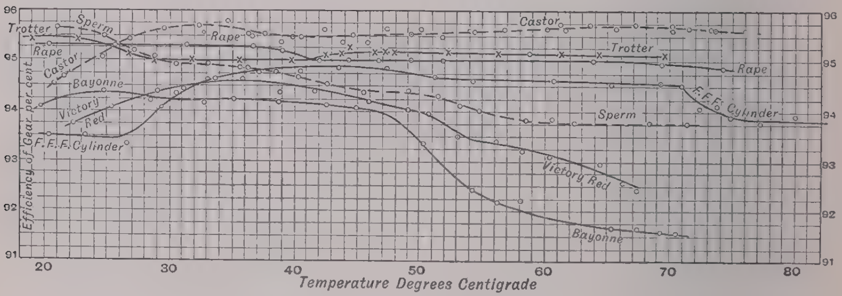

FIG. 49.

(v.) *Effects of Mixture.*—As practical experience showed that the lubricating value of a mineral oil could be increased by adding a certain proportion of animal or vegetable oil to it, some experiments on various mixtures were made. It was found that the addition of Rape oil in any proportion to the mineral oils did not appear to increase the efficiency very appreciably—an increase of 0·2 per cent was noted—but the critical temperature of the oil to which the addition of Rape was made was raised considerably. This effect of raising the critical temperature could be obtained with the addition of as small a quantity of Rape as $2\frac{1}{2}$ per cent, and increasing this amount up to 25 per cent did not appear to make any very marked improvement as regards changing the critical point. The general effect of varying the percentage of Rape oil added to a mineral oil is shown in *Fig.* 51. Experiments were also made on the effect of adding Castor oil in various proportions to a mineral oil, and similar results to those observed in the case of Rape were obtained. To determine whether the beneficial effect of adding the fixed oil to the mineral oil was due to the fatty acids

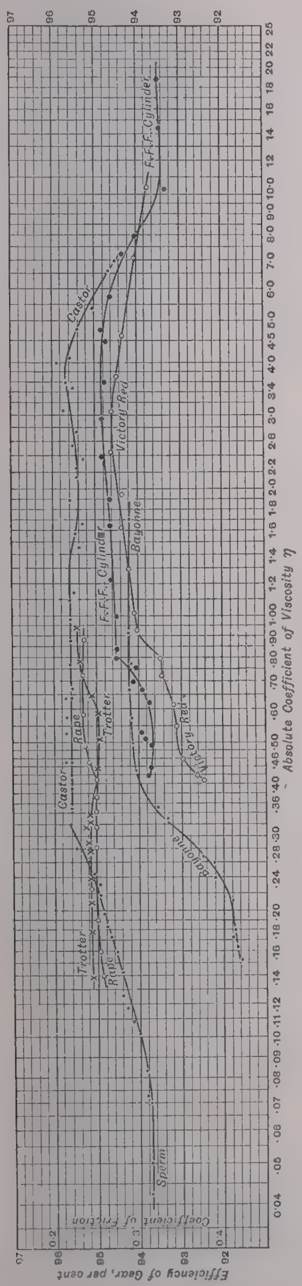

FIG. 50.

contained in the fixed oil, the following comparative tests were made:

(1) Tests on Bayonne oil alone.

(2) Tests on Bayonne oil with 10 per cent of acid Rape added.

(3) Tests on Bayonne oil to which 10 per cent of Rape oil, from which the fatty acids had been removed, was added.

(4) Tests on Bayonne oil to which 1·0 per cent of Rape oil fatty acids had been added.

The results are shown in *Fig.* 52. It will be seen that the effect of adding 1 per cent of fatty acids to the Bayonne is to produce a marked improvement in the efficiency and to raise the critical point from 47° C. to 57° C. The addition of the Rape oil from which the fatty acids had been extracted produced, on the other hand, practically no improvement. The general results of the tests may therefore be taken as confirmatory of the hypothesis that the fatty acids in the fixed oils are the main factors in the relatively greater lubricating efficiency of these oils.

A series of experiments was also undertaken to determine the effect of adding deflocculated graphite to the oils. This is a special preparation of graphite in a finely divided state which when mixed with oils forms a colloidal mixture called "Oildag," from which the graphite cannot be separated by mechanical means. The general effects of adding Oildag to the lubricants was as follows:

Trotter and Rape.—General lubricating efficiency unaffected by the addition.

Castor.—A small rise (about 0·5 per cent) in the efficiency due to the addition was observed.

Bayonne.—The temperature efficiency curve did not show the characteristic critical point, the efficiency falling gradually with rise of temperature up to 80° C.

FFF Cylinder.—A small increase of efficiency (0·2 to 0·4 per cent) due to the addition, and a rise of the critical point from 72° C. to 90° C. was noted.

Victory Red.—The critical period was smoothed out and a rise in the efficiency of about 0·5 per cent was noted.

The general results showed that the addition of the Oildag was to reduce appreciably the differences between the mineral oils and to bring their lubricating efficiencies to nearly the same value.

Oildag appears, therefore, to have the effect of rendering an inferior mineral oil as good a lubricant as a superior one in that it not only raises the lubricating value of an inferior oil, but considerably reduces the rate of fall of efficiency which usually occurs at temperatures above the critical value.

(vi.) *Tests on the Addition of Flaked Graphite to the Lubricants.*—The results of the use in the testing gear of a mechanical mixture of oil and graphite in a finely divided state was also tried. In these experiments the graphite was maintained in suspension in the oil by the churning action of the pump and gears, but when the test was stopped it settled out and was deposited on the surfaces of the gear and casing.

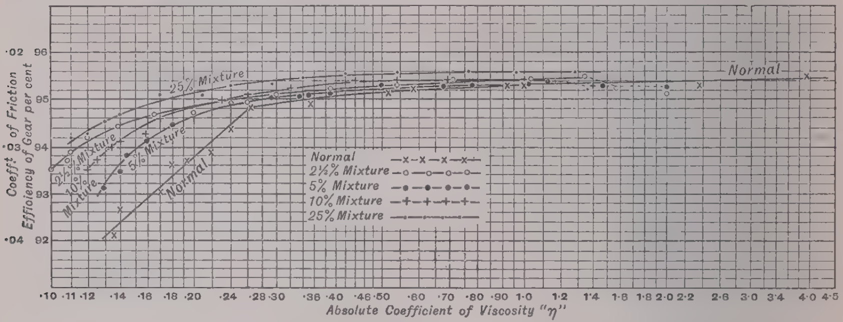

FIG. 51.

The results of the tests showed that the effect varied with the nature of the oils used. In the case of the Trotter and Bayonne oils a marked improvement in efficiency due to the addition of the graphite was found, but the Castor and Victory Red oils were not materially affected. In the FFF Cylinder oil the critical point was raised by 18° C.

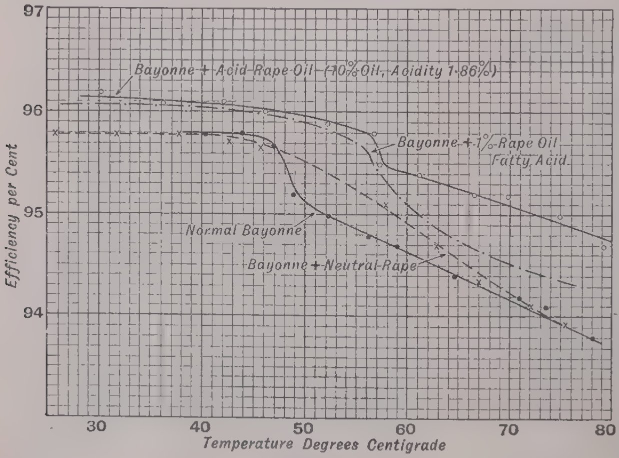

FIG. 52.

It was observed, however, that the rate of wear of the worm-wheel was considerably greater with the flaked graphite than when normal oils or normal oils with Oildag were used.

The results broadly indicated that the addition of graphite to the oils tested has a small but appreciable beneficial effect on their lubricating properties, but it is not certain that this would be the case with all oils.

V. THE FRICTION OF DRY SOLID SURFACES

§ (31) LAWS OF FRICTION.—As would be expected from the imperfect knowledge of the molecular and molar actions which take place at the surfaces of separation of solid bodies in contact, the nature of the surface action is still obscure and, in consequence, the so-called laws of solid friction are largely empirical. Further, it is now recognised that these laws are only rough approximations owing to the fact that the experiments upon the results of which they are based were, for the most part, made on surfaces which were not clean and were usually contaminated by the presence of some fluid moisture, the presence of which materially affected the frictional resistance.

In the case of two solid bodies in contact over a surface the component of any external force tending to cause relative motion of the two bodies by sliding over this surface is exactly balanced by the frictional resistance between the surfaces up to a certain limiting value of the external force, and if this value is exceeded, sliding of the bodies takes place.

The fundamental law of solid friction is that this limiting value of the frictional resistance is a definite fraction of the normal force with which the surfaces in contact are pressed together.

Coefficient of Friction: Angle of Repose.—The value of this fraction is called the coefficient of friction f, and depends on the nature of the surfaces. For example, in *Fig.* 53 let XY be the trace of the surface of contact, and let P, inclined at an angle ϕ to the normal, be the resultant force exerted on one body by the other body.

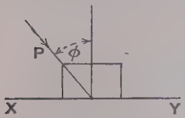

FIG. 53.

Then the force with which the bodies are pressed together is P cos ϕ and the lateral force tending to make them slide over each other is P sin ϕ. Now by the law of solid friction P sin ϕ cannot exceed P cos ϕ without sliding taking place, and therefore at the instant of sliding

$$P \sin \phi = fP \cos \phi$$

or

$$f = \tan \phi.$$

It follows, therefore, that the greatest angle of obliquity of the resultant pressure to the normal to the surfaces is the angle whose tangent is the coefficient of friction. This angle is called the angle of repose, and a knowledge of its value for various substances is important in the design of engineering structures. The following table is commonly used by engineers, and is based on that drawn up by General Morin after very extensive investigations:

TABLE I

	f.	ψ.
Dry masonry and brickwork	0·6-0·7	31°-35°
Timber on stone . . .	About 0·4	22°
Iron on stone . . .	0·7-0·3	35°-16·6°
Timber on timber . .	0·5-0·2	26°·5-11°
Timber on metals . .	0·6-0·2	31°-11°
Metals on metals . . .	0·25-0·15	14°-8°·5
Masonry on dry clay .	0·51	27°
Masonry on wet clay .	0·33	18°
Earth on earth . . .	0·25-1·0	14°-45°

When once sliding has taken place the frictional resistance may retain the value which it had at the instant sliding began, or, as is commonly the case, its value may be appreciably reduced and take up a value which depends on the relative velocity of the surfaces. It will be clear, therefore, that between the surfaces of solids in contact there may be two kinds of friction, (1) the frictional resistance before sliding takes place, and which may have any value up to the limiting resistance depending on the normal pressure and the coefficient of static friction, and (2) the frictional resistance when sliding, in which the coefficient of friction may be smaller than the statical coefficient, and which may also depend to some extent on the motion.

§ (32) STATIC FRICTION.—The subject of static friction is of considerable importance in the theory of the stability of engineering structures, and has received much attention on account of its wide application in civil engineering practice. In the design of structures consisting of masonry and brickwork, it is assumed that the pieces are in contact over the plane surfaces which constitute the joints, and that the mortar or cement used for bedding the surfaces together is incapable of resisting any forces other than compression and friction. It is obvious, therefore, that an essential condition for the stability of the structure is that the obliquity of the pressure should at no joint exceed the angle of repose for the materials.

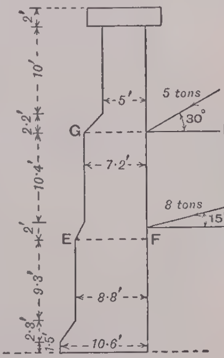

FIG. 54.

As an illustration of the application of the data of Table I. the stability of the buttress in *Fig.* 54 may be calculated. This is supposed to be made of strong brickwork, weighing 112 lbs. per cubic foot of the dimensions given in the cross-section, and of a uniform width of 5 feet. The buttress has to sustain two inclined thrusts applied to it at the points indicated, the upper one being the thrust of a roof principal which is 5 tons, inclined at an angle of 30° to the horizontal, and the lower one the thrust of an arch which is 8 tons, inclined at an angle of 15° to the horizontal. It is evident that the joints which are most liable to slide are GH, where the thrust of the roof is applied, and the joint immediately below the point of application of the arch-thrust which is at EF. If these joints are secure the stability of the others need not be investigated. Considering the joint GH, the lateral force tending to cause sliding is 5 cos 30 = 4·32 tons. The weight of the buttress above GH is 21·6 tons, which, added to the vertical component of the thrust, gives a total normal pressure on the joint of 24·1 tons. The maximum resistance to sliding may be calculated from the value of f for brickwork, which from the Table in § (31) is seen to be ·6, and is therefore 14·4 tons, or more than three times the actual lateral force. The joint is therefore safe.

Again, taking the joint EF, the total lateral force on the buttress above EF is

$5 \cos 30 + 8 \cos 15 = 4{\cdot}32 + 7{\cdot}75 = 12{\cdot}07$ tons. The weight of the buttress above EF is 44·3 tons, which, added to the vertical components of the two thrusts, gives a total normal pressure on the joint of 48·8 tons. The maximum resistance to sliding is therefore $\cdot 6 \times 48{\cdot}8$ or 29·3 tons, or more than twice the lateral force due to the thrust. The buttress is therefore safe as regards lateral movement. To complete the investigation it would, of course, be necessary to consider the resistance of the buttress to overturning or crushing at any joint.

§ (33) THE FRICTIONAL STABILITY OF EARTH.[1]—A structure of earth, whether produced by excavation or embankment, preserves its figure partly by the friction between its grains and partly by means of their mutual cohesion. It is by cohesion that a bank of earth is enabled to stand with a vertical face for a few feet below its upper edge, whereas friction alone would make it assume a uniform slope.

The cohesion of earth is, however, gradually destroyed by the action of air and moisture, so that its friction alone is the only force which can be relied upon to produce permanent stability. It is therefore customary to treat the stability of a mass of earth as arising wholly from the mutual friction of the grains, and to take as the basis of all investigations on stability the principle that the resistance to displacement by sliding along a given plane in a loose granular mass is equal to the normal pressure exerted between the parts of the mass on either side of that plane multiplied by a specific constant. This constant is the coefficient of friction of the mass and is the tangent of the angle of repose.

Now in a granular mass any plane whatever may be considered as a plane joint, and hence it follows that the condition for the stability of a granular mass is that the direction of the pressure between the portions into which it is divided by any plane should not at any point make with the normal to that plane an angle greater than the angle of repose.

Again, it follows, from a consideration of the distribution of internal stresses in a solid, that the plane at any point of it on which the obliquity of the pressure is greatest is perpendicular to the plane which contains the axes of greatest and least pressure, so that the pressure of greatest obliquity and the greatest and least pressures are all parallel to one plane. The relation between them may therefore be obtained from the stress ellipse of a body subject to pressures parallel to one plane, the equation of which is $P^2 = a^2 \sin^2 \alpha + b^2 \cos^2 \alpha$, where P is the stress on a plane whose normal is inclined to the axis of y at an angle α, and a and b are the maximum and minimum stresses. Thus, in *Fig.* 55, let $OA = a$, $OB = b$, and let zz be a plane whose normal makes an angle θ with OM where OM represents the stress on zz. The angle MOQ therefore represents the obliquity of the stress on zz. Also, if R is the middle point of PQ,

$$PQ = a - b, \quad RP = RQ = RM = \frac{a-b}{2},$$

and evidently the angle MOQ is a maximum when RM is perpendicular to OM, and then

$$\text{Maximum angle of obliquity} = \sin^{-1} \frac{a-b}{a+b},$$

and in that case $OM^2 = (a+b/2)^2 - (a-b/2)^2 = ab$, or stress on $zz = \sqrt{ab}$.

Again, for any value of the obliquity, we have, if $OM = p$,

$$\left(\frac{a-b}{2}\right)^2 = \left(\frac{a+b}{2}\right)^2 + p^2 - 2\left(\frac{a+b}{2}\right) p \cos \theta,$$

or $$-ab = p^2 - (a+b) p \cos \theta,$$

which gives the relation between the maximum and minimum stresses and the stress whose obliquity to the plane on which it acts is θ. Now in the case of a mass of earth whose upper surface is either horizontal or inclined to the horizontal at a definite angle, it is clear that on any plane parallel to the surface, and whose depth below the surface is small compared with the lateral dimensions of the surface, the pressure is vertical and of a uniform intensity equal to the weight of the vertical prism standing on unit area of the given plane.

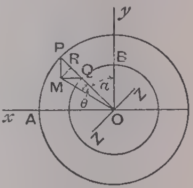

FIG. 55.

Further, it follows that the stress on any vertical plane parallel to the horizontal trace of the first plane must be in a direction parallel to this plane, for considering the equilibrium of a small prism ABCD (*Fig.* 56) whose centre is at O and whose faces are parallel to XOX and YOY, it is evident that the forces exerted by the other parts of the mass on the faces AB and CD are directly opposed and that they are independently balanced. The forces on AC and BD are therefore independently balanced, which cannot be the case unless their direction is parallel to YOY. Stresses related in this manner are said to be conjugate stresses, and it is evident that their obliquities to the planes on which they act are the same.

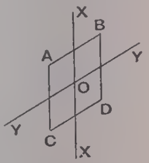

FIG. 56

If, therefore, we consider in *Fig.* 55 another stress p' which is conjugate to p, *i.e.* $\theta' = \theta$, we have

$$\frac{a+b}{2} = \frac{p+p'}{2 \cos \theta'}, \text{ and } \frac{a-b}{2} = \sqrt{\left(\frac{p+p'}{2 \cos \theta}\right)^2 - pp'}.$$

---

[1] See Rankine's *Applied Mechanics*, p. 212.

Also, if ϕ be the *maximum* obliquity, it follows that, since

$$\sin\phi = \frac{a-b}{a+b},$$

$$\therefore \frac{(p+p')^2}{4pp'} = \frac{\cos^2\theta}{\cos^2\phi},$$

i.e. p and p' are the roots of the quadratic

$$P^2 - 2P\cos\theta + \cos^2\phi = 0,$$

or
$$\frac{p'}{p} = \frac{\cos\theta - \sqrt{\cos^2\theta - \cos^2\phi}}{\cos\theta + \sqrt{\cos^2\theta - \cos^2\phi}}.$$

Applying this condition to the equilibrium of a mass of earth in which one conjugate plane is a plane parallel to the surface of the earth and at a depth h below it, it is evident that the pressure per unit area of this plane is $wh\cos\theta$, where w is the weight per cubic foot of the earth and θ is the inclination of the surface to the horizontal. The pressure on the other conjugate plane, which is vertical, is, as we have seen, parallel to the surface, but as regards its magnitude it may be either the greater or the smaller of the two conjugate pressures; *i.e.*, calling this conjugate pressure p, the value of p may be either

$$wh\cos\theta\,\frac{\cos\theta - \sqrt{\cos^2\theta - \cos^2\phi}}{\cos\theta + \sqrt{\cos^2\theta - \cos^2\phi}}$$

or
$$wh\cos\theta\,\frac{\cos\theta + \sqrt{\cos^2\theta - \cos^2\phi}}{\cos\theta - \sqrt{\cos^2\theta - \cos^2\phi}}.$$

To find which value to take in any special case, recourse is had to a statical principle known as Moseley's Principle of Least Resistance, which is stated as follows.[1] If the forces which balance each other in or upon a given body or structure be distinguished into two systems called respectively active and passive, which stand to each other in the relation of cause and effect, then will the passive forces be the least which are capable of balancing the active forces consistently with the physical condition of the body or structure.

This proposition may be regarded as self-evident, since the passive forces being caused by the application of the active forces to the body or structure will not increase after the active forces have been balanced by them, and will therefore not increase beyond the least amount capable of balancing the active forces.

In a mass of earth loaded with its own weight the gravity of the mass is evidently the active force and the lateral pressure the passive force, and, therefore, the latter will have the least value which is consistent with the conditions of stability. In the case, therefore, of a bank of earth with a plane upper surface, the pressure parallel to the steepest declivity on a vertical plane at a point distant h below the surface is

$$wh\cos\theta\,\frac{\cos\theta - \sqrt{\cos^2\theta - \cos^2\phi}}{\cos\theta + \sqrt{\cos^2\theta - \cos^2\phi}},$$

or, if the ground surface be horizontal,

$$wh\frac{1-\sin\phi}{1+\sin\phi}.$$

To find the resultant pressure against a vertical plane of depth H below the surface it is evident that, since the pressure is directly proportional to the depth, we may apply the ordinary rules of hydrostatics, from which the centre of pressure is two-thirds of the total depth from the surface and the resultant force is

$$\frac{wH^2}{2}\cdot\cos\theta\frac{\cos\theta - \sqrt{\cos^2\theta - \cos^2\phi}}{\cos\theta + \sqrt{\cos^2\theta - \cos^2\phi}}.$$

§ (34) CASE OF THE SUPPORTING POWER OF EARTH FOUNDATIONS. (i.) *Theory.*—In the case treated above the conjugate pressure was caused solely by the vertical pressure due to the weight of earth above the point considered, and its value was therefore the smaller of the two conjugate pressures.

It is evident, however, that this conjugate pressure may be increased beyond this least amount by the application of the pressure of an external body—for example, the weight of a building founded on the earth. In this case the conjugate pressure will be the least which is consistent with the vertical pressure due to the weight of the building, and if that conjugate pressure does not exceed the greatest conjugate pressure consistent with the weight of the earth above the stratum on which the building rests, the mass of earth will be stable. The most important case in practice is when the surface of the ground is horizontal.

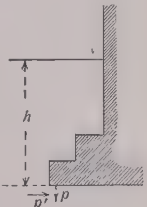

FIG. 57.

Thus, in *Fig.* 57, let p be the intensity of the pressure on a horizontal stratum due to the weight of the building. Then the horizontal conjugate pressure p', being the passive force, is given by

$$p' = p\frac{1-\sin\phi}{1+\sin\phi}.$$

The effect of p' is to cause an upward thrust on the earth immediately above the footings of the foundations, and calling this p'', then since p'' is also a passive force,

$$p'' = p'\frac{1-\sin\phi}{1+\sin\phi}.$$

Now $p'' = wh$, where w is the weight per cubic foot of the earth and h is the depth of the foundation below the surface of the ground, and therefore

---

[1] Rankine's *Applied Mechanics*, p. 215.

$$p=p''\left(\frac{1+\sin\phi}{1-\sin\phi}\right)^2=wh\left(\frac{1+\sin\phi}{1-\sin\phi}\right)^2.$$

It is evident that, if h has a less value than that given by this relation, there will be a tendency for the building to sink into the ground by forcing the earth upwards.

h, therefore, is a minimum value to the depth of the foundations.

Again, if the depth is such that there is a tendency for the earth pressure to overcome the pressure due to the weight of masonry, as in the case of the floor of a dock before the water is admitted, then p'' is the active force, and

$$p'=p''\left(\frac{1-\sin\phi}{1+\sin\phi}\right)$$

or $$p=p''\left(\frac{1-\sin\phi}{1+\sin\phi}\right)^2=wh\left(\frac{1-\sin\phi}{1+\sin\phi}\right)^2.$$

The value of h determined from this relation gives a maximum which cannot be exceeded without danger of the masonry being forced upwards.

In applying this formula it must be remembered that by hypothesis the lateral extent of the mass of earth is large compared with the depth. When this is not the case, as in the region at the back of a retaining wall, the frictional resistance of the wall will affect the pressure distribution. It has been shown by Boussinesq[1] that at a distance x from the face of the retaining wall, if θ be the angle of friction between wall and earth, and $a^2=1-\sin\ \phi/1+\sin\ \phi$, then for x less than ah the

$$\text{Horizontal pressure}=\frac{w(h+x\tan\ \theta)a^2}{1+a\tan\ \theta}.$$

$$\text{Vertical pressure}=\frac{w(h+x\tan\ \theta)}{1+a\tan\ \theta}.$$

The ratio of the pressures is a^2 as in Rankine's theory. When $x=0$ the horizontal and vertical pressures become $wha^2/1+a\tan\theta$, $wh/1+a\tan\theta$, and the tangential force on the face is evidently $wha^2\tan\ \theta/1+a\ \tan\ \theta$.

(ii.) *Experimental Verification.*—The limits of accuracy in practice of the Rankine formula has been the subject of several very careful experimental investigations, and it has been found that provided the material is perfectly free from moisture the accuracy is remarkably high. Thus in some experiments by Wilson[2] on dry sand, the following results were obtained from direct observations of the ratio of the pressures, and by calculation of the ratio from the observed angles of repose of the sand.

TABLE II

DRY SAND

	Ratio of Pressures.		
	Maximum.	Minimum.	Mean.
By Rankine theory	0·339	0·296	0·320
By experimental measurement of the pressures	0·336	0·305	0·319

In these experiments the values of the angle of repose were obtained in two ways, one by placing the sand in a heap and subjecting it to vibrations until the surface had taken up a definite slope, and the other by placing the sand in a box with a sliding end which was opened gently after tapping. The extreme variation in the value of the observed angle of repose by these methods was from 30°·0 to 32° 53′.

The pressures were obtained by placing the sand in a cast-iron cylinder 11½ inches in diameter, 14 inches deep, provided with movable pistons at the top and bottom ends, the pistons being compressed between the platens of a 100-ton testing machine. In this way pressure equal to that due to a depth of 1341 feet was obtained. The instrument used for measuring the pressure consisted of two steel discs of 3 inches diameter, separated by a ring, and containing mercury, the displacement of which due to the pressure was noted. By placing this alternately parallel to, and at right angles to, the direction in which the external pressure was applied, it was possible to determine the ratio of the two externally applied pressures which gave the same displacement of the mercury and, therefore, the same pressure on the gauge. From the fact that the relation between the load and gauge indications for any position was a linear one, it followed that the ratio of the two loads was equal to the ratio of the horizontal and vertical pressures for the same load.

§ (35) EFFECT OF MOISTURE ON THE STABILITY OF EARTH.—It is well known that the effect of moisture is to increase the cohesion and hence the stability of earth and sand. This is due to the surface tension of the film of water separating the grains, the amount of the traction depending on the amount of moisture. It was found by Wilson that, commencing with sand initially dry, the force between the grains increased with the percentage moisture up to a certain point and then decreased, but so long as the interstices were not entirely filled with water there was still some tractive force, and hence the ratio of horizontal to vertical pressure should be less than that for dry sand. On carrying out a series of experiments on sand containing varying percentages of moisture in the apparatus described above, Wilson fully verified these conclusions, the ratio of the pressures corresponding to the varying degrees of moisture being as follows:

---

[1] *Minutes of Proceedings Inst. C.E.* lxv. 214.

[2] *Proc. Inst. Civil Engineers*, 1901-2, cxlix.

TABLE III

WET SAND

	Percentage of Water.			
	0.	6.	12.	17.
Mean ratio of horizontal to vertical pressure	·319	·221	·212	·280

It is of interest to note that the minimum value of the ratio is obtained when the interstices are half filled with water. It is clear, therefore, that in the design of masonry dams or retaining walls to withstand earth pressure, the use of Rankine's formula with a value of the angle of repose determined from experiments on the dry material will give a result which is on the safe side.

§ (36) THE KINETIC FRICTION OF DRY SOLID SURFACES.—As mentioned above, when once sliding has commenced between the surfaces of two bodies in contact, there is in the majority of cases a sudden fall in the amount of the frictional resistance so that the coefficient of kinetic friction for two substances is usually less than the coefficient of static friction. Jenkin and Ewing[1] have shown that for hard substances such as steel on steel the two coefficients are equal, but when one or both surfaces are of relatively softer material, such as brass or greenheart, the coefficient of kinetic friction is less than that of static. They also found that when the two coefficients differ, the change, at low speeds at any rate, is not instantaneous at the instant at which relative motion begins, but takes place gradually and without discontinuity. Cases have been noted by Kimball in which the coefficient of kinetic friction is greater than that of static friction. Leather on cast iron appears to be an instance of this. A marked falling off in the value of the coefficient of kinetic friction as the relative speed of sliding is increased appears to be a universal characteristic of dry sliding surfaces. There is also in many cases a further progressive fall in the value of the coefficient with time which is probably due to the abrasive action of the surfaces tending to produce greater smoothness.

(i.) *Experiments on Brake Blocks.*—Both of these characteristics are noticeable in the results of Captain Galton's[2] experiments on the frictional resistance of cast-iron brake blocks on steel waggon wheels, as will be seen from Table IV.

TABLE IV

Relative Velocity of Brake and Wheel in Miles per Hour.	Coefficient of Friction.			
	First 3 Seconds.	5 to 7 Seconds.	12 to 16 Seconds.	24 to 25 Seconds.
60	·062	·054	·048	·043
50	·10	·07	·056	..
40	·134	·10	·08	..
30	·184	·111	·098	..
20	·205	·175	·128	·07
10	·32	·209	..	..
5	·36	..	..	..

A similar reduction in resistance due to increase of speed was found in Captain Galton's experiments on the frictional resistance of locomotive driving wheels on steel rails. These results are shown in Table V.

TABLE V

Speed in M.P.H.	Coefficient of Friction.	Speed in M.P.H.	Coefficient of Friction.
10	·11	38	·057
15	·087	45	·051
25	·08	50	·04

It may be remarked that similar speed effects in the case of locomotive driving wheels on steel rails was found by M. Poirée, but the actual values of the coefficients were about twice those given in the table. This difference was probably due to the state of the atmosphere during the trials, which is known to have a considerable effect on the frictional resistance. A common set of rules for driving wheels in different conditions is as follows:

Rails very dry—frictional resistance 600 lbs. per ton.
Rails very wet—frictional resistance 550 lbs. per ton.
Rails in ordinary English weather—frictional resistance 450 lbs. per ton.
Rails in foggy weather—frictional resistance 300 lbs. per ton.
Rails in frosty and snowy weather—frictional resistance 200 lbs. per ton.

(ii.) *Friction of Woven Fabrics.*—In recent practice the use of metal as a material for the friction surfaces of the brake blocks of railway carriages and the clutches of motor vehicles has been in many cases discontinued owing to the discovery that woven fabrics can be made which, when used as linings for brakes and clutches, give a higher coefficient of friction with greater dissipation of heat without burning and sparking, and have a much greater durability than can be obtained with metals.

One of these materials is known as the

---

[1] *Phil. Trans. R.S.* clxvii., Part ii.

[2] *Engineering*, xxv. 469.

Ferodo fabric, which consists of layers of woven asbestos bonded together in a special manner.

In an extensive series of tests at the National Physical Laboratory the following results were obtained:

Material.	Pressure Lbs./Sq. In.	Work absorbed in Ft.-lbs./Sq. In. per Minute at 1000 Ft. per Minute.
Ferodo fibre .	60	39,000
Ferodo bonded asbestos compressed	60	18,000
Standard . .	50	15,500

The value of the coefficient of friction obtained and the work absorbed with Ferodo fibre at different speeds are given in Table VI.

It is claimed that the average life of Ferodo blocks on the cars and trailers of the London Electric Railway is respectively 12,000 and 22,000 miles as against 8000 for cast-iron blocks. With cast iron at £6 per ton, the economy per block per 1000 miles is given as 0·75 pence. As many as 600 brake applications are made by each train per day, the average speed, including stops, being 17·17 miles per hour, and the average mileage per set of blocks per car being 16,416.

Table VI

Tests on Ferodo Fibre

Pressure Lbs./Sq. In.	Coefficient of Friction.			Work absorbed in Ft.-lbs./Sq. In. per Minute.		
	Speed (Ft. per Minute).			Speed.		
	600	2900	5500	600	2900	5500
16	·73	·64	..	..	..	..
27	..	..	·56	..	..	80,000
29	·70	·63	..	12,000	..	..
39	..	·64	..	..	70,000	..

The deceleration averages 5 feet per second per second as against 3 feet per second per second with metal block. With this increased deceleration services have been speeded up to $1\frac{1}{4}$-minute headways during "rush" hours. The more rapid braking of the trains has also led to a higher percentage of coasting minutes, the tests showing that coasting is as high as 38 per cent of the total running time.

Notwithstanding this high rate of braking, there has been an entire freedom from accidents to passengers, and there is also a very considerable improvement in the tyres, the surfaces of which are highly polished, and there is an entire absence of cutting and scoring. The economy in this respect is shown by the fact that the mileage of motor wheels provided with Ferodo brake blocks is approximately 35,600 per $\frac{1}{16}$-inch radial wear of the tyre compared with 7000 in the case of metal blocks.

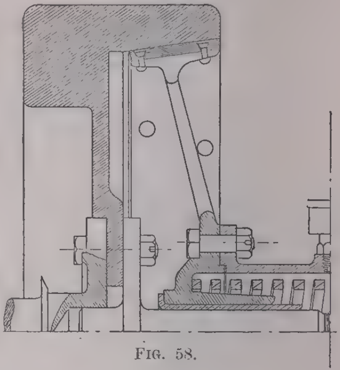

Fig. 58.

An illustration of the application of the fabric to a clutch is shown in *Fig.* 58.

§ (37) The Transmission of Power by Friction. (i.) *Belts.*—One of the most convenient methods of the distribution of power from a central supply to a number of small machines is by means of belt or rope drives from pulleys on a line of shafting driven by the prime mover, to corresponding pulleys on the various machines. When the pulleys are at rest and no power is being transmitted, the tensions on the two sides of the belt are equal; but when the driving pulley commences to rotate, slipping of the surfaces of the pulleys over the surface of the belt is prevented by friction, and rotation of the driven pulley consequently takes place. The relation between the tensions on the two sides of the belt and the coefficient of friction of the belt on the surface of the pulley may be found as follows:

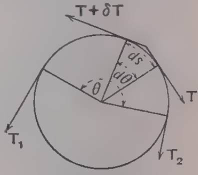

Fig. 59.

Let θ in *Fig.* 59 be the whole arc of contact of the belt over the pulley. Consider any element ds of the arc of the belt of which the tensions at the ends are T and $T+\delta T$. Then if $d\theta$ be the angle subtended by ds at the centre, we have resolving along the radius

$$(T+\delta T)\sin\frac{d\theta}{2}+T\sin\frac{d\theta}{2}=R,$$

the normal pressure of the element of belt ds on the surface of the pulley. Thus $R = T\delta\theta$.

Also resolving perpendicular to the radius

$$(T + \delta T)\cos\frac{d\theta}{2} - T\cos\frac{d\theta}{2} = \text{Friction} = \mu R = \delta T.$$

We have therefore $dT = \mu R = \mu T d\theta$, whence by integration over the whole arc of contact $T_1/T_2 = e^{\mu\theta}$.

For leather belts working on iron pulleys μ has been found to range from 0·3 to 0·4. For wire rope running at the bottom of a grooved pulley $\mu = 0{\cdot}15$. A common value for θ in the case of leather belts is 2·5 radians. Taking $\mu = 0{\cdot}3$ this gives $T_1/T_2 = 2$, or the tension on the tight side is twice the tension on the slack side. For approximate calculation of the size of a belt to transmit a given horse power $T_1btV/2 \times 33{,}000 = \text{H.P.}$ transmitted where V is the velocity of the surface of the pulley in feet per minute, b is the breadth and t the thickness of the belt in inches, and T_1 is the maximum working tension of leather, which may be taken as equal to about 320 lbs. per square inch.

(ii.) *Effect of Slipping.*—Belts are not used in cases in which a very exact velocity ratio between the driving and driven shafts is essential, on account of the tendency of the belt to slip over the surface of the pulley. There is also a definite amount of slipping which follows as a consequence of the elasticity of the belt. The amount of this slipping may be estimated as follows. The actual mass of the belt which passes any fixed point either on the tight side or the slack side in unit time is the same. Let l_0 be the length of this mass when the tension is zero, and let b, t and E be the breadth, thickness, and modulus of elasticity of the belt. Also let T_1 and T_2 be the tensions on the tight and slack sides of the belt. Then on the tight side the length passing any fixed point in unit time will be $l_0(1 + T_1/btE)$ and on the slack side the corresponding length will be $l_0(1 + T_2/btE)$, and it is evident, therefore, that these numbers will represent the velocities of the belt on the tight and slack sides, *i.e.* the velocities on the two sides will be in the ratio of $(1 + T_1/btE)$ to $(1 + T_2/btE)$. Further, it is easy to show that the velocity of the surface of the driving pulley must be equal to that of the tight side of the belt, and that the velocity of the surface of the driven pulley must be equal to that of the slack side of the belt. Thus the belt comes on to the surface of the driving pulley at tension T_1 and leaves it at a lower tension T_2. It has therefore contracted while in contact with the pulley, and it is evident that the nature of this contraction must be a slip against the frictional force exerted by the pulley, with the result that the belt continually slips over the surface of the pulley to the point where it first makes contact. In the same manner the belt comes on the driven pulley at a tension T_2 and extension takes place gradually from the point at which contact begins to the point at which it leaves.

Now the work delivered to the driving pulley is $(T_1 - T_2)\,bt \times$ (velocity of surface of driving pulley) and the work communicated to the driven shaft is $(T_1 - T_2)\,bt \times$ (velocity of surface of driven pulley), *i.e.* the efficiency of power transmission $= (1 + T_2/btE)/(1 + T_1/btE)$, or approximately $1 - (T_1 - T_2)/btE$.

Ex.—The value of Young's modulus for leather is approximately 20,000 lbs. per sq. in. Assuming $T_1 = 2T_2$, which will be the case when the coefficient of friction is about 0·3 and that the maximum working tension of a leather belt is 320 lbs. per sq. in., we have

Efficiency of transmission $= 1 - {\cdot}016 = 98{\cdot}4$ per cent.

The amount of slip is therefore 1·6 per cent.

(iii.) *Friction Drive.*—Another instance of the transmission of power by friction is seen in the attempts which have been made to substitute a friction drive for the ordinary spur gear arrangements commonly adopted in motor cars to obtain variable and reverse speeds. This has been successfully carried out in the well-known "G.W.K." motor car, in which the friction gear takes the form of a metal disc driving a fibre-faced wheel at right angles to it, the speed variation being obtained by varying the distance of the centre of the fibre-faced wheel from the axis of the metal driving disc. Reversal of direction can, of course, be obtained by moving the driven wheel to the opposite side of the disc axis.

In the case of the "G.W.K." car the driving disc is fixed axially, while the driven wheel, which is capable of being moved along its shaft to obtain the various gears, is pivoted at one end and pulled towards the driving disc by means of a spring at the other end. This is so arranged that the contact pressure between the two friction elements is lightest on top gear and increases as the gear ratio is lowered. This method has an obvious advantage over one in which the pressure between the wheels is constant at all speeds, since the amount of the pressure must be fixed to give an adequate frictional resistance at low speeds, and this means that the top gear on which 90 per cent of the running is done is used with a pressure between the wheels about three times in excess of what is necessary.

The coefficient of friction between the fibre material and the polished steel disc used in the "G.W.K." car is about 0·5. It is found in practice that it is safe to allow a peripheral pull on the driven wheel of 100 lbs. for each inch width of the frictional material irrespective of speed.

It is claimed by the makers of the "G.W.K." car that frictional transmission, in the case of cars up to 10 or 12 h.p., has considerable advantages over the ordinary gear-box in that it is much more simple to drive and the cost of replacements due to unskilful handling and ordinary wear is much smaller.

§ (38) Rolling Friction.—The resistance to the motion of wheels and rollers over a smooth plane has sometimes been attributed to the inaccuracies of the surface, and it has been supposed that if these were removed, the resistance would entirely disappear, provided that both roller and plane were made of elastic materials and the load on the roller were not sufficient to cause permanent deformation of either surface. It was no doubt some hypothesis of this kind which led the earlier experimenters on the subject to denote the relations which they obtained by the term "laws of resistance to rolling."

The researches of Osborne Reynolds[1] have, however, shown that in all cases in which surfaces roll over each other, an appreciable amount of slipping of the surfaces over each other takes place and it is the frictional resistance to this slipping which constitutes the resistance to rolling.

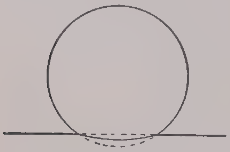

Fig. 60.

This may be seen as follows: Since no material is perfectly hard, when a heavy roller rests on a surface, the weight of the roller will cause it to indent the surface, and the surface of the cylinder will flatten out as shown in *Fig.* 60. It is evident, therefore, that when rolling takes place the distance rolled through the roller in one revolution will not be the circumference of its undisturbed surface. For example, suppose that an iron cylinder rolls on an indiarubber surface across which lines have been drawn at intervals of 0·1 inch, and that as the cylinder rolls across these lines the surface of the rubber extends so that the intervals become 0·11 inch, closing up after the cylinder is past. Then the cylinder measures its circumference on the extended plane and the actual distance rolled through will be one-tenth less than the circumference. Hence if, following Reynolds, we agree to call the distance which the roller would roll through if there were no extension or contraction, its "geometrical distance," then, in the case above, the cylinder rolls through less than its geometrical distance. On the other hand, if we have an indiarubber roller rolling on a steel surface and the surface of the roller extends 10 per cent in passing over the iron surface, it is evident that the roller will pass over a distance in one turn 10 per cent greater than its circumference. It must not be supposed, however, that, if the roller and the plane are of the same material these effects will balance each other. In the case of the flat surface the effect of the materials surrounding a depression will be to stretch the material in the depression still further, whereas in the case of the rounded surface with a small flat on it the material surrounding the flat will compress the material in the flat and decrease its lateral expansion. The magnitude of this latter effect will, of course, depend on the smallness of the diameter of the roller. There are thus two independent causes which affect the progress of a cylinder which rolls on a plane, the relative softness of the materials and the diameter of the roller. These two causes will act in conjunction or in opposition according to whether the roller is harder or softer than the plane. Thus an iron roller on an indiarubber plane will roll through less than its geometrical distance, and an indiarubber roller on an iron plane will roll through a distance more than, less than, or equal to its geometrical distance, according to the relation between its diameter and softness.

(i.) *Slipping and Rolling.*—The precise nature of the slipping action which takes place during rolling is somewhat complicated and is best studied after a preliminary consideration of the relatively simpler cases of the deformation of a soft elastic material between two parallel plates which approach and recede from each other without tangential motion.

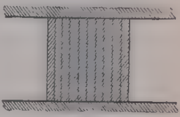

Fig. 61.

Let *Fig.* 61 represent the section of a block of indiarubber between the two plates when in the non-compressed state, and suppose the section to be marked with a series of vertical lines at equal intervals apart. Let the plates approach each other, compressing the rubber, which expands laterally. If there were no friction between the rubber and plates the section would remain rectangular as in *Fig.* 62 and the lines would still be equidistant. If, however, there be a frictional resistance between the rubber and plates which resists the lateral expansion, the section will bulge in the middle as shown in *Fig.* 63. The effect of the friction on the spacing of the lines will be that up to a certain distance, such as *or*, from the centre of the section, the friction will be sufficient to prevent slipping and, there-

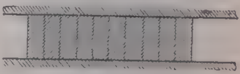

Fig. 62.

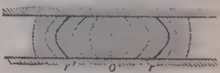

Fig. 63.

---

[1] See *Phil. Trans. R.S.* clxvi.

fore, up to this point the ends of the lines will preserve their original distances apart. Beyond the extremity of *or* slipping will commence and will go on increasing to the edge of the section. From *r* outwards, therefore, the distance between the ends of the lines will continually increase.

If now the surfaces gradually separate again, the lines between *o* and *r* will assume the same forms which they had at corresponding points of the compression, but since the portion beyond *or* has been extended by the compression, it will have to contract and the friction between the surfaces will oppose this contraction. Hence the lines beyond *or* which during compression were curved outwards will gradually straighten and curve inwards as shown in *Fig.* 64.

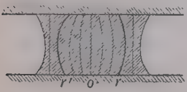

FIG. 64.

It is important to note that during these two actions the smaller the coefficient of friction the greater will be the expansion of the lines during compression, and that as the work spent in friction during separation depends on the amount of this expansion, the work will obviously increase up to a certain point as the coefficient of friction diminishes.

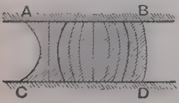

FIG. 65.

In both of the above cases it will be seen that the directions of slipping on opposite sides of the centre are opposite to each other. In the case of a roller, however, it is evident that the material immediately in front of the centre of the surface of contact is being compressed and that behind it is being expanded. This action may be approximately represented in the case of the two plates with rubber between them by supposing the upper plate AB to have been first inclined towards C, so that the material under A was compressed and then inclined towards D so as to raise the end A, thus causing a compression under B and an expansion under A. The sectional lines will therefore assume the form shown in *Fig.* 65, and it is clear that the slipping on each side of the centre now takes place in the same direction. This shows that in the action of rolling the whole of the slipping is in the same direction and tends to oppose the rotation. It is this slipping against the frictional resistance between the surfaces which gives rise to the resistance to the motion of the roller, and hence, as Reynolds showed, the correct denomination of the resistance is "rolling friction." The analogy of the action of the indiarubber between the two plates with the case of a cylinder rolling in a plane surface is not, however, exact, as there is the important difference that in the latter case it is not the entire surface of a bar which is being compressed and expanded but a portion of a continuous surface in which, whatever lateral extension may exist immediately under the roller, must be compensated by a lateral compression immediately in front and behind it.

The nature of the deformation caused by an iron roller moving over an indiarubber plane may be shown as follows. In *Fig.* 66, which represents a section through the cylinder and plane surface, the lines on the indiarubber are supposed to represent lines initially vertical and at equal distances apart. The motion of the roller is towards B, and *or* and *or′* limit the surfaces on which there is no slipping. C and D are the limits of the surface of contact and beyond these points the rubber is laterally compressed owing to the lateral extension of the material under the roller. The lines in this region are, therefore, less than their natural distance apart. From D to *r* the material is being compressed, slipping is taking place, and the lines are convex outwards. From *r* to *r′* there is no slipping, but from *r′* to C expansion with slipping is taking place and the lines are concave outwards. It is clear, therefore, that the distance apart of the lines from *r* to *r′* will depend on the amount of the lateral compression from D outwards, and it is quite possible that this may be such that the distance between the lines from *r* to *r′* may be equal to the natural distance, in which case, as we have seen, the roller will roll through its geometrical distance whatever the actual slipping between D*r* and C*r′*. According to Reynolds this is what actually takes place when an indiarubber roller rolls on an iron plane. The actual slipping is obviously equal to the difference between the intervals between *r* and *r′*, and the intervals at D or C, and will always be greater than the loss of geometrical distance rolled through.

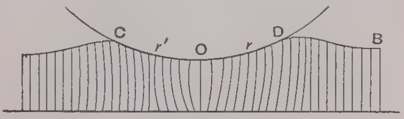

FIG. 66.

From the foregoing examination of the action of rolling, the importance of the distinction between the real and apparent slip in all cases of rolling contact is clearly brought out, the apparent slip being defined as the difference between the circumference of the roller and the distance moved through by its centre in one revolution.

An explanation is also offered of the well-known fact that in general the lubrication of roller bearings is not attended with any beneficial effects in the way of increase of efficiency, but may actually cause a loss of efficiency. Thus referring to *Fig.* 66 it is clear that if the coefficient of friction is very great r and r' will coincide with D and C and there would be no slipping, and hence no work would be spent in friction. On the other hand, if the coefficient of friction were zero, r and r' would coincide with O and there would be no friction and no work spent in overcoming it. Therefore the work spent in friction is zero for two values of the variable which is the coefficient of friction, and since it is positive for all intermediate values it must pass through a maximum value. Hence for some position of r and r', *i.e.* for some value of the coefficient of friction, the work spent in friction is a maximum.

The above conclusions have been verified by Osborne Reynolds by direct experiment, for the details of which reference may be made to the article cited. In particular it may be mentioned that the experiments showed that a hard roller on a soft surface rolls short of its geometrical distance, whereas a soft roller on a hard plane rolls more than its geometrical distance, and that when both roller and plane are of equal hardness the roller rolls through less than its geometrical distance.

§ (39) The Practical Application of Rolling Friction in the Design of Mechanism.—In recent years the loss of energy due to friction of the journals and thrust collars of mechanism has been greatly reduced by the use of ball and roller bearings. Contrary to expectation the insertion between the cylindrical bearing surfaces of mechanism of one or more rings of hardened steel balls running in hardened steel grooves or races so arranged that the sliding action is replaced by the rolling of the balls in the races has proved highly successful under heavy loading. As the effect of a design of incorrect type is likely to prove disastrous in practice, a brief account of conditions to be fulfilled and errors to be avoided may be gathered from the following illustrations of ball bearings which have been tried in practice with varying degrees of success.[1]

(i.) *Ball Bearings.*—One of the earliest types is shown at A, *Fig.* 67. This was formed of a hardened steel sleeve with a V or rounded groove fixed to the shaft, the outer races consisting of two conical rings screwed into the casing by means of a fine thread, with the idea that the races could be adjusted for wear. Since the wear of the race takes place only on the loaded side it is obvious that any adjustment of this kind would be fatal to true running of the shaft.

This fault was remedied in the design B in which the races consisted of two conical rings screwed on the shaft, the outer stationary portion being made flat. In this case the adjustable ring was always rotating and, therefore, the wear was fairly even all round and adjustment was possible, although, as experience has shown, quite unnecessary.

Later two plain races as shown at C, with a cage to keep the balls in position, were found to be successful, the final evolution of the race being shown at D where the races are grooved to a radius of about $\frac{9}{16}$ that of the ball.

In the design of ball thrust bearings the races of the early types were made with 45° grooves as shown at E. The running of this type was very unsatisfactory, with much scratching of the balls. The substitution of a flat surface for one of the grooves as at F was an improvement but not altogether satisfactory. It was found, however, that balls running between two flat rings with a cage G to hold the balls ran quite satisfactorily. This design was still further improved from the weight-carrying point of view by substituting grooves of slightly greater radius than the ball, as in H. For certain purposes, however, the flat race is to be preferred, since, if there is any chance of the shaft getting out of line with its housing, there is less likelihood of trouble in heating and vibration. A high degree of accuracy in the manufacture of balls for ball bearings is very essential. For example, in the case of balls half an inch in diameter, Professor Goodman has found that a distortion of one-thousandth of an inch corresponds with a load of about 130 lbs. of the ball. Hence, if one of the balls in a thrust bearing is one-thousandth of an inch larger than the others, that ball will have about 130 lbs. more load upon it than the others, and probably failure will occur.

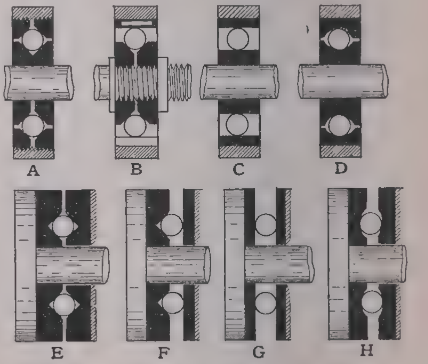

Fig. 67.

In the Skefko ball bearing (*Fig.* 68) the surface of the outer ring is spherical, with the centre at the axis of the shaft. There are two grooves on the inner ring, which can be tilted to one side to allow the balls to be slipped into position, which is a considerable advantage. There is the further advantage that such a bearing can be used on a shaft which is moving out of truth. These bearings are particularly applicable to the case of motor cars and aeroplanes where the framing is not very rigid.

---

[1] Goodman, *Proc. Inst. Aut. Eng.*, 1913–14, viii.

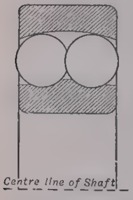

Fig. 68.

(ii.) *Safe Working Load in a Ball Bearing.*—From the results of his experiments, Professor Goodman has been led to adopt the following formula for calculating the maximum working load on a ball bearing:

$$W=\frac{knd^3}{ND+Cd},$$

where W = maximum working load in lbs.,
n = the number of balls in the bearing,
d = the diameter of the ball in inches,
N = the revolutions per minute,
D = the diameter of the ball race in inches; the diameter being taken from the point of contact of the ball with the inner race in a journal bearing, and from the centres of the balls in a thrust bearing.

The constants C and k are as follows:

	C.	k.
For thrust bearings—		
Flat races .	200	500,000
Hollow races .	200	from 1,000,000 to 1,250,000
For journal bearings—		
Flat races .	2000	1,000,000
Hollow races .	2000	from 2,000,000 to 2,500,000

A comparison between the friction of an ordinary white metal bearing and that of a ball bearing is shown in *Fig.* 69. It will be seen that in the case of the white metal bearing the starting effort is very much greater than the normal resistance after it has been running for a considerable time. With ball bearings the reverse is the case, and this, apart from the limiting ratio of the resistances, is an additional reason for the use of ball bearings in machinery which stops and starts frequently.

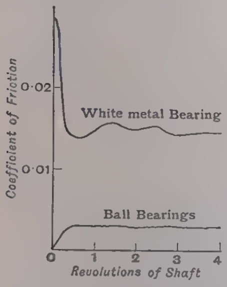

Fig. 69.

For very large bearings, in which the loads are correspondingly high, it is customary to replace the balls by hardened steel rollers. The difficulties in obtaining satisfactory running are greater in these bearings than where balls are used, on account of the end thrust of the rollers brought about by very slight inaccuracies in the machining. A slight amount of end thrust in a roller bearing may increase the frictional resistance tenfold. Various devices to obviate end thrust, such as the insertion of a hardened steel ball between the ends of the roller and the face of the housing, have been tried, but without any great success.

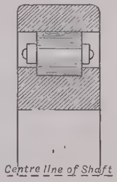

Fig. 70.

One of the most successful roller bearings which have been recently brought out is illustrated in *Fig.* 70. In this the roller runs in a hardened steel rectangular groove ground in the sleeve with great precision, and after an extensive series of tests on it Professor Goodman states that this is the only roller bearing which, in his experience, is practically free from end thrust.

VI. The Relation between Friction and Heat Transmission in the Case of the Motion of a Fluid over a Surface having a Temperature differing from that of the Fluid

§ (40) Heat Transmission. (i.) *Theory.*—The heat interchange between a solid surface and a fluid in contact with it, for a given difference of temperature between them and apart from radiation effects, will evidently be proportional to the rate at which the fluid particles are carried up to the surface, *i.e.* to the diffusion of the fluid in the neighbourhood of the surface. This diffusion may be either (1) molecular, *i.e.* the diffusion of the molecules in a mass of fluid at rest, or (2) molar diffusion, by means of the movement of small portions of the fluid in the form of eddies. The transmission of heat by molecular diffusion constitutes what is known as the thermal conductivity of the fluid, and that by molar diffusion is usually denominated heat convection. Now in the case of a fluid moving over a surface in laminar or streamline motion, there is no molar diffusion between adjacent streamlines or laminae, and, therefore, any transmission of heat to or from the surface in a direction normal to the streamlines must take place by thermal conductivity. On the other hand, when the motion becomes turbulent, it is evident that the eddies constitute the mechanism by means of which the heat is transmitted.

In § (25) it has been shown that in the motion of a fluid over a surface there is always a thin layer at the surface which is in laminar motion when the general motion of the fluid is turbulent, and if the surface be hotter or colder than the fluid it is clear that the heat transmission between layer and surface will take place by means of conductivity, and between the outside of the layer and the mass of the fluid, by eddy motion or convection. In Part I. of this article dealing with "Viscosity," §§ (1), (2), it has been shown that in the case of laminar motion the transfer of momentum between adjacent layers which constitutes the phenomenon of viscosity is effected by the internal diffusion of the fluid, and further that in the case of turbulent motion the corresponding phenomenon of mechanical viscosity is due to the mass diffusion brought about by the eddy-making and turbulence. It would appear, therefore, that the mechanism by which the transfer of momentum which constitutes frictional resistance and that by which the transfer of heat is brought about is essentially the same whether the motion be laminar or turbulent.

The probability of this effect was first pointed out by Osborne Reynolds[1] in 1874 in a paper on the heating surfaces of steam boilers. In this paper Reynolds described an experiment in which, by blowing air through a hot metal tube, the probable accuracy of his theory was demonstrated by the fact that the temperature of the issuing stream of air was approximately independent of the speed of the air current. The method of reasoning leading to this conclusion may be stated as follows. Consider the case of a fluid moving through a parallel pipe of circular cross-section with mean velocity V_m, and let the inner surface of the pipe be maintained at a uniform temperature T_s. Then, neglecting the thermal conductivity effect in the thin layer at the boundary, and assuming all the transmission to take place by eddy motion, the ratio of the momentum lost by skin friction between any two sections distant dx apart, to the total momentum of the fluid, will be the same as the ratio of the heat actually supplied by the surface to that which would have been supplied if the whole of the fluid had been carried up to the surface.

Thus, if dp is the fall of pressure between the sections,
dT the rise of temperature between the sections,
W the weight of fluid passing per second,
V_m the mean velocity of the fluid,
a the radius of the pipe,
T_m the mean temperature of the fluid between the sections.

Then, by the above relation,

$$\frac{(dp)\pi a^2}{W/g \,.\, V_m} = \frac{W dT}{W(T_s - T_m)}.$$

The heat lost per unit area of the pipe is

$$\frac{\sigma W/g \,.\, dT}{2\pi a dx},$$

where σ is the specific heat per unit mass at constant pressure, and if R denote the skin friction per unit area,

$$R = \frac{\pi a^2}{2\pi a} \cdot \frac{dp}{dx}.$$

Hence if Q be the heat transmitted per unit area,

$$Q = \frac{R\sigma(T_s - T_m)}{V_m}. \quad . \quad . \quad . \quad (1)$$

It may be noted that there may be appreciable divergence between the above value of the heat transmission and that actually observed, for, as Reynolds pointed out, "ultimately it is by conductivity that the heat passes from the walls of the pipe to the fluid, so that there will probably be in the result a coefficient $F(k/\nu)$, where k is the coefficient of thermal conductivity of the fluid, the form of which must be determined by experiment."

(ii.) *Experiments.*—A series of experiments were carried out by Dr. T. E. Stanton in 1895 with the object of testing the accuracy of the above relation.[2] The fluid used was water, which was circulated through thin copper tubes heated on the outside by means of a steam jacket. The mean temperature of the tube was estimated from the value of its coefficient of expansion and the increase in length, the value of the surface temperature being then calculated from the known heat transmitted and the thermal conductivity of copper.

In making the experiments it was arranged that the total rise of temperature should not exceed a few degrees, and should be small compared with the range of temperature between metal and water. In this way, in a series of experiments in which V_m was varied, the value of $f(k/\nu)$ referred to above would be approximately constant. Further, since it was known that $R = cV_m{}^n$, writing the relation (1) in the form

$$\frac{Q}{T_s - T_m} = Dv^{n-1},$$

where D is constant, the value of $n - 1$ could be obtained by the usual method of logarithmic plotting.

On making this determination for several sizes of tubes, and with as large a range of speed of flow as could be obtained, it was found that the value of n was practically identical with that found in the frictional determinations (*i.e.* n varied from 1·82 to 1·86), and hence the truth of the relation (1) in its most important practical aspect was fully demonstrated. The fact that the heat abstracted from a hot metal surface by a fluid flowing over it is, for a given difference of temperature between fluid and metal, nearly proportional to the speed at which the fluid moves over the surface, has been of great importance in the design of steam engine condensers, the radiators of internal combustion engines, and the heating surfaces of steam boilers. The application of the Reynolds theory to the case of the design of surface condensers for steam engines has shown[1] that for a surface condenser of given area of cooling surface and supply of cooling water, in order to obtain the greatest velocity of flow, the length of the tube should be as great as possible, and that the most efficient design will be secured by using small tubes of as great a length as is consistent with the extreme limits of frictional resistance to flow allowed. This condition can be easily fulfilled in practice by arranging the tubes in separate compartments, through which the cooling water circulates in series, and thus the *effective* length of the tube can be increased to any desired amount.

---

[1] *Proceedings, Manchester Literary and Philosophical Society*, 1874.

[2] *Phil. Trans. Royal Society*, Series A, cxc.

It may be remarked that, if any means existed of determining the thickness of the layer in laminar motion at the boundary, a check between theory and experiment would be found as follows. Consider first the transmission of heat by eddy motion between the mass of fluid in the interior of the pipe and the outer surface of the layer in laminar motion, which may be assumed to have a velocity U.

Then equation (1) becomes

$$Q = \frac{R\sigma(T_1 - T_m)}{V_m - U}, \quad . \quad . \quad . \quad (2)$$

where T_1 is the temperature of the outside of the layer.

Again, considering the transmission through the surface layer, we have

$$Q = \frac{k(T_s - T_1)}{t}, \quad . \quad . \quad . \quad (3)$$

where T_s is the temperature of the surface, t the thickness of the layer, and k the coefficient of thermal conductivity,

and
$$R = \mu \frac{U}{t}. \quad . \quad . \quad . \quad . \quad (4)$$

Combining (2), (3), and (4), we have

$$Q = \frac{R\sigma(T_s - T_m)}{V_m} \cdot \frac{1}{1 + p(\sigma\mu/k - 1)}, \text{ where } p = \frac{U}{V_m}. \quad (5)$$

If, therefore, the value of p were known, it would be possible, by experiments with a fluid flowing over a surface for which the value of R was always known, to obtain a check on the theory.

Unfortunately, no definite information on the value of p is at present available. From an examination of the criterion, due to Lorenz, for the steady motion of fluid between two planes moving tangentially to each other, Mr. G. I. Taylor has arrived at the conclusion that in the case of a pipe u/V_m should become nearly constant as the velocity is increased, and independent of the nature of the fluid. As regards its value, the criterion of Lorenz indicates that it may be approximately 0·38. Alternatively the value of p may be calculated from equation (5) by substitution of the known values of R, $(T_s - T_m)$, V_m, μ, and k in carefully made experiments.

296	5·08	51·65	39·65	26·0	·217	10·5	·29

Such a series of experiments have been carried out by Dr. A. Soenneken[1] in the case of water flowing through heated metal pipes, the results of which are given in Table I., together with certain of Stanton's results.

---

[1] Stanton on "The Efficiency and Design of Surface Condensers," *Proc. Inst. C.E.*, 1898–99, cxxxvi.

[1] Soenneken, König. Tech. Hochschule Munich, 1910.

It will be clear from the calculated values of p in the above table that the use of the values of 0·38 derived from the theory of Lorenz will not give results greatly in error. The low values of p found from Stanton's results are probably due to the fact that they were obtained from short lengths of pipe in which the ratio of length to diameter was only 34, and that on this account the mean thickness of the surface layers would probably be appreciably less than that finally obtained at a considerable distance from the inlet.

Reverting to equation (5) it will be seen that if the value of $\sigma\mu/k$ for any particular fluid is approximately equal to unity, the agreement between the heat transmission given by equation (1) and that actually observed should be fairly close if the assumptions on which the theory is based are correct.

Now for air $k=1{\cdot}6\mu C_v$,

where C_v is the specific heat at constant volume, and since

$$\sigma=1{\cdot}4C_v,$$

we have

$$\frac{k}{\sigma\mu}=1{\cdot}14,$$

so that experiments with air should furnish a rough demonstration of the accuracy or otherwise of the extension of the Reynolds theory given above.

In some experiments made by Mr. J. R. Pannell[1] at the National Physical Laboratory in 1912 the results given in Table II. were obtained.

Table II

Flow of Air in heated Brass Pipe 4·88 cm. diameter, 61 cm. long

Velocity of Flow in Cm. p.s.	Heat transmitted, Calories per Sq. Cm. p.s.	Temperature.		Friction, Dynes per Sq. Cm.	Value of $\frac{R\sigma(T_s-T_m)}{V_m}$.	Ratio of $\frac{\text{Calculated Heat}}{\text{Observed Heat}}$.
		Surface.	Fluid.			
1180	·0205	37·4	22·5	5·14	·0155	0·76
940	·0162	36·2	22·7	3·18	·0109	0·68
2188	·0369	43·0	26·2	14·9	·0267	0·73

It will be seen that the agreement between calculated and observed heat is not satisfactory, so that assuming that no serious errors were made in the observations on which the figures in the table are based, it would appear that the assumptions on which the extended theory is based are inconsistent with the actual facts. The one whose validity may reasonably be questioned is the discontinuity between the layer at the boundary and the eddying fluid which is implied in the reasoning leading up to the theoretical equation (5).

It will be clear from the state of motion in the neighbourhood of the boundary which is indicated in the curves of *Fig.* 27 that no such discontinuity exists and that the two motions shade off into each other gradually. It is evident, therefore, that the matter requires further investigation before any reliable prediction of the *amount* of the heat transmission can be made from a knowledge of the frictional resistances of fluid and surface.

§ (41) Effect of Surface Roughness on Heat Transmission.—Apart from the practical value of the theory of heat transmission outlined above in giving an accurate measure of the improvement to be effected in heat transmission by increasing the *speed* of flow, the relation also indicates a possibility of increasing the efficiency of the transmission by increasing the coefficient of friction between fluid and surface. It is well known that by roughening the surface over which fluid is in motion the frictional resistance can be increased two or three fold. For example, in Mr. W. Froude's experiments on the resistance to the towing of planks in water, it was found that the resistance of a surface similar to that of sandpaper was more than double that of a varnished surface under the same conditions. In experiments at the National Physical Laboratory the frictional resistance of brass pipes has been increased threefold by serrating the inner surface by a series of sharp ridges produced by a cutting tool. It may be mentioned, however, that the application of the Reynolds theory to the case of rough surfaces is not *a priori* demonstrable, since the precise nature of the modification of the fluid motion as the surface roughness is increased is a matter for speculation, and it is by no means certain that an increase in surface roughness corresponds with an increase in the turbulence which is the main factor in the heat transmitted.

For the purpose of testing the applicability or otherwise of the Reynolds theory to the case of surface roughness, a series of experiments were made at the National Physical Laboratory in 1917 on two pipes $1\frac{1}{8}$ inch diameter, of which one was in the smooth drawn condition in which it was received and the surface of the other was roughened by machining with a screw-cutting tool so as to form a double series of sharp ridges intersecting each other. The depth of the serrations was about 0·01 inch.

---

[1] Pannell, *Report Advisory Committee Aeronautics*, 1916–17, viii. 22.

In making the experiments, each pipe was set up in a vertical position and a current of water circulated through it by means of a centrifugal pump provided with speed regulation, so that the mean velocity of flow could be varied from about 15 cm. per second, slightly above the critical value, to about 90 cm. per second. The outside of the pipe was wound with Eureka wire connected to the supply mains through a variable resistance and so arranged that the temperature of the pipe could be maintained at the desired value above the temperature of the water. The mean surface temperature of the pipe was estimated from the extension of the pipe measured by an extensometer specially designed for the purpose. For the estimation of the initial and final temperatures of the water, thermo-junctions embedded in thin brass tubes were placed with their axes in the axis of the pipe at the extremities of the experimental length and connected to a potentiometer. The estimation of the flow of water through the pipe was obtained from a calibrated meter. The frictional resistance of the pipe was found from the fall of pressure along the experimental length.

In order to compare the relative effects due to surface roughening, the ratio of the intensities of surface friction of the rough and smooth pipes have been plotted (*Fig.* 71) on a base of speed of flow through the pipe, and on the same diagram is plotted the curve showing the corresponding ratio of the heats transmitted per unit area per degree difference of temperature. It will be seen that throughout the whole range of speed considered the heat transmitted from the roughened pipe exceeds that transmitted by the smooth pipe by an amount greater than that by which the friction has been increased by the roughening, so that the application of the Reynolds theory to the case of surface roughening was fully demonstrated. In applying these results to practice, it is important to make sure that the conditions of turbulence are similar to those which existed in the experiments described above. For example, from the characteristics of the motion of a fluid at the inlet of a pipe referred to in § (6) (iii.), it would appear probable that had the experimental length of pipe in the above experiments been placed at the inlet to the pipe instead of some considerable distance from it, the effect of roughness on the heat transmission would not have been so marked owing to the absence of turbulence in this particular region. In order to investigate this more closely, a further research was carried out in which the heated surface represented the gills of an air-cooled internal combustion engine. The practical importance of this investigation will be obvious from the fact that if an improvement in heat transmission of the order of that obtained in the roughened pipe could be produced in the cooling surfaces of aircraft engines by artificial roughening, the possibility of considerable increase in efficiency and saving of weight would be opened up.

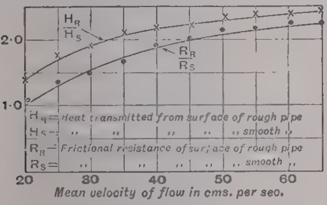

FIG. 71.

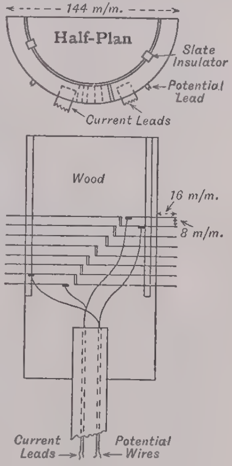

FIG. 72.

For this purpose the apparatus shown in *Fig.* 72 was constructed. This consisted of eight copper discs of approximately the dimensions and spacing of the gills of an air-cooled engine surrounding a cylinder of wood, and set up in a wind channel through which air could be circulated at speeds up to 60 feet per second. The method of making an experiment consisted in heating the gills by a current from a storage battery and measuring the amount of current and fall of potential along them. In this way the mean surface temperature of the gills and the amount of heat abstracted by the air could be calculated. Observations of the velocity and temperature of the cooling air were taken at the same time. The thickness of the copper gills was 0·055 mm., the external and internal diameters being 146 and 114 mm. and the pitch 8 mm.

The roughening was made by a special pair of steel dies by means of which the surfaces were corrugated into serrations 0·5 mm. deep and 1·8 mm. pitch. A series of observations was first made on the smooth gills. These were then taken out of the wind channel, roughened by the dies and replaced, and the experiments repeated under the same conditions of wind speed, and surface temperature as before.

The results of the two sets of observations are shown in *Fig.* 73, the ordinates of the plotted points being the heat abstracted in calories per second per degree difference of temperature between gill and air current, and the abscissae the mean wind speed in cm. per second.

It will be seen that, in complete contrast with the results of the pipe investigation, the roughening had practically no effect on the heat transmission, thus indicating that for these particular surfaces the dimension in the direction of flow was so limited that the convection of momentum to the surface was not more intense for a rough than for a smooth surface. The anticipation that the conditions as regards turbulence in this case were probably similar to those existing at the inlet of a parallel channel appeared therefore to be justified. It is probable that considerable improvement in the design of the cooling surfaces of aircraft engines and radiators may yet be effected by a suitable increase in their frictional resistances, but further research is necessary before the direction in which it may be looked for is apparent.

FUEL CALORIMETRY

§ (1) Introductory.—The measurement of the calorific value of fuels is a branch of calorimetry which has been systematised in order that it may be practised by operators not possessed of the knowledge or experimental aptitude of the trained physicist and chemist. Large numbers of determinations of the calorific value of fuels are made daily, with a reasonably high degree of accuracy and concordance by a host of semi-skilled operators. The latter, however, merely follow instructions in the use of methods which involve the scientific application of fundamental principles of physics and chemistry to the solution of the problem of measuring exactly the heat evolved in the complete oxidation of readily combustible matter. The physical and chemical principles applied in Fuel Calorimetry are essentially identical with those applied in the measurement of the heat evolved in chemical reactions in general, and the methods employed are simply specialised adaptations to a restricted field of the general methods employed by the physicist in tackling the varying problems of calorimetry presented in the pursuit of physical, chemical, and physiological researches. The broad principles and general methods of

Calorimetry have been dealt with in the article under that heading.

§ (2) Methods and Conventions of Fuel Calorimetry.—In this article the specialised methods applied to the measurement of the heat evolved in the combustion of fuel will alone be considered. These methods are, however, also of rather divergent descriptions, owing to the physical differences between the various "fuels." The physical differences referred to chiefly concern the question of the phase or state of the fuel, *i.e.* whether it is solid, liquid, or gaseous at ordinary temperatures. For instance, the calorific value with which fuel calorimetry is concerned is: for methane, the heat evolved by the combustion of *gaseous* methane; for alcohol, the heat evolved by the combustion of *liquid* alcohol; and for sugar or sulphur, the heat evolved by the combustion of *solid* sugar or sulphur. While the supplemental heat attributable to both condensation and solidification is included in the calorific value of a fuel such as sulphur, and that of condensation in the calorific value of alcohol, neither is included in the calorific value of methane, or other substance which is in the gaseous state at ordinary temperatures. Similarly the calorific value as usually determined and accepted for fuel expresses the heat resulting from their combustion when the products of combustion are in the state or phase in which they normally occur at ordinary temperatures. That is to say, any carbon dioxide produced by the combustion of a fuel is assumed to remain in the gaseous state, whereas silicon dioxide or silica would be assumed to be in the solid state, and water in the liquid state.

There is, however, a convention by which the water resulting from the combustion of hydrogen and its carbon compounds in fuels is sometimes considered to remain wholly in the gaseous state among the products of combustion, and the calorific value realised under this convention is termed the *net* calorific value. It is less than the common or *gross* calorific value by the latent heat of vaporisation of the water resulting from the combustion of the fuel. In the common measurements of the net calorific value of a fuel, a further deduction is made from the gross value of the sensible heat of the condensed water in cooling from 100° C. to ordinary temperatures. The figure thus obtained is the conventional net calorific value of the fuel, but the former figure, which differs from the gross calorific value only by the latent heat of vaporisation of the water resulting from the combustion, is the true thermodynamic net calorific value which should be used in calculations of the efficiencies of internal combustion engines, flame temperatures, etc. Except in the case of uncombined hydrogen, the net calorific value of a fuel is a figure which has little real significance, because the uncondensable products of combustion, such as carbon dioxide, nitrogen, and excess of oxygen, pass away at the same temperature as the uncondensed water vapour. In most uses of fuel, this temperature is considerably higher than that of the atmosphere, and the sensible heat of the uncondensable products of combustion as well as the latent heat of vaporisation of the water accompanying them has to be determined for the particular temperature at which they are passing away whenever the question of the thermal efficiency of a particular application of a fuel is investigated.

In considering the calorific value of many of the complex commercial fuels, it is necessary for comparative purposes to bear in mind that a certain component, *e.g.* naphthalene, may be available in more than one state or phase. For instance, in certain mixed fuels there may be a small proportion of gaseous naphthalene; in others a more considerable proportion of molten naphthalene or of naphthalene in solution, while finally naphthalene may be in the solid state as a component of a mixed solid fuel, or indeed in that state be used as a fuel without admixture. The calorific value of a substance such as naphthalene, which is available in three states, will differ according to its phase and its latent heat of vaporisation, of liquefaction, or heat of solution in a particular medium which serves as the liquid vehicle for it. The greater part of the combustibles to which technical fuel calorimetry is commonly applied are, however, complex mixtures which are used in the one state, viz. solid, liquid, or gaseous, in which they usually occur, and it is the calorific value of the fuel in that one state with which fuel calorimetry ordinarily is concerned.

When the fuel is a solid, whether a simple substance, such as carbon, sulphur, phosphorus or silicon, or a complex mixture of cellulosic or hydrocarbon material such as wood, coal, etc., its calorific value is ordinarily determined by measuring the heat evolved on the rapid or almost instantaneous combustion in oxygen of a known weight of the fuel. When the fuel is a liquid which is not very readily volatile, such as the higher alcohols, oil, tar, etc., its calorific value is determined in substantially the same way. When the fuel is a gas, however, though the same method is applicable, it is generally preferred to burn the fuel at a uniform measured rate of consumption for an extended period, and to measure the heat evolved during the time in which a known quantity of the gas is burned. If provision is made for the continuous consumption of the gas at a uniform rate, and for the calorimetric device to furnish a continuous record of the fluctuations in the evolution of heat from the combustion of the gas, it is possible to produce a calorimeter which automatically registers any variations in the calorific value of the gas over a long period. The usual methods of gas calorimetry are, therefore, distinct from the usual methods of the calorimetry of solid and liquid fuels, though there is some overlapping of the two methods in the calorimetry of the more highly volatile liquid fuels, such as motor-spirit, ethyl-alcohol, ether, etc. The continuous calorimetry of a supply of solid fuel, such as coal, furnishing automatically a register of fluctuations in the calorific value of that fuel, is a problem which awaits attack, and of which a satisfactory solution would be of the utmost value in industry. Even in regard to oil fuel, continuous calorimetry is practically unknown, though the problem does not present the same difficulties as that of solid fuel, and a satisfactory solution of it is not far to seek.

There are a number of points in fuel calorimetry to which consideration must be given in the case of almost all types of fuel calorimeters and of all classes of fuel. They may be classified broadly as follows: (*a*) Sampling the fuel; (*b*) Weighing or measuring the portion of the sample on which the determination is made; (*c*) The supply of oxygen for combustion; (*d*) Choice of medium for reception of the heat evolved; (*e*) Thermometry, or the measurement of the rise of temperature of the medium; and (*f*) Incidental heat losses and corrections.

§ (3) SAMPLING THE FUEL.—In general the sampling of fuel for determination of its calorific value follows the course adopted for sampling it for chemical analysis, but as many more samples of fuel are now taken for calorimetry than for analysis, and often by persons not trained in general methods of sampling, a few words on it may appropriately be said here, though, strictly speaking, sampling does not fall within the scope of calorimetry as such.

There are few materials more difficult to sample properly than coal and coke, owing chiefly to the unequal distribution of earthy matter, slate, etc., in the coal as won and supplied to the consumer. Where coal or coke passes through a mechanical breaker which reduces all lumps to a relatively small size, the procedure of sampling a large bulk is greatly simplified, and if ½-cwt. portions are drawn from the outlet of the breaker at intervals corresponding with the passage through it of 5 or 6 tons, and these ½-cwt. portions are subsequently mixed, further broken, quartered, the quarter broken smaller and again quartered, a finely broken small sample is ultimately obtained from which the final sample for the determination of calorific value may be ground. This procedure answers well on gas works, etc., where coal is frequently broken before carbonisation, and coke before sale for household use, but the breaking of coal lowers its value for most other uses and this aid to proper sampling is not generally available. In such cases larger portions, representative of both the large and the small coal, must be taken from each waggon-load, or 5 to 10 ton lot, and these portions mixed to form an average sample, a quarter of which must be roughly broken and dealt with as before. Many elaborate directions have been issued for the sampling of coal and coke deliveries, but a consideration of the particular circumstances will generally suggest the best method if it is borne in mind that the first bulk sample must be large and must be thoroughly mixed before the first quartering. Gain or loss of humidity in the course of sampling must also be avoided.

The sampling of liquid fuel is relatively an easy matter, though, with heavy petroleum oils and certain classes of tar and tar oils, stratification and deposition of solid matter are apt to occur in storage tanks, and warming by means of steam coils and stirring are needed before the sample is drawn from the tank. Liquid fuels frequently contain varying proportions of water, partly in solution and partly in suspension, and on this account a sample drawn from a single barrel is seldom representative of a consignment of many barrels. Barrels should be rolled about to agitate the contents thoroughly before they are sampled.

The sampling of gaseous fuel varies greatly in method according to the circumstances of its origin and the object of the determinations of calorific value. Obviously if all that is needed is an average sample of the output of a producing plant, or of the delivery from storage vessels, different methods will be followed from those adopted if samples are required with a view to ascertaining the extreme fluctuations in calorific value of the gas produced or delivered. It may be said generally, however, that fuel gas supplies vary more in calorific value than might be expected from general knowledge of the diffusion of gases, and of processes for generating fuel gas. Even town gas supplies, derived from works where facilities for mixing and storing appear ample, quite commonly show fluctuations of 2 to 3 per cent on either side of the mean calorific value. Other fuel gases, such as acetylene produced in generators for welding and cutting purposes, are apt to vary still more in calorific value, partly owing to variations in the purity of the raw material used, and partly owing to effects incidental to the rate of generation, etc. Fortunately a continuous supply of fuel gas is generally available for calorimetry, and it is a relatively easy matter with the types of gas calorimeter commonly in use to make a number of determinations, and thereby to ascertain the fluctuations in value of the gas, as well as to eliminate errors due to the taking of casual samples.

§ (4) Weighing or Measuring the Sample.—The portion of either a solid or a liquid fuel used for a calorimetric determination will usually be weighed, but a gaseous fuel is commonly measured and the calorific value per unit weight calculated, if required, from the specific gravity of the gas. The utility of determinations of calorific value of coal, coke, etc., is largely relative to that of other lots of similar fuel, and since these fuels contain more or less free water according to the extent to which they have been exposed to rain (or underground water) or stored under cover, it is essential that the determinations of calorific value should be made on a dried sample. If the water given up in drying is determined, the calorific value of the particular lot of coal or coke in the condition in which it was when sampled can be readily calculated. Unless expressly stated otherwise, it is customary to express the calorific value of a solid fuel in terms of unit weight of the dried material. Since many coals, when finely ground and dried, are extremely hygroscopic, the precautions usually taken in weighing hygroscopic substances must be observed when weighing out the portions for calorimetry. Fuel oils, as a rule, contain very little water, but when certain grades of tar, crude petroleum, etc., are being examined it is necessary to determine the water present, which, moreover, frequently varies greatly in different samples taken from the same bulk.

Gaseous fuel is usually measured saturated with water at atmospheric temperature and pressure, and the calorific value of unit volume so measured is corrected to refer to unit volume in one or other of two standard conditions, viz.: (1) at 0° C., 760 mm. and dry, which are the normal conditions for gas measurements in scientific work, or (2) at 60° Fahr., 30 inches and saturated with water vapour, which are the normal conditions for the sale of gas in this country and generally for technical and industrial measurements of gas. The volume of gas in these conditions is only one ten-thousandth less than its volume at 15° C., 760 mm. and saturated, which are the conditions in which gas is measured for commercial and technical purposes in most continental countries.

§ (5) Supply of Oxygen for Combustion.—The oxygen required for the combustion of the fuel in the calorimeter is obtained in most calorimeters for gaseous fuel through a supply of atmospheric air, but with solid and liquid fuel it is difficult to ensure complete and rapid combustion unless the oxygen is supplied in a more highly concentrated form. In the early calorimeters the oxygen was furnished by potassium nitrate or a similar salt, which was intimately mixed with the fuel, but with the advent of commercial supplies of oxygen compressed in steel cylinders other sources of concentrated oxygen were almost entirely displaced in calorimetry by the oxygen cylinder. Without the latter the Berthelot bomb type of calorimeter could not have come into general use. It is possible, however, to dispense with compressed oxygen if it is not available, by using a peroxide as a source of oxygen. Sodium peroxide is thus used in the Roland Wild fuel calorimeter, but there is in this case a liberation of heat from the reaction between the products of combustion and the reduced peroxide, for which a deduction has to be made from the total heat measured by the calorimeter. The uncertainty as to this deduction with fuels of a widely different ratio of carbon to hydrogen militates against the more general employment in industrial calorimetry of this convenient type of calorimeter.

§ (6) Medium for Reception of the evolved Heat.—The heat evolved by the combustion of the fuel is absorbed as far as possible by water in nearly all the more exact types of calorimeter. The high specific heat of water and its universal availability are the chief factors in its favour, but it has certain disadvantages which have led to the adoption in a few calorimeters of other liquids, or of air or other gas, for the absorption and measurement of the heat evolved on the combustion of the fuel. It may be said broadly, however, that the calorimeters in which water is displaced by another liquid or by a gas are of special and restricted applicability. Certain semi-automatic and recording calorimeters dispense with water, but the majority of them need calibrating against a water calorimeter owing to uncertainty as to the specific heat of the liquid or gas which is used instead of water. The water or other medium is contained in a glass or metal vessel or tube, by which and the combustion chamber or burner a portion of the heat evolved is retained. It is customary in bomb and other non-continuous calorimeters to determine experimentally the mean specific heat of these parts of the calorimeter, and to reckon their heat absorption in terms of the weight of water which would show the same rise of temperature if the same number of heat units were imparted to it. This is commonly known as the "water-equivalent" of the calorimeter, and has to be determined for each instrument. Its determination by present methods introduces an uncertainty in the results of bomb calorimetry of nearly 0·2 per cent. In calorimeters of the flow type in which a heat equilibrium becomes established, the analogous uncertainty in the results may be reduced to less than 0·1 per cent.

§ (7) THERMOMETRY.—The rise of temperature caused by the combustion of the fuel in the calorimeter is usually measured by mercury thermometers, either used directly or used as reference standards to check the records of some other thermometric device. Thus the degree of accuracy attainable in fuel calorimetry generally depends ultimately on the sensitiveness of the mercury thermometer, which when all sources of error are considered and corrections applied cannot be much higher than 0·005°, and in most cases even with high-class thermometers is not, in reality, higher than 0·01°.

The errors in thermometry in connection with bomb calorimetry have been fully discussed by G. N. Huntly in the *Journal of the Society of Chemical Industry*, 1910, xxix. 917, and in the *Analyst*, 1915, xl. 41. Briefly, the capillary tube errors may amount to, but will not exceed, one unit of the divisions if the thermometer is used without special calibration, but this may be reduced to 0·01 division or 0·001° by calibration in special cases. External and internal pressure and temporary depression of zero errors are negligible in the conditions of use of thermometers in bomb calorimetry. The other errors can best be eliminated by determining the water equivalent of the calorimeter with the same weight of water at different temperatures, and therefrom plotting the apparent water equivalent as a function of the temperature. In determining the water equivalent, a pure substance such as benzoic acid or pure cane sugar of which the calorific value is accurately known is burned in the calorimeter.

The errors in thermometry in connection with flow and other calorimeters in which the rise of temperature measured is more than 10° comprise many of the foregoing, and others, such as that for the varying length of stem exposed to the atmosphere, which may be largely eliminated by appropriate design of the calorimeter. While the exposure of the thermometer stem to the air of the room may conceivably in certain calorimeters account for an error of as much as 0·1°, it is very rare that the error is more than one-fifth of this amount, owing to the fact that the thermometer stem is usually so situated that its temperature is more nearly that of the bulb than that of the air of the room. The correction which would otherwise be appropriate for the exposed stem of the thermometer becomes largely merged in the general correction for radiation and other heat losses from the calorimeter itself.

In all calorimetry where readings are made on two thermometers it is essential that the thermometers should be re-standardised at intervals of about twelve months until it is demonstrated thereby that there is no further change of zero through lapse of time. The artificial ageing of thermometers, though of great service, is not always equally effective, and is frequently neglected even with thermometers purporting to be of high grade.

§ (8) INCIDENTAL HEAT LOSSES.—Radiation from the instrument is, with the majority of types of calorimeter, the most important of the incidental heat losses. In the bomb type of calorimeter its effect may be eliminated (*i.e.* reduced to not more than 0·05 per cent) by the application of a formula, deduced from Newton's law of cooling, by Regnault, Pfaundler, and Oussoff. The following observations are needed: T_0, the mean temperature of the calorimeter, and t_0, the final temperature during the initial period; t, the final temperature of the principal or combustion period, and T′, the mean temperature of the calorimeter during the final or cooling period. Then if n is the number of minutes in the principal period, V_0 the mean loss of heat in a minute during the initial period, V the mean loss of heat in a minute during the principal period, V′ the mean loss of heat in a minute during the final period, and S the sum of the minute readings of the thermometer during the principal period, we find for the correction $n\mathrm{V}$ the value

$$n\mathrm{V}_0+\frac{\mathrm{V}'-\mathrm{V}_0}{\mathrm{T}'-\mathrm{T}_0}\left(\frac{t_0-t}{2}+\mathrm{S}-n\mathrm{T}_0\right).$$

For let q be the rate of loss of heat per unit difference of temperature between the calorimeter and the air, T the air temperature, $t_1, t_2 \ldots t_n$ the temperatures of the calorimeter at the ends of the first, second . . . n' minutes; t_n is equal to t the final temperature. The mean temperatures during the first, second . . . nth minutes are $\frac{1}{2}(t_0+t_1)$, $\frac{1}{2}(t_1+t_2) \ldots \frac{1}{2}(t_{n-1}+t)$, and by Newton's law of cooling the loss of heat in each minute is

$$q\left\{\tfrac{1}{2}(t_0+t_1)-\bar{\mathrm{T}}\right\},\ q\left\{\tfrac{1}{2}(t_1+t_2)-\mathrm{T}\right\} \ldots,$$
$$q\left\{\tfrac{1}{2}(t_{n-1}+t)-\mathrm{T}\right\}.$$

The total loss of heat in the principal period is $n\mathrm{V}$. Thus adding these quantities

$$n\mathrm{V}=q\left\{(t_1+\ldots t)+\tfrac{1}{2}(t_0-t)-n\mathrm{T}\right\}$$
$$=q\left\{\mathrm{S}+\tfrac{1}{2}(t_0-t)-\bar{n}\mathrm{T}\right\}.$$

Also since T_0 is the average temperature during the initial and T′ during the final period,

$$\mathrm{V}_0=q\left\{\mathrm{T}_0-\mathrm{T}\right\},\ \mathrm{V}'=q\left\{\mathrm{T}'-\mathrm{T}\right\}.$$

Thus $$q=\frac{\mathrm{V}'-\mathrm{V}_0}{\mathrm{T}'-\mathrm{T}_0},$$

while $$\bar{\mathrm{T}}\doteq\mathrm{T}_0-\frac{\mathrm{V}_0}{q}.$$

Substituting these values we have

$$n\mathrm{V}=n\mathrm{V}_0+\frac{\mathrm{V}'-\mathrm{V}_0}{\mathrm{T}'-\mathrm{T}_0}\left\{\mathrm{S}+\tfrac{1}{2}(t_0-t)-n\mathrm{T}_0\right\}.$$

Huntly has pointed out (*loc. cit.*) that for a given instrument, a given class of fuel, and a constant rate of stirring, this formula may be simplified, because these are the three conditions which determine the shape of the time-temperature curve, and if they are constant $S/T' - T_0$ becomes a constant which can be ascertained once for all.

The foregoing formula eliminates also the losses due to evaporation, and the gain from the development of heat due to the friction of the stirrer. The value of the radiation correction can be reduced to an amount which may be neglected by using in the calorimeter water a few degrees lower in temperature than the surrounding air. This method of equalising the heat transfers to and from the instrument is frequently applied in continuous water-flow calorimeters in order to render unnecessary special corrections for radiation, etc.

The heat of fusion of the ignition wire, and the heat of combustion of any cotton or collodion attached to it, are allowed for, if conditions are kept constant, in the determination of the water equivalent of the bomb calorimeter. A certain amount of nitric acid is produced from the atmospheric nitrogen initially in the bomb, or from nitrogen (if any) in the fuel, and this is fairly constant for a bomb of given capacity used on similar fuels with the same oxygen pressure, etc. It will be responsible for a liberation of 3 to 12 calories, according to circumstances, and is deducted from the observed calorific value in all the more accurate calorimetric work. A little water is put in the bomb before it is closed, and this absorbs the nitric acid formed, which is subsequently determined by titration with standard alkali, and the necessary deduction calculated accordingly. If the fuel contains sulphur, the latter is oxidised in the bomb wholly to the trioxide, which is absorbed by the water therein. It is customary to assume that in the combustion of fuel in grates and furnaces, sulphur is oxidised to sulphur dioxide only, and a deduction is accordingly made from the observed calorific value in respect of the additional heat developed in the bomb from the sulphur. The proportion of sulphur present is ascertained by a determination of the sulphuric acid in the water contained in the bomb. The assumption that sulphur in fuel, *e.g.* coal, when the latter is consumed in a furnace, is oxidised to sulphur dioxide only is now known to be incorrect, as sulphur trioxide is always formed also—more or less according to the furnace conditions, etc. It is, on the whole, better to omit the sulphur correction, as, at least in some uses of a fuel, it is possible that very nearly the whole of the sulphur is burnt to the trioxide.

§ (9) DETAILS OF MANIPULATION. — The principal corrections and sources of error in fuel calorimetry, with the Berthelot bomb in particular, have been enumerated, and it is only necessary in regard to determinations of calorific value with the bomb to refer to one or two points in its manipulation with different types of fuels. It is usually filled with oxygen to a pressure of 25 atmospheres, but higher pressures are used with a view to securing complete combustion of coke, anthracite, and other not readily combustible fuels. The platinum or gold lining of the Berthelot bomb is replaced in the Mahler and other industrial types by an enamel lining, which does not affect the accuracy of the results obtained so long as it remains sound, but it needs renewal from time to time. The capacity of the bombs for industrial use is generally appreciably greater than that of the platinum-lined Berthelot bomb, reaching as much as 750 c.c. as compared with 250 to 600 c.c. for the latter.

§ (10) HIGHLY VOLATILE LIQUIDS.—The determination in the bomb of the calorific value of highly volatile liquid fuels, such as petrol, benzol, and, in particular, the motor-spirits produced by the cracking of heavy mineral oil, etc., is a problem presenting special difficulties. The partial volatilisation of such liquids in the bomb leads to error in the results, due partly to the heat of evaporation of an uncertain proportion of the substance and partly to incomplete combustion of the vapour. Berthelot's method of weighing out the volatile liquid in a small glass bulb which is sealed, or in a tiny thin-glass flask with ground-in stopper, and placing round this in the bomb a known weight of camphor, naphthalene, or other combustible of known calorific value, answers well. The ignition and combustion of the camphor expels the liquid, which is forthwith completely burnt. A less satisfactory alternative, also suggested by Berthelot, is the use of a capsule of collodion, into which the ignition wire passes, for containing the volatile liquid, which is then burned without the addition of camphor, etc. Some workers substitute celluloid for collodion.

The calorific value of highly volatile liquids may also be determined, if their latent heat of evaporation has been ascertained, by combustion of the vapour in a special lamp or burner in one of the forms of flow calorimeter used for gaseous fuels, and this is the best method when large numbers of determinations have to be made on different samples of volatile liquid, *e.g.* motor-spirit.

§ (11) WATER-FLOW GAS CALORIMETERS.—The most widely known of the early forms of water-flow gas calorimeter is that of Junkers, which, however, resembles in principle an instrument designed earlier by Hartley. These calorimeters and subsequent modifications of them consist of an assembly of parallel vertical condenser tubes, down the interior of which pass the products of combustion from a gas burner, while water flows upwards round their exterior. The gas burner is in the centre of the vertical cylindrical space formed by the annular water chamber of the condenser, which water chamber extends inwards at the top and forms a roof over the burner chamber. The gas is burned at a uniform rate, measured by an experimental meter of the wet type, and the rate of flow of the water, which forms a counter current to the gaseous products of combustion, is also uniform and is measured. The difference between the inlet and outlet temperatures of the water flowing through the instrument affords a measure of the calorific value of the gas, since the quantities of water and of gas supplied to it in any convenient interval of time are known. Another form of water-flow calorimeter, designed by C. V. Boys, has the water flowing through a continuous coil of tube, the heat-absorbing surface of which is increased by coils of Clarkson wire or discs joined to it by tin or solder, while the products of combustion pass in a counter current through the annular spaces in which the tube is coiled. The Boys calorimeter is the standard instrument prescribed by the gas referees for ascertaining the calorific value of town gas supplies in the United Kingdom.

Various modifications of the Hartley, Junkers, and Boys calorimeters have been introduced, especially in the United States of America, mostly with the object of eliminating possible sources of small errors, for which corrections can be readily introduced wherever the degree of accuracy of the determination in other respects warrants it. Many of these errors are wiped out automatically if the testings are made in a room of uniform temperature, and with the water supply to the instrument at a very slightly lower temperature than the air of the room. Since there is a contraction of volume on the combustion of most gases, an error is introduced if both the gas and the air supplied for its combustion are fully saturated with water vapour, due to the heat of vaporisation of the water vapour condensed from the lost volume being added to the heat directly resulting from the combustion of the gas. Atmospheric conditions of temperature and humidity in the United Kingdom are, as a rule, such that the results obtained with a gas calorimeter supplied with air which has not been artificially humidified need very little, if any, correction on account of the humidity of the air and the contraction on combustion.

Errors of thermometry, as already mentioned, are common to nearly all types of fuel calorimeters, and can be eliminated in gas calorimetry by the usual precautions and corrections. Errors due to radiation and convection currents vary with the form of the gas calorimeter, and if the calorimeter room is of fairly uniform temperature, can be eliminated by the use of a correction factor, which varies slightly with the room and water temperatures. It can be determined experimentally for a particular set of working conditions.

The errors of the calorimetry proper are commonly of smaller dimensions than the error of measurement of the gas burnt in the calorimeter. This measurement has ordinarily a minimum error of one-third of 1 per cent either way, but it is quite easy to reduce this error to about ±0·2 per cent, which may be taken as the possible error in the calorimetry proper when all ordinary precautions are observed. In special conditions and with exceptional precautions, the aggregate error in gas calorimetry, including the error of gas measurement, need not exceed ±0·2 per cent.

§ (12) Recording Calorimeters.—Calorimeters for producing a continuous record of the calorific value of gas have been made for some years past by Junkers and others, and in the United Kingdom the gas referees are now required by the Gas Regulation Act to prescribe a recording calorimeter for testing continuously the calorific value of the gas supplied to consumers in all the larger towns. As a fact, however, up to the time of writing, no recording gas calorimeter has been approved as of a sufficiently high degree of accuracy and trustworthiness for use in such official testings. The design of an instrument which will meet these conditions is now earnestly engaging the attention of physicists, and several patterns are already on trial. A recording gas calorimeter should embody means for: (1) furnishing a flow of gas to a burner at a known and constant rate, in terms of unit volume at normal temperature, pressure, and humidity, irrespective of fluctuations in the temperature, absolute pressure, and density of the gas; (2) furnishing a flow of water through the calorimeter at a known constant rate, irrespective of fluctuations in its temperature (and of the consequent fluctuations in its viscosity), salinity or hardness, and content of dissolved gases, and (3) measuring the difference in temperature of the water entering and leaving the calorimeter, and recording on a sufficiently open chart the product of it and the factor which for the given rates of flow of water and gas gives the calorific value of unit volume of the gas.

There are minor points, such as the effect of varying humidity of the air supplied for combustion of the gas, which have to be borne in mind in the construction of an ideal recording gas calorimeter. It is a comparatively easy matter to design an instrument which will afford a fairly precise record for, say, 24 hours, at the beginning and end of which period its indications are checked by personal observations. The problem now is to design a recording calorimeter which will automatically make all necessary adjustments and give a trustworthy record throughout a longer period, say 8 or 14 days.

§ (13) CALORIFIC VALUES OF CERTAIN FUELS.—The accompanying table gives typical or average results for the calorific value of samples of various industrial fuels, with the approximate error of the determination by the best methods and operators in the case of a particular example. The margin of difference between the calorific values of different samples of the same class of fuel is, of course, very much larger than this error of determination.

W. J. A. B.

TABLE OF CALORIFIC VALUES

	Average Calories per Kilo.	Error of Determination. Calories.
Anthracite (dry)	8,300	±15
Admiralty Smokeless Steam Coal (dry)	8,250	±15
Bituminous Steam Coal (dry)	8,000	±15
Bituminous Gas Coal (dry) .	7,800	±15
Scotch Splint Coal for blast furnaces (dry) . . .	7,400	±15
Durham Oven Coke (dry) .	7,600	±15
Gas Coke (dry)	7,400	±15
Peat (air-dried, 20 per cent of water)	4,200	±10
Heavy Petroleum, for boiler-firing and Diesels . . .	10,700	±15
Kerosene	11,000	±15
Petrol	11,100	±20
Benzol, motor-spirit grade .	10,000	±20
Alcohol (Methylated Spirit)	6,400	±15

Gases measured at 60° F., 30 in. and saturated.

	Calories per Cubic Foot.	
Coal Gas (South Metropolitan Gas Co., 1921) .	140	±0·30
Town Gas in Great Britain (average), 1921 . . .	120	±0·25
Water Gas, uncarburetted .	75	±0·20
Mond Gas (South Staffordshire)	38	±0·10
Suction Producer Gas, from anthracite	35	±0·10
Producer Gas, from gas-coke	37	±0·10
Oil-Gas, after compression .	275	±0·50

FUELS FOR PETROL ENGINES. See "Petrol Engine, The Water-cooled," § (5).

FUNCTION, UNKNOWN, EXPERIMENTAL DETERMINATION OF, when the non-dimensional variables connected by the unknown function have been discovered by the method of dimensions. See "Dynamical Similarity, The Principles of," § (31).

FUNCTION, UNKNOWN, MORE ACCURATE DETERMINATION OF, by dynamical similarity, in the case of heat loss from long circular wires past which air is streaming. See "Dynamical Similarity, The Principles of," § (33).

FUSION, LATENT HEAT OF: a term used to denote the quantity of heat required to convert unit mass of a solid at the melting-point into liquid at the same temperature. See "Latent Heat," II.

GAMMA, THE RATIO OF SPECIFIC HEATS OF GASES, at constant pressure and at constant volume. See "Engines, Thermodynamics of Internal Combustion," § (19) (ii.); "Thermodynamics," § (15).

GAS CALORIMETER

§ (1) INTRODUCTORY.—To measure the heat of combustion of gas some form of flow calorimeter is usually employed. The gas is burned at a measured rate in a special burner, which is surrounded by a coil of metal tubing through which there is a steady and continuous flow of water. The apparatus is so arranged that the products of combustion as they rise from the burner give up practically the whole of their heat to the water. An increase in the temperature of this water is thus produced, and by measuring this increase and the total flow when the temperatures have become steady, the heat produced can be calculated. In some forms of apparatus air is used in place of water.

It is necessary to wait until a steady state has been reached, for when the apparatus is first started much of the heat is used in raising the temperature of the calorimeter itself. The fundamental quantities which it is necessary to know are the rate of flow of the gas, the quantity of water passing in a given time, and the difference in temperature between the inflowing and the outflowing water. Corrections are required, as described in the article on "Fuel Calorimetry," for the loss of heat by radiation from the calorimeter and for the heat given out by the steam formed by the combustion in condensing to water. The escaping products of combustion, moreover, may be either warmer or cooler than the gas and air entering the calorimeter; they may occupy a smaller volume and are saturated with water vapour. They may therefore contain a small quantity of heat due to combustion, which must be added to that found from the flow of water, or if the temperature of the water is low they may give up heat not due to the combustion, and this must be subtracted from the calorific value found from the flow and rise of temperature of the water.

§ (2) THE STANDARD CALORIMETER OF THE GAS REFEREES.—In *Fig.* 1 is shown the Boys Gas Calorimeter, the standard instrument authorised for use by the Gas Referees. The calorimeter is composed of three parts: (1) The base A, which carries a pair of steatite burners B and a regulating tap. The upper surface of the base is covered by a plate of metal, perforated at the centre and held in place by three centring blocks C. Below the plate is a recess the bottom of which is covered by felt, and six holes Z drilled in the base give communication with the outer air. A tube X of fibre conducts the air to the base of the burners.

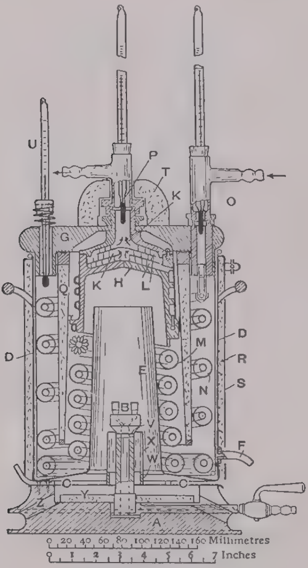

FIG. 1.

(2) An annular copper vessel D, jacketed by felt R and protected by an outer covering S, rests on the blocks C and is centred by them; the interior surface of this vessel forms a chimney E; it is also fitted with a condensed water drip F. Air enters between the blocks C.

(3) The top of this vessel D is closed by the lid G, to which is attached the water circulating system of the calorimeter. The water enters at O through an inlet box which contains the thermometer by which its temperature is measured.

In order to maintain a uniform flow the water-supply comes from an overflow funnel fixed to the wall at a height of about one metre above the base of the calorimeter. A tube leads from this funnel to the inlet pipe of the calorimeter, and in this tube is a diaphragm with a hole about 2·3 mm. in diameter. A second tube is connected to the water-supply through a regulating tap, while a third tube, the open end of which is at a height of about two inches above the bottom of the funnel, is connected to the waste sink. The tap is opened until there is a slight trickle of water through this third pipe; thus a constant head is preserved.

The water circulates through a helix of copper tubing to the bottom of the calorimeter and then up again to the top, where it enters a temperature equalising box H; hence it passes through baffles to the outflow box P; this contains the second thermometer, by which the temperature of the outflowing water is measured before it finally escapes as indicated in the figure. Between the outer and inner coils M and N is placed a brattice or annular partition Q containing cork dust so as to act as a heat insulator; the top of this is closed in an air-tight manner by a wooden ring which prevents the access of moisture to the cork.

The products of combustion rise in the chimney E, then pass down over the coils M between the chimney and the inner surface of the brattice, rising again in the annular space between its outer surface and the inside of the vessel D, and finally escape through a number of holes in the lid, their temperature being measured by a thermometer fitted, as shown at G, for this purpose. Their heat is given up to the water circulating in the coils, and its amount is measured by the rise in temperature of this water as indicated by the difference between the thermometers O and P.

The steam formed by the combustion is condensed by its passage over the coils, and the water of condensation escapes by the outlet F and is measured.

§ (3) METHOD OF EXPERIMENT.—In carrying out an experiment the gas is fed to the burner through a meter and a pressure regulator. The tap of the calorimeter is regulated so that the meter hand makes one revolution in from 60 to 75 seconds. The water is allowed to flow through the calorimeter and the gas lighted; the whole is left for not less than 30 minutes for the temperatures to become steady, the thermometers being read from time to time. The escaping water passes into a change-over funnel, the position of which can be rapidly altered so as to direct the flow either into a measuring flask suitably placed to receive it, or to a waste water sink; during the preliminary interval the water runs to waste. As the meter hand approaches division 75, after the temperatures have become steady, the observer reads the inlet temperature; as the hand passes the 100 mark he shifts the change-over funnel so as to direct the flow into the measuring flask, and starts a stop-watch. As the hand passes division 25 he reads the outlet temperature. At each quarter turn afterwards the outlet temperature is read until fifteen readings have been taken; the hand is then at 75; as it passes division 100 for the fifth time—*i.e.* after four complete turns—the change-over funnel is shifted and the stop-watch stopped. At each turn of the meter except the last, when the hand is between 75 and 100, the temperature of the inlet water is read; thus there are four readings of this temperature. Immediately after the flow has been directed to the waste, the temperatures of the gas and air supply and of the effluent gases are read; the barometer reading, and also the readings of the wet and dry bulb thermometers, used to determine the hygrometric state of the air, are also taken, and the amount of water of condensation which has escaped from the outflow F is noted.

The difference between the mean of the fifteen outlet temperatures and that of the four inlet temperatures gives the rise of temperature of the water; the quantity which has passed is known from the indications of the measuring flask. The product of these two quantities measured in proper units gives the total heat produced—this, as already indicated, needs certain corrections; if the thermometers are divided in centigrade degrees and the measuring vessel in cubic centimetres, the result is in calories. The meters employed under the Gas Referees' regulations allow one-twelfth of a cubic foot of gas measured at a temperature of 60° F. and a pressure of 30 inches of mercury to pass in each revolution, and when in use the time of a revolution should be about one minute. If the pressure and temperature at the time of observation have not these standard values, the meter readings require correction. This is facilitated by a table given in the Notification of the Gas Referees,[1] to which the reader is referred for further particulars, including details as to the application of the various corrections.

The measuring vessel is a flask with a comparatively narrow neck graduated from 1600 to 2400 c.c. In the ordinary use of the calorimeter the amount of water passing in four minutes should be adjusted so as to be sufficient to fill it above the lowest graduation, but insufficient in five minutes to come above the highest division. This flask must be certified by the Referees; the regulations also require that the meter should be checked from time to time, and instructions are given as to the use of the wet and dry bulb thermometers employed to measure the hygrometric state of the air.

§ (4) Recording Calorimeters.—As explained in the article on "Fuel Calorimetry," the Gas Referees are required to prescribe a recording calorimeter for testing continuously the calorific value of gas supplied in the larger towns, and various investigators are at work on the problem. At the present time no instrument has been prescribed. Among the instruments already produced are the Simmance and the Thomas recorder.

§ (5) Simmance's Total Heat Recording Calorimeter. — This instrument consists, as any such apparatus must, of two parts, the calorimeter proper and the recording device; the calorimeter is a flow calorimeter, modified, as will be described shortly; the record is obtained from a curve which gives continuously the temperature difference between the inflowing and outflowing water. If the gas be supplied at a constant known rate corrected for pressure, temperature, and humidity, and the water flow also at a known uniform rate, the temperature difference measures the heat produced by the combustion.

The gas is supplied through a pressure regulator to the meter; it passes through a specially constructed governor placed some three feet above the calorimeter, and then through a vertical iron pipe to the burner, whence it issues at the pressure of the atmosphere in the combustion space. Any change in the density of the gas or in the atmospheric pressure causes a change in the pressure under the bell of the governor, and the movement which occurs operates a valve, thus checking or increasing the flow of gas to the burner. It is claimed that the rate of efflux from the burner orifice is thus regulated and remains constant whatever the density of the gas may be. In a report on the instrument recently issued by the Department of Scientific and Industrial Research [2] it is stated (p. 22) "that the claim that the gravity meter automatically applies a correction for the varying pressure of the gas is substantially true."

Arrangements are made whereby the air supplied for combustion is maintained at the temperature of the cold water and is saturated at that temperature, while the products of combustion escape at a temperature about 1°·5 above this. The water enters the calorimeter tubes under a constant head, and the flow is controlled by a needle valve enabling a fine adjustment to be made. In this manner a uniform flow both of gas and water is secured.

---

[1] Metropolis Gas, *Notification of the Gas Referees for the year 1918*. H.M. Stationery Office.

[2] Fuel Research Board, Technical Paper No. 2, *Report on the Simmance Total Heat Recording Calorimeter*, by Thos. Gray and Alfred Blackie. H.M. Stationery Office.

The temperature difference is measured by a differential air thermometer; the inlet and outlet boxes each respectively contain, in addition to the ordinary thermometers, a thin-walled copper box; each of these is connected by capillary copper tubing to one of a pair of aneroid bellows; they thus form the bulbs of a differential air thermometer. The two bellows are rigidly coupled by a connecting rod; thus the position of the rod depends on the difference of pressure of the air in the two bellows, and the rod moves as this pressure difference varies.

Changes in the pressure difference are indicated by a suitable mechanism attached to the rod and recorded by a pen on a moving chart. Before starting the calorimeter, when the whole apparatus is at one temperature, a connection is opened between the bellows so that the pressures in the two are equal; the connection is then closed and the apparatus started; as one of the two copper boxes is heated the pressure of the enclosed air rises proportionately to the rise of temperature, and hence the mechanism indicates the temperature difference between the outflowing and inflowing streams.

If the chart moves uniformly and the water flow is also maintained at a uniform rate, the ordinates of the curve traced measure the total heat produced.

The calorimeter is put into adjustment by determining the calorific value of the fuel in the ordinary way by the aid of the thermometers provided with the instrument; the pen is then set at this value corrected to normal pressure and temperature, and the instrument gives a continuous record.

The report already quoted concludes with the statement that "the variation of the recorder seldom exceeded 2 per cent, notwithstanding the fact that the temperature of the air and water were not artificially controlled, and there is a prospect that the limits of error may be substantially reduced."

§ (6) THE THOMAS RECORDING CALORIMETER.—In this instrument the cooling medium is air, not water; the gas is burned in a closed space; the products of combustion pass downwards through a tube surrounding the burner. The tube is surrounded by a second tube through which a stream of cooling air passes upwards; this tube is open at the top, but is covered by a cap which forces the cooling air to flow back outside the tube, and finally to escape into the atmosphere. The difference of temperature between the incoming and outgoing air is recorded by the instrument, and the rate of flow being known, and also the specific heat of air, the total heat produced by the combustion is obtained.

The temperature difference is measured by two resistance thermometers connected to a special form of Wheatstone's bridge in such a manner that the difference between the two resistances is recorded; the galvanometer of the bridge acts as relay actuating the recording mechanism. The gas to be tested, the air required for combustion, and the cooling air are supplied through three wet meters, which are connected together in such a way that the quantities supplied bear a constant ratio to each other. These meters are partially submerged in water in a large tank, and the air supply is drawn from above the water in the tank; it is thus saturated at the pressure and temperature of the tank. The gas supply passes through a governor which is also submerged in the tank; it is subject, therefore, to the same changes of pressure and temperature as the cooling air.

Since the quantities of gas burned and of air employed to cool the products of combustion to their initial temperature bear a constant ratio to each other, the rise of temperature is a measure of the total heat produced independently of the rate of flow. The gas and the air required for its combustion are supplied in proper quantities by the respective meters and mix in a mixing chamber before they reach the burner.

The apparatus is set by burning gas of which the calorific value has been determined independently; it will then record variations in the calorific power.

GAS-CONSTANT. The ratio of the product of the pressure and volume of any gas to its absolute temperature which is a constant quantity if the gas laws are assumed to hold strictly. Its value if *p* is measured in atmospheres and *v* in cubic centimetres is 82·04. See "Thermodynamics," § (6).

GASES, SPECIFIC HEATS OF, AT HIGH TEMPERATURES

§ (1) Introduction.—An increase in the internal energy of a gas may be accompanied not only by an increase in the linear and rotational kinetic energy of the molecules as a whole, but also (except for monatomic gases) by an increase in the intra-molecular energy of vibration of the atoms. This energy taken up in atomic vibration might be expected to increase with the temperature, thus leading to a greater increase of internal energy per degree rise of temperature, or in other words a higher molecular thermal capacity or volumetric heat, at constant volume.

All gases which are not monatomic do in fact show a specific heat increasing with the temperature. The monatomic gases should, according to the kinetic theory of gases, all have a volumetric heat which is independent of the temperature and equal to $\frac{3}{2}$R, where R is the absolute gas constant $=1{\cdot}987$ cal. per gram mol. Moreover γ, the ratio of the volumetric heats at constant pressure and volume, should be 1·66. Both these results have been verified experimentally. Kundt and Warburg found γ for mercury vapour 1·67 and Ramsay found it for argon 1·659 and for helium 1·652. Pier has measured the volumetric heat of argon up to 2000° C. by explosion experiments with oxygen and hydrogen, and up to this temperature could find no sensible variation from the theoretical value 2·98 cal. per gram molecule.

In the case of a perfect gas there can be no variation of volumetric heat with the pressure, since

$$\left(\frac{\partial C_v}{\partial v}\right)_T = AT\left(\frac{\partial^2 p}{\partial T^2}\right)_v \quad \text{and} \quad \left(\frac{\partial C_P}{\partial p}\right)_T = -AT\left(\frac{\partial^2 v}{\partial T^2}\right)_p,$$

and the right-hand side of each equation is zero if pv and T occur in the characteristic equation in the first degree only. In the case of air Witkowski found that Cv and Cp increased with the pressure when the temperature was constant, but the variation only becomes large at very low temperatures, and above 0° C. the volumetric heats are nearly independent of the pressure. For the three diatomic gases N_2, O_2, and CO, which are of importance in connection with internal combustion engines, it may safely be assumed that C_p and C_v are independent of the pressure for the range of temperature 100° C.–3000° C.

It has been suggested [1] that the volumetric heats of CO_2 and H_2O may be dependent to an appreciable extent on pressure as well as on temperature and that they will diminish for any given temperature the greater the density. This is the reverse of what has been observed at low temperatures, and, as shown below, it seems unlikely that, with CO_2 at any rate, it is so to any sensible extent for the temperatures of 1000° C. and upwards with which one is chiefly concerned. In the case of superheated steam, for which the critical temperature is 365° C., the experiments of Knoblauch and Mollier have shown conclusively that the volumetric heats increase considerably with the pressure for temperatures up to 500° C. Probably there is some variation with pressure above this temperature, but the amount is likely to be too small to be of any importance in internal combustion engines: according to Knoblauch and Jacob the variation of Cp between 2 and 8 atmospheres at 500° C. is only about 0·6 per cent, and this will probably diminish rapidly as the temperature gets well above the critical temperature. Since the critical temperature of CO_2 is some 330° C. lower than water, it seems very improbable that its volumetric heats vary appreciably with the pressure at gas-engine temperatures.

§ (2) Methods of Measurement.—Attempts to measure the volumetric heats of air, CO_2, and H_2O at high temperatures have been of three types.

(i.) Constant pressure experiments, in which the gas is heated externally, usually at atmospheric pressure.

---

[1] W. T. David, *Phil. Mag.* xxxix. 551.

(ii.) Experiments in which the change of mean temperature of a mass of gas is measured while a known amount of work is done on or by the gas. The change of temperature is calculated from the change of pressure, as measured on an indicator diagram.

(iii.) Explosion experiments, the gases being kept at constant volume.

The principal measurements in the constant pressure class (i.) have been made by Regnault,[1] Wiedeman,[2] Holborn and Austen,[3] Holborn and Henning,[4] and Swann[5]; those of class (ii.) by Dugald Clerk[6]; and those of class (iii.) by Mallard and Le Chatelier,[7] Langen,[8] and more recently by Pier[9] and Bjerrum.[10]

In April 1908 the late Professor B. Hopkinson gave,[11] in his paper on "The Thermal Efficiency of Gas Engines," a curve of internal energy and temperature for the working fluid in his engine compiled from the best data at that time available. In September of the same year the Committee appointed by the British Association to investigate "Gaseous Explosions, with Special Reference to Temperature," made its first report. In this a valuable summary of the position of knowledge at that date as regards specific heats of gases at high temperature is given, together with a careful criticism of the probable accuracy of the various methods of experiment.

(i.) *Constant Pressure Experiments.* — The highest temperature reached in experiments of the constant pressure type is 1400° C., by Holborn and Henning,[1] and it is doubtful whether anything higher could usefully be attempted owing to the very great technical difficulty of carrying out constant pressure experiments at these high temperatures.[12] Since 1908 the results of Swann's experiments on air and CO_2 have been published, and although they were only made at 20° and 100° C. they are important as giving a reliable datum-line figure for the volumetric heats at ordinary temperatures. The Gaseous Explosions Committee accepted Swann's values as correct to 1 per cent, as follows:

	At 20° C.	At 100° C.	
Air		5·0	Cal. per gr. mol.
Carbon dioxide .	6·93	7·76	,, ,,

(ii.) *Clerk's Experiments.*[13]—The experiments of Clerk (class ii.) cover about the same range of temperature as those of Holborn and Henning and gave results about 10 per cent higher for the mean volumetric heat. The accuracy of results from these experiments depends very largely on a correct allocation of heat loss to the cylinder walls between the compression and expansion strokes. Clerk first assumed the loss during the two strokes to be the same except for the difference of mean temperature of the gas, but this is now known to be very far from true, and the difference accounts in part for the high values obtained for the volumetric heat. In order to obtain reliable results from experiments of this type it is necessary to know more of the condition of the surface layers of gas near the cylinder walls during compression and expansion.

(iii.) *Explosion Experiments.*—The majority of attempts to measure volumetric heats at really high temperatures have been by the explosion method, in which a known mixture of gases enclosed in a vessel of constant volume is heated by internal combustion. The temperature after explosion is inferred from the rise of pressure, and from this, and the known heat of combustion of the constituent gases, a value is obtained of the mean volumetric heat of the vessel contents between the initial and final temperatures.

In interpreting the results of experiments of this kind there are several points of importance to consider:

(*a*) The correctness of the volumetric heats by this method depends entirely on an accurate allowance being made for any loss of energy by conduction of radiation up to the point of maximum pressure.

(*b*) The maximum temperature inferred from the maximum pressure is a mean temperature for the volume of gases. The actual temperature range within the gas is very wide: Hopkinson[14] has estimated as much as 1900°–1100° C. when the mean from pressure observations was 1600° C. If the specific heat were the same at all temperatures there would be no change of pressure during an equalisation of temperature, and Mr. S. Lees[15] of Cambridge University has recently shown that, taking the estimated conditions in Hopkinson's experiment, the error from this cause is probably well under 1 per cent and therefore less than experimental errors of measurement.

(*c*) The mean volumetric heats are calculated on the assumption that all the available heat of combustion has been generated in the gas at the moment of maximum pressure. That is to say that all the carbon and hydrogen are then present as CO_2 and H_2O. If any of the gases are still uncombined, or in other words if any of the CO_2 and H_2O are dissociated at the highest temperature reached, and are present as $CO+O$ and $2H_2+O_2$, the effect will be to lower the maximum temperature and give a higher value to the calculated volumetric heat. On this account many of the results from explosion experiments have been called "apparent volumetric heats"; meaning that any effect of dissociation is included in them so that the true volumetric heat will be lower than the "apparent" value.

It is important to notice that this use of "apparent" volumetric heats is highly unsatisfactory for two reasons: the amount of dissociation and, therefore, the apparent volumetric heat depends not only on temperature but on pressure, and will therefore vary according to the starting pressure of the experiment; and, secondly, the apparent volumetric heat of products of combustion containing both CO_2 and H_2O cannot properly be calculated from the apparent volumetric heats of CO_2 and H_2O found separately. CO_2 and H_2O have a dissociation product, O_2, in common, and the presence of one in a dissociated state will depress the amount of dissociation of the other, and *vice versa*. For this reason the only satisfactory method is that used in some of the more recent experiments, of which results are given below, in which an excess of one of the combining elements is maintained during combustion sufficient to depress the dissociation to a negligible amount. In this way true volumetric heats are obtained.

§ (3) **Results of Experiments.**—Hopkinson has given, in his paper,[1] figures for the mean volumetric heats of air, CO_2, and H_2O up to 800°, 1400°, and 1900° C., based on the work of Holborn and Henning, Holborn and Austen, Langen, and Clerk. These figures Hopkinson considered to give the best compromise between the rather discordant results at high temperatures of Holborn and Henning, and Langen.

Hopkinson's figures are as follows:

Mean Volumetric Heat in Calories per Gram Molecule for Range 100° C. to t° C.

t° C.	800.	1400.	1900.
CO_2 . .	8·9	10·45	11·65
H_2O . .	6·56	7·8	10·0
Air . .	5·03	5·55	5·95

The energy curves obtained from them are shown dotted in *Fig.* 1.

Since the above figures were given by Hopkinson, a number of values for the volumetric heats of N_2, CO_2, and H_2O have been published by Bjerrum, based upon his own and Pier's results of explosion experiments with hydrogen, carbon monoxide, and acetylene. These carry the observed volumetric heat values up to 2400° C., 2700° C., and 3000° C. for N_2, CO_2, and H_2O respectively.

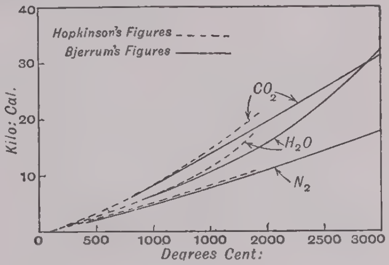

FIG. 1.

The figures given by Bjerrum are as follows:

For Nitrogen [2]

t° C.	Mean Values 0° C.–t° C.	Volum. Heat. Cal. Gram Mol.
200	Holborn and Henning	4·73
630		4·91
1000		5·25
1347		5·31
	Mean Values 18° C.–t° C.	
1519	Pier's experiments recalculated by Bjerrum	5·43
1783		5·58
1951		5·79
2182		5·87
2367		5·93

For Water-vapour [2]

t° C.	Mean Values 110° C.–t° C.	Volum. Heat. Cal. Gram Mol.
620	Holborn and Henning	6·51
1000		6·95
1327		7·40
	Mean Values 18° C.–t° C.	
1811	Pier's experiments recalculated by Bjerrum	7·92
2110		8·54
2377		9·37
2663	Bjerrum	10·00
2908		10·5
3064		10·9

For Carbon Dioxide [3]

t° C.	Mean Values 0° C.–t° C.	Volum. Heat. Cal. Gram Mol.
200	Holborn and Henning	7·48
630		8·6
1000		9·33
1364		9·84
1611	Pier	9·98
1839		10·28
2110		10·47
	Mean Values 18° C.–t° C.	
2714	Bjerrum [4]	10·9

There is no doubt, in the light of Swann's experiments on air, that the values given by Holborn and Henning for nitrogen up to

---

[2] *Zeitschrift für Elektrochemie*, 1912.

[3] *Ibid.*, 1911.

[4] *Zeitschrift für Physik. Chemie*, 1912.

600° C. are too low. Bjerrum recommends the formula $C_v = 4{\cdot}9 + {\cdot}00045\ t$° C. given by Pier, or his own formula[1] based on the theory of quanta, which give practically identical results up to 3000° C. and agree with Swann's value for air at 100° C.

By plotting energy temperature curves from the figures given above, and taking into account Swann's for air and CO_2 at 100° C., the following values for the mean volumetric heats between 100° C. and higher temperatures t° C. have been calculated, and are given as being probably the most accurate at this time available. Where volumetric heats are given by Bjerrum for ranges 18°–t° and 110°–t°, the same figures have been assumed to hold for ranges 0°–t° and 100°–t°. In the higher ranges for water, where Bjerrum gives figures for ranges 18°–t°, the energy has been calculated from Bjerrum's figures as though water were a gas down to 0° C., and 600 cal. subtracted as the energy of the imaginary gas at 100° C.

It has recently been shown[2] that if, using these figures as true volumetric heats and Nernst's constants for the dissociation of CO_2 and H_2O, the actual conditions in an engine cylinder are calculated, then results are obtained which are in excellent agreement with the best experimental engine results.

MEAN VOLUMETRIC HEATS BETWEEN 100° C. AND t° C. IN GRAM CALORIES PER GRAM MOLECULE.

§ (4) CRITICAL COMPARISON OF VOLUMETRIC HEAT FIGURES. (i.) *General.* — Bjerrum has accepted Holborn and Henning's figures up to 1200° C., except as regards their values for nitrogen at low temperatures. This is now known to be too low, and the formula given by Pier and accepted by Bjerrum agrees with Swann's value for air at 100° C., which the B.A. Committee considered correct to within 1 per cent. Hitherto Holborn and Henning's results between 800° and 1400° have been considered as probably too low. Callendar's opinion is that their results, although consistent among themselves, may be subject to systematic errors, making them, over the range 0°–1400° C., as much as 10 per cent too low. This, however, was when Langen's explosion results were the best available for the higher temperatures. The more reasonable view now is to regard the constant pressure results as being confirmed by the recent explosion experiments, and probably accurate to 2 per cent or 3 per cent up to 1200° C.

Above 1200° C. the new figures lie very much below the old, both for carbon dioxide and water. Hopkinson considered that Langen's results were probably too high on account of incomplete combustion and insufficient allowance for heat loss. Part of the difference is probably accounted for, at least in the case of CO_2, by the occurrence of dissociation at the high temperatures in Langen's experiments. In the experiments on which Pier and Bjerrum base their volumetric heat values, precautions were taken to prevent dissociation by having an excess of one of the combining elements present. Bjerrum's experiments were, in fact, designed with a view primarily to measuring the amount of dissociation of CO_2 and H_2O at various temperatures and pressures by comparing the pressures, and hence temperatures, reached with an excess, first of nitrogen, and then of one of the combining elements, present.

§ (5) BJERRUM'S THEORETICAL CALCULATIONS FROM VOLUMETRIC HEAT FIGURES.—Taking a formula given by Einstein, and modified by Nernst and Lindemann, which expresses the distribution of energy in a complex molecule according to the theory of quanta, Bjerrum has developed an expression for the mean volumetric heat of a gas over any range of temperature. Using his own, Pier's, and Holborn and Henning's values for the mean volumetric heats, and evaluating the constants in the formula by means of them, Bjerrum found that the formula can be made to give values for the mean volumetric heat which follow closely the experimental values over the range 0°–3000° C.

In the case of CO_2 some confirmation of the volumetric heat values can be obtained from optical considerations. The formula for volumetric heat involves terms depending on the free period of internal vibration of the molecule. Values of such free periods calculated from observed values of the volumetric heat are found to show very fair agreement with the periodicities at which absorption bands occur in the spectrum of CO_2. Conversely, if the actual wave-lengths for the principal absorption bands are used in the formula, values of the volumetric heat are obtained which only differ by 3 per cent or 4 per cent from observed values up to about 3000° C.

Water exhibits a highly complicated spectrum in the ultra-red region, and this has not yet been sufficiently explored to make it possible to compare the periodicities of actual absorption bands with those calculated from volumetric heat values. It is probable that the complex spectra so far observed are due to the existence of double molecules, and more observations at high temperatures and low pressures are needed before comparison can be made with high-temperature volumetric heat values. Water seems to show, moreover, a rapid increase of volumetric heat above 2000° C., which is not at present understood, and which it is impossible to express in a formula developed entirely from quanta theory. Up to 2000° C. the mean volumetric heat can be closely expressed by a formula of the same type as that for CO_2, but in order to make it follow the observed values above this temperature it was necessary to add to the formula an empirical term involving the fourth power of the temperature.

§ (6) PROBABLE ACCURACY OF EXPERIMENTAL RESULTS.—Of the new explosion experiments under review those by Pier were undertaken primarily with a view to measuring volumetric heats, those by Bjerrum to measuring dissociation. Pier's experiments were all done with initial pressure one atmosphere; Bjerrum's, on the other hand, in order to increase the amount of dissociation, at much lower pressures—about one-seventh of an atmosphere. The point is important in considering the amount of heat loss from the explosion vessel.

The chief cause of uncertainty in all results of explosion experiments lies in estimation of the heat loss during the rise to maximum pressure. Pier neglected this altogether, but fortunately, owing to his method of experimenting, this does not affect the value of his results. Bjerrum did a number of experiments with varying initial pressures, and, on the assumption that heat loss per cent is inversely proportional to pressure, has estimated the heat loss in his own and, where necessary, in Pier's experiments, and has applied corrections accordingly. The magnitude and reliability of his corrections are dealt with under each gas separately.

Pier's method of measuring volumetric heats was to make his explosion experiments comparative, taking as his standard of comparison the monatomic gas argon. The volumetric heat of argon, according to the kinetic theory of gases, should be constant and equal to 2·98 calories per gram molecule. Pier first exploded hydrogen and oxygen with excess of hydrogen and then with excess of argon, but keeping a small excess of hydrogen to prevent any sensible dissociation. By doing experiments at different starting temperatures he was able to obtain figures for the mean volumetric heat of both argon and water-vapour, and to show that argon, at least up to 2000° C., shows no sensible departure from the theoretical value. These results depend on a knowledge of heat loss, which Pier assumed to be zero. Bjerrum has estimated the heat loss in these experiments at 1·8 per cent, and has recalculated Pier's results for the other gases on this basis, and on the supposition that the volumetric heat of argon is constant and equal to the theoretical value. It is impossible, indeed, to conceive of a variation of volumetric heat in a monatomic gas, and this assumption seems justified on experimental as well as theoretical grounds.

(i.) *Nitrogen.*—Pier obtained the ratio between the volumetric heats of nitrogen and argon by comparing the quantities of the two inert gases present with an explosive mixture of oxygen and hydrogen when the same temperatures were produced. In this case the results are therefore purely comparative, and, since heat loss may be taken as being the same under similar conditions of temperature and pressure, Pier's neglect of it does not vitiate his results except in so far as allowance must be made for differences of initial pressure. The magnitude of the loss in these experiments, in which the pressure rise takes place in about one-hundredth of a second, was, according to Bjerrum, only about 2 per cent in any case.[1] So that Pier's comparative results for nitrogen should be accurate to the order of his experimental errors, which were about 1 per cent. On the whole it seems reasonable to expect the figures given by Bjerrum for nitrogen are accurate to within ±1 per cent up to 2000° C. and ±2 per cent up to 3000° C.

(ii.) *Water-vapour.*—The principal experiments on which the figures for water-vapour are based are those of Pier, carried out with initial pressures approximately atmospheric, and for which Bjerrum estimates the heat loss as 1·8 per cent. These carry the values up to 2377° C. Bjerrum has extended this range up to 3064° C. by experiments at low initial pressures (about one-seventh atmosphere), in which he estimates the loss as 14 per cent. This figure he gives with much confidence, but it must be pointed out that a difference of 2 per cent in the allowance for heat loss makes a difference of about 8-9 per cent in the volumetric heat values up to 3000° C. Indeed, in some further experiments with an excess of argon, also by Bjerrum, he finds it necessary to fix the heat loss allowance as 12 per cent in order to bring them into line with the rest of his results. This figure of 12 per cent, he says, was a not improbable one, but does not say why; possibly it was because the argon experiments were at slightly higher initial pressures.

---

[1] This figure agrees exactly with that estimated by David (*Proc. Roy. Soc.* A, xcviii. 308) for the heat loss up to maximum temperature, when allowance is made for the difference in maximum temperature and explosion time according to the empirical formula given by him.

In estimating the probable accuracy of the figures for water-vapour, it seems, therefore, that we must allow that there may be an error of ±5 per cent up to 3000° C., and possibly more. Up to 2000° C. the uncertainty is considerably less. It seems likely that the possible error is not more than ±2 per cent or 3 per cent.

(iii.) *Carbon Dioxide.*—In dealing with CO_2 one has the advantage, as with nitrogen, of being able to make the experiments comparative as between two inert gases, as was done by Pier. On the other hand, the rate of combination where carbon is involved is very much lower than with oxygen and hydrogen. Pier found that the combustion of carbon monoxide was too slow to be any use except for mixtures giving a final temperature over 2200° C. He therefore used combustions of acetylene and oxygen, first with excess of nitrogen, then excess of O_2, and finally with CO_2 and O_2. There is no doubt that Pier was getting very considerable loss of heat before the point of maximum pressure, as is clear from the very low value of the heat of combustion of acetylene which he calculated from his experiments.

It is curious that Pier never realised the importance of his heat losses, and was forced to suppose the formation of an endothermic compound of water and CO_2 to explain his heats of combustion of acetylene. There is some evidence that aldehydes are formed during combustion in an engine cylinder, but it is very unlikely that the quantities are as great as Pier supposed. Bjerrum, however, has accepted Pier's figures, being comparative, as substantially correct, and, as mentioned previously, they receive some confirmation from the spectrum of CO_2.

Bjerrum has extended the range of Pier's figures from 2110° C. to 2714° C. by explosions of CO and O_2, first with excess of CO and then of nitrogen. As before, his experiments were done first with a view to dissociation measurements, but in this case he used initial pressures of one-quarter and one atmosphere. Using his results at these two pressures, he estimates his heat loss correction, and gives 10·9 as the mean volumetric heat from room temperature to 2714° C. The combustion time was of the order of one-tenth second as against one-hundredth second for the oxygen and hydrogen experiments, and the correction on the mean specific heat due to heat loss is in consequence as much as 15 per cent of the value given, in spite of the pressures at which he was working being higher than in the case of his experiments on water-vapour.

Pier has given the formula

$$C_v=6\cdot8+3\cdot3\times10^{-3}t-0\cdot95\times10^{-6}t^2+0\cdot1\times10^{-9}t^3$$

as representing his experimental results upon CO_2 up to 2110° C. This formula gives 10·75 for the range up to 2714° C., so that there is good agreement between Bjerrum's and Pier's figures.

An idea of the optical confirmation of the CO_2 figures may be given as follows: The internal or vibrational energy of a triatomic molecule will be shared between the three mutual vibrations of the three atoms, (1) with (2), (2) with (3), and (3) with (1). In the case of CO_2, since the mutual attraction between a carbon and oxygen atom may be supposed greater than between the two oxygens, it is a reasonable assumption that, of the three vibrations, there will be two of high frequency and one of lower. If the three wave-lengths λ_1, λ_2, and λ_3 of the Nernst-Lindemann quanta function which occurs in the volumetric heat formula are evaluated from observed values of the volumetric heat on the above assumption that $\lambda_2=\lambda_3$ the values obtained by Bjerrum are $\lambda_1=8\cdot1$, $\lambda_2=\lambda_3=5\cdot0$. With these constants the formula gives values of the volumetric heat which follow the actual values closely over the range 0°–2000° C., *e.g.*:

Temperature Range.	Volumetric Heat, Cal. Gm. Mol.	
	Observed.	Calculated.
0–200	7·48	7·44
0–2110	10·47	10·43

Now there are actual absorption bands in the spectrum of CO_2 at $\lambda_1=14\cdot7$, $\lambda_2=4\cdot3$, and $\lambda_3=2\cdot7$. If these values are put into the formula and the volumetric heats calculated from purely optical data, the volumetric heats for the same ranges as above are 7·67 and 10·04. The optical data, therefore, give values within 3 per cent or 4 per cent of the observed ones, and on the whole it seems probable that the latest values of the volumetric heat given by Bjerrum up to 2700° C. may be taken as correct to ±3 per cent or ±4 per cent.

GYROSCOPE

§ (1) DESCRIPTION OF THE GYROSCOPE. INERTIA AND BALANCE.—The gyroscope consists usually of a massive wheel or disc mounted on bearings so as to be free to spin rapidly about its axis of symmetry. The gyroscope as commonly made is symmetrical about an equatorial plane, perpendicular to the axis of symmetry; but this equatorial symmetry is unessential. Any rigid homogeneous solid of revolution may form the spinning element; and, more generally still, the gyroscope may even be irregular in form provided that it is "dynamically symmetrical" about the axis of spin. The conditions necessary for dynamical symmetry are (i.) that the centre of mass O of the gyroscope shall lie on the axis of spin; (ii.) that the axis of spin shall be a principal axis of inertia; (iii.) that the moments of inertia about all axes through O perpendicular to the spin-axis (say, all "diameters") shall be equal. If any body were taken of irregular form with centroid O, and with unequal moments of inertia A, B, C about its mutually perpendicular principal axes through O, and if it were mounted to spin about the C axis, it would differ from the normal gyroscope only in having A and B unequal instead of equal.

In the practical making of gyroscopes the closely approximate symmetry of form is found inadequate to secure these conditions of dynamical symmetry, and a final process of "balancing" is requisite to make the gyroscope run smoothly at high speed. If, in violation of condition (i.), the centroid is not on the spin-axis, but at a short distance from it, the gyroscope is said to be defective in "static balance." With this defect, if the gyroscope is without spin the equilibrium under gravity fails to be neutral (except when the axis is vertical); and when the gyroscope spins about the fixed axis a revolving centrifugal force is thrown on the bearings. A true circular disc, mounted eccentrically on a spin-axis normal to its plane, illustrates the state of bad static balance.

If, in violation of condition (ii.), the principal axis of inertia is not coincident with the spin-axis, but makes a small angle with it, the gyroscope is said to be defective in "dynamic balance." The defect cannot be detected statically; but, when the gyroscope spins, a torque in a revolving axial plane is thrown on the bearings. A true circular disc mounted centrically but obliquely on a spin-axis illustrates the state of bad dynamic balance.

The two defects are both remedied by the addition or removal of small masses of determinable amount and position; and when balanced to run quietly in this way the gyroscope is usually regarded as satisfying all the necessary conditions. But, in violation of condition (iii.), the moments of inertia about different diameters of the gyroscope may be slightly unequal. An elliptical disc mounted centrically and normally on its spin-axis illustrates this defect. The elimination of whirling stress may be regarded as having for its direct consequence the annulment of the product of inertia for every pair of perpendicular planes of which one is axial and the other is normal to the spin-axis; and in consequence the elimination ensures that the conditions (i.) and (ii.) are satisfied. But if the moments of inertia A and B are left unequal, condition (iii.) is violated and the gyroscope is defective. The defect cannot be detected statically, nor by spinning the gyroscope about the fixed axis. It is only when the axis is itself in motion that the uncanonical form of the gyroscope is revealed.

§ (2) THE MOUNTING OF THE GYROSCOPE. DEGREES OF FREEDOM.—In gyroscopic mechanisms each individual gyroscope may have any number of degrees of freedom, up to the limit of six degrees, and these degrees of freedom may arise in an unlimited variety of ways. Most commonly the centroid of the gyroscope remains a fixed point, and only the three angular degrees of freedom about the centroid are left for consideration; and, as the spinning movement accounts for one freedom, there remain only the two degrees of freedom associated with the direction of the gyro-axis z. These two degrees of freedom usually occur as the relative movements of three consecutive members of a chain of pieces. The gyroscope or rotor R (*Fig.* 1) is free to spin about its axis z; and this axis is coincident with the line of bearings of a ring or frame or casing Q, which supports the rotor R. The spinning freedom is thus a rotation about the line z. The casing Q is mounted on a frame or ring P, so as to be free to turn about a line y, intersecting z at O. The rotation of Q relatively to P about y provides the second degree of freedom of R. Finally the ring P is mounted on a fixed base-piece B so as to be free to turn about an axis x, intersecting y at O. The rotation of P relatively to B about x provides the third degree of freedom of R. In the commonest form of apparatus of this sort the axes x and y of the ring P are made perpendicular, and the axes y and z of the casing Q are also made perpendicular, and the fixed axis x is perpendicular to the horizontal base of B and consequently a vertical line. The apparatus usually described as the "Wheatstone gyroscope" is of this type (*Fig.* 1A).

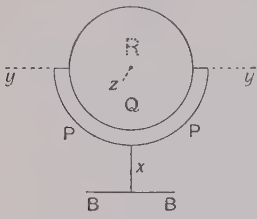

FIG. 1.

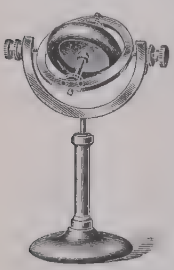

FIG. 1A.—Wheatstone Gyroscope Model in Perspective.

A gyroscope mounted in this way, with complete angular freedom, is sometimes spoken of as a "free" gyroscope. If the hinge-line x is locked the gyroscope has only two degrees of freedom, and is then often described as "constrained." The gyro-axis z is then restricted to move in a circular cone with y as axis and yz as angle. Very specially (and commonly) yz is a right angle, and z is thus restricted to move in a fixed plane normal to y. (In the Wheatstone gyroscope the gyro-axis then turns round a fixed horizontal axis.)

If the hinge y is locked and x is left free then, similarly, the gyroscope has only two degrees of freedom, and z is restricted to describe a circular cone about x (or a plane normal to x).

More generally the gyro-axis z might in any way be left free, by mechanical constraints applied to the casing Q, to move only along a definite route (generating a cone of arbitrary form), and the gyroscope would again have two degrees of freedom.

It is to be observed that the reduction from three degrees of freedom to two degrees may occur without the suppression of the freedom of rotation about x or y. The complete angular freedom of the gyroscope arises from the fact that any angular rotation about O may in general be derived as the resultant of suitable components about x, y, and z. This fails to be true, however, when x, y, and z happen to be coplanar; and this occurs for each of two positions, when the relative rotation of P and Q brings the planes xy and yz into coincidence. For angular velocities about coplanar lines have as their resultant an angular velocity about a line lying necessarily in the same plane. For the Wheatstone mounting (*Fig.* 1A), x and z themselves coincide in these two positions (when the gyro-axis is vertical), and the loss of freedom is often attributed to the identity of the two rotations about the coincident lines; but the identity, though sufficient to account for the loss, is not essential. (The proposal to avoid the danger of this loss of freedom, when three degrees of freedom are to be preserved, by adding an extra member N to the chain of pieces PQR introduces a fresh objection; for the links N, P, Q of the chain BNPQR then have an indeterminate position for any one direction of z, and would move about at random.)

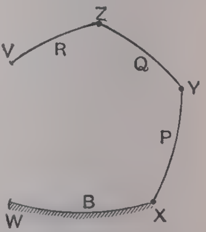

FIG. 2.

The case of a gyroscope with only one degree of freedom, as for x and y both locked, leaving the spinning movement about z as the sole freedom, should be mentioned as the ultimate and simplest form of freedom; but it has no gyroscopic importance.

If abstraction be made of the directions of the three axes x, y, and z of the gyroscopic apparatus, without regard to position in space or any other detail, a unit sphere centred at O and cutting the lines x, y, z at points X, Y, Z gives a completely representative figure on the spherical surface (*Fig.* 2). The fixed point X represents the fixed axis of the base-piece B; the great-circle arc XY represents the ring P; Y represents the axis y connecting the ring P and the casing Q; YZ represents the casing Q; and Z represents the gyro-axis. To complete the figure, any arbitrary line w of the base B gives a fixed point W, and WX represents the base B; and if any line v of the rotor R gives the point V, the arc ZV represents the rotor R. With this open quadrilateral WXYZV, with WX fixed and all the sides of constant length, the complete angular freedom of VZ is given by the rotation of XY about X, of YZ relatively to XY about Y, and of ZV relatively to YZ about Z. And it is when the angle at Y is zero or two right angles that the triangle XYZ degenerates into a great-circle arc, and one degree of freedom is lost; Z having then no movement possible except in the direction perpendicular to XYZ.

§ (3) GYROSCOPIC EXPERIMENTS.—As preliminary to a formal account of the kinematics and dynamics of the gyroscope, it may be convenient to state briefly the results of a number of simple experiments with the Wheatstone gyroscope. When checked by the principles developed later there will appear the reasons underlying these various movements; and there will arise also certain qualifications necessary to some of the statements that seem empirically correct. Familiarity with such experimental results is to some extent serviceable, in lack of more complete information, as a rough working knowledge of practical gyroscopics.

The experiments with the rapidly spinning gyroscope may be briefly described as follows, the degrees of freedom being as stated in each separate case:

(i.) Axis x locked, y free; any forces applied to Q. The gyroscope offers no resistance to the turning of Q about y.

(ii.) Axis x free, y locked; any forces applied to P or Q. The gyroscope offers no resistance to the turning of P and Q about x.

(iii.) Axes x and y both free; B moved about in any manner. Then z retains its original and arbitrary direction unchanged. But if, during the movement of B, x comes to coincide with z (or passes very near z) a violent "kick" occurs and z abruptly changes direction.

(iv.) Axes x and y both free; z horizontal; a weight hung on one end of z and released. Then z remains horizontal, and P and Q rotate uniformly about x at a rate proportional directly to the weight and inversely as the spin of the gyroscope. If the movement of P is "hurried" by a torque applied to P about x the weight rises, and if P is hindered the weight descends.

(v.) Axes x and y both free; z pointing in any direction; a smooth straight-edge is laid perpendicular to z and pressed against the spindle of R. The spindle does not yield to the pressure but moves along the straight-edge in the same sense as if it were rolling along the straight-edge by reason of the spin.

(vi.) Axes x and y free, z horizontal; forces are applied to P as if to turn P about x. The turning about x is resisted and tilting of Q about y occurs. When z reaches the vertical the resistance, after diminishing, disappears and P is freely rotatable in the sense of the spin. If the direction of rotation of P is then reversed a sudden "jolt" occurs, Q begins to capsize, the rotation of P is resisted, and z presently again becomes vertical. The rotation of P is then again unresisted in the sense of the spin.

§ (4) KINEMATICS OF THE GYROSCOPE.—If the gyroscope executes any kind of movement, a description of that movement at any moment may consist in a statement of the component angular velocity Ω about the axis z, usually called the "spin," and the instantaneous rate of movement ω of the axis z. The latter has now come (by an enlargement of the original use of the term) to be called the "precession." The plane in which the axis z moves is the instantaneous plane of precession, and the diameter u of the gyroscope drawn normal to this plane is the instantaneous axis of precession. In the representative spherical diagram (*Fig.* 3) the resultant angular movement of the gyroscope is represented by the spin Ω about Z, together with a velocity ω of Z along (Z) the spherical curve which is the path of Z. If the quadrantal triangle ZTU is completed, then ZT, the tangent to the curve (Z), represents the plane of precession, TU the central plane of the gyroscope, and U the axis of precession. The resultant movement of the gyroscope is compounded of angular velocities Ω about Z and ω about U. The triangle itself has ZU as normal at Z to the curve (Z), and ZU touches at K the curve which is the envelope of ZU and the evolute of (Z). The point K is also the centre of the small circle that osculates the curve (Z) at Z; and ZK ($=\rho$, say) is the angular radius of curvature of (Z) at Z. The movement of the triangle ZTU as a rigid figure is given by the rolling of ZU on the evolute curve, and consists instantaneously of an angular velocity n about K. The components of n about Z and U are $n \cos \rho$ and $n \sin \rho$ respectively, giving velocities $n \cos \rho$ of U along TU and $n \sin \rho$ of Z along ZT. The latter velocity is by hypothesis ω, and therefore $\omega = n \sin \rho$. Hence $n = \omega/\sin \rho$; and the component angular velocities of the triangle ZTU are $\omega \cot \rho$ about Z and ω about U. The gyroscope and the triangle have movements identical in respect of the components about U and differing only in the components about Z.

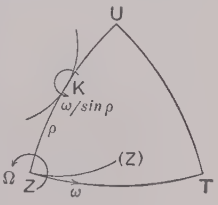

FIG. 3.

§ (5) DYNAMICS OF THE GYROSCOPE.—The angular momentum of the gyroscope is the resultant of the separate angular momenta associated with the two component angular velocities, and is therefore compounded of $C\Omega$ about the axis z and $A\omega$ about the diameter u. The rates of change of these two vectors give rise to two separate torques or couples which, as kinetic reactions, are together equivalent to whatever system of applied forces may be acting on the gyroscope. They may be calculated separately.

The vector rate of change of any space-vector r having angular velocity $\bar{\omega}$ is given by the linear velocity of its extremity, and is compounded of $\dot{r}$ radially and $r\bar{\omega}$ normal to the vector in the plane of its movement. The angular momentum $C\Omega$ about OZ, corresponding to the vector r, thus gives rise to a torque $C\dot{\Omega}$ about OZ and a torque $C\Omega\omega$ about OT. The angular momentum $A\omega$ about OU gives rise to a torque $A\dot{\omega}$ about OU and a torque $-A\omega^2 \cot\rho$ about OT, since $\omega \cot\rho$ is the angular velocity of the triangle about Z.

As the torque about OZ is $C\dot{\Omega}$ it follows that the angular acceleration $\dot{\Omega}$ of the spin Ω is the same as would be produced by the same torque about z if the axis z were stationary. When, however, the gyroscope is supposed to be already set spinning on frictionless bearings, or (in practice) to be supplied with an electrical driving torque counterbalancing the resistances, the applied torque about the axis z is then zero, and hence $C\dot{\Omega}$ is zero and Ω remains constant independently of any movement imposed on the axis z. (This property of a gyroscope is not true if condition (iii.) of § (1) is violated. Unequal values of A and B give rise to fluctuations in the spin Ω.)

It is convenient to represent the torques by equivalent forces, acting at Z perpendicular to OZ, and producing the same moments as those of the torques. These forces are:

$A\dot{\omega}$ along the great-circle tangent ZT at Z.
$A\omega^2 \cot\rho$ along the inward normal ZK at Z.
$C\Omega\omega$ along the normal at Z. (*Fig.* 4.)

The last force $C\Omega\omega$ has direction and sense which, if rotated through one right angle about Z in the sense of the spin Ω, gives the direction and sense of the velocity ω along ZT.

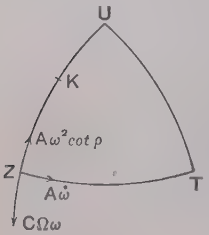

FIG. 4.

Of these three forces (or the torques they represent) it may be noticed that the first two are independent of the spin and of the moment of inertia C, and depend only on A and on the movement of the axis z. They would constitute the whole torque if either C or Ω were zero. A thin rod along OZ credited with the same moment of inertia A would give rise to these same forces; or a single particle of mass A at Z would alone suffice. And the expressions $\dot{\omega}$ and $\omega^2 \cot\rho$ are the components of the acceleration of Z along the tangent ZT and the normal ZK; for $\dot{\omega}$ is the rate of change of the velocity ω of Z, and $\omega^2 \cot\rho$ is the product of the velocity ω and $\omega \cot\rho$ the rate of turning of the tangent ZT about Z. The mass A at Z would thus give the same two forces.

§ (6) THE GYROSCOPIC TORQUE. RULES FOR THE PRECESSION.—The torque $C\Omega\omega$ is known as the "gyroscopic torque." It has OT for its axis and UZ for its plane. In many practical uses of the gyroscope the value of Ω is so large that this torque dominates the rest, and may be taken by itself as sufficiently representative of the whole kinetic reaction. The simple rule then is that the plane of the applied torque and the plane of precession are perpendicular planes through the axis of the gyroscope; and that the torque has a moment equal to the product of the angular momentum $C\Omega$ of the gyroscope and the rate of precession ω. A variety of rules have been proposed as indications of the sense of precession.

(α) The most common statement takes some such form as this: The precession is such that, after a precessional movement continued through one right angle, the axis of the gyroscope would coincide with the axis of the torque, and the sense of the spin would agree with that of the torque. But in practice there is a certain awkwardness and inconvenience in the need to consider a merely hypothetical position of the gyroscope.

(β) A briefer equivalent is to mark the sides of the quadrantal triangle, such as ZTU, with arrows circulating round the triangle and representing the senses of Precession, Spin, and Torque in that (alphabetical) order.

(γ) Rules more readily applied may be stated for *forces*, taken as equivalents of the gyroscopic torque. Thus, as above, if a force perpendicular to the axis of the gyroscope act at a point of the axis, the corresponding force-vector, when swung through a right angle in the sense of the spin, points then in the sense and direction in which the point moves as a consequence of the precession. More realistically the force may be supposed actually applied to the thin smooth spindle of the gyroscope by lateral pressure of a straight-edge; and the precession then makes the spindle slip along the straight-edge; and the sense of travel is *as if* the spindle were *rolling* on the straight-edge by reason of its spin.

(δ) A similar form of statement is true for a force parallel to the axis and supposed to act on the rim of the gyroscope; namely, if the force-vector normal to the wheel is carried round, as if rigidly connected with the wheel, through one right-angle in the sense of the spin, it then indicates the precessional movement of the rim.

§ (7) Kinetic Reaction, Angular Momentum, and Energy.—In regard to the torques of § (5) it should be remarked that $A\dot{\omega}$ and $A\omega^2 \cot \rho$ depend on the (surface component of the) acceleration of Z; and that if that acceleration be itself expressed in terms of any convenient set of components, it is only necessary to multiply each of those separate components by A in order to obtain the required torques. And similarly $C\Omega\omega$ depends on the velocity of Z; and if that velocity presents itself as composed of any set of components it is only necessary to multiply each component by $C\Omega$, and turn it round through one right-angle backwards (*i.e.* against Ω) about Z, in order to obtain the corresponding contribution to the gyroscopic torque.

Of angular momentum it should be borne in mind that, unlike linear momentum, it has only magnitude and direction and is not a located vector. The sum of the momenta of the elements of a gyroscope (with its centre at rest) about any line parallel to the axis is the same as about the axis itself. The gyroscope might be replaced by another equal gyroscope with a parallel axis, inside the same casing, and the gyroscopic torque would not be affected by the change. Further, if the same casing contained several gyroscopes, each spinning on an axis fixed relatively to the casing, the gyroscopic torque for any movement of the casing would be only the same as for a single contained gyroscope with an angular momentum equal to the vector sum of those contributed by the several gyroscopes.

The principle of energy demands that the applied forces should do work on the gyroscope equal to the increase of its kinetic energy. The forces $C\Omega\omega$ and $A\omega^2 \cot \rho$ at Z acting normally to the velocity of Z along ZT, do no work, and the force $A\dot{\omega}$ does work at the rate $A\dot{\omega}\omega$. If the spin varies, the torque $C\dot{\Omega}$ causing the variation does work at the rate $C\dot{\Omega}\Omega$, and the sum $A\dot{\omega}\omega + C\Omega\Omega$ is thus the time-differential of the kinetic energy $\frac{1}{2}(A\omega^2 + C\Omega^2)$.

§ (8) Simple Cases of Motion of a Gyroscope.—The three torques found in § (5), which usually act in combination, may occur separately for special movements of the gyroscope.

(i.) The torque $A\dot{\omega}$ occurs alone if $\Omega = 0$ and $\rho = \pi/2$—*i.e.* if the gyroscope has no spin and its axis is rotating in a plane. The torque $A\dot{\omega}$ also occurs alone, initially, if ω is momentarily zero, with any value for Ω. Hence under the action of a torque the gyro-axis moves initially in the plane of the torque itself. [The direction of motion begins to turn, however, at a rate $(C/A)\Omega$.]

(ii.) The torque $A\omega^2 \cot \rho$ occurs alone if $\Omega = 0$ and ω is constant—*i.e.* if the gyroscope has no spin and its axis describes a cone of any form at a uniform rate. The torque measures the normal pressure on the guiding curve or cone. If ρ also is constant the cone or curve is circular and the torque is constant.

(iii.) The gyroscopic torque $C\Omega\omega$ occurs alone if $\rho = \pi/2$ and ω is constant—*i.e.* if the axis of the gyroscope rotates uniformly in a plane. It may be noticed in this case how, in detail, after a turn of the axis through an angle 2α the time-integral of the torque-vector accounts for the change of momentum. The torque-vector $C\Omega\omega$ moves round one right-angle in advance of the axis. The mean of the vectors ranging over the angle 2α is $C\Omega\omega$ $(\sin\alpha/\alpha)$ along the angle-bisector, and the time is $2\alpha/\omega$; hence the time-integral of the torque gives a momentum $2C\Omega \sin \alpha$ one right-angle beyond the angle-bisector of the gyro-axes. The change of momentum is $C\Omega \times 2 \sin \alpha$ and it has the same direction. In particular when $2\alpha = \pi$, with reversal of the axis, the change of momentum is $2C\Omega$.

(iv.) If ω and ρ are both constant, Z in *Fig.* 3 describes a circle with centre K, and the triangle ZTU rotates uniformly about K as a fixed point. The axis of the gyroscope describes a circular cone of angle ρ. The torque outwards from the axis of the cone is $C\Omega\omega - A\omega^2 \cot \rho$. For the customary rapid spin this is positive in sign; but if ω were rapid also the torque, specially, is zero for the case $C\Omega = A\omega \cot \rho$. This conical steady motion is then a free movement of the gyroscope. If, say, the stationary casing containing the spinning gyroscope is struck a heavy blow, giving an impulsive torque $A\omega$ about a diameter of the gyroscope, the impulse creates suddenly an angular momentum $A\omega$ and there ensues a conical motion of the axis z with $\tan^{-1}(A\omega/C\Omega)$ for the angle of the cone. This motion, being rapid, gives a blurred effect, visually, and is generally spoken of as a "wobble"; but it is nevertheless technically a "steady motion."

The constant torque $C\Omega\omega - A\omega^2 \cot \rho$ necessary in general for the conical steady motion of the gyroscope is linear in Ω but quadratic in ω. Hence, for an assigned value of the torque giving movement on the cone of angle ρ, there is a unique value of the spin for any assigned rate of precession; but two rates of precession for any assigned spin are given by the roots of a quadratic equation, and may be real or coincident or imaginary. The steady motions of a top (which may be regarded as a frameless gyroscope) illustrate these results.

(v.) If the gyro-axis is guided by any smooth constraints, adequate to take any lateral pressures, the torques $C\Omega\omega$ and $A\omega^2 \cot \rho$ are supplied by the constraints, and the agent controlling the precessional movement of the axis has only to supply the torque $A\dot{\omega}$. The gyroscopic torque falls on the rigid constraints, and the agent experiences no "gyroscopic resistance" whatever.

§ (9) GYROSCOPE WITH TWO DEGREES OF FREEDOM ON A ROTATING BASE.—Instead of prescribing directly a movement of Z (*Fig.* 2) the movement prescribed may be that of Y, leaving the movement of Z to ensue as a dynamical consequence. In a simple case YZ may be taken to be a quadrant, and XY also a quadrant, and Y may be made to move uniformly along its path, the great circle with centre X, at the constant angular rate n. The point Z is thus constrained to lie on a meridian, say, of the sphere; the meridian being XZ and rotating at rate n about the pole X. If θ is the polar distance XZ (equal to the angle XYZ) the velocity of Z has components $\dot{\theta}$ along the meridian and $n \sin \theta$ along ZY perpendicular to the meridian. The corresponding components of the gyroscopic torque give forces at Z equal to $C\Omega n \sin \theta$ along the meridian and $C\Omega\dot{\theta}$ perpendicular to it. (It is supposed that Ω and n would agree in sense if the angle θ were reduced to zero.) The acceleration of Z as determined from its component velocities and the local rate of rotation $n \cos \theta$ of ZX at Z (or otherwise) has components

$$\left.\begin{aligned} &\frac{d}{dt}(\dot{\theta}) - (n \sin \theta)(n \cos \theta) \\ \text{and}\quad &\frac{d}{dt}(n \sin \theta) + (\dot{\theta})\,(n \cos \theta), \end{aligned}\right\} \quad . \quad . \quad . \quad (1)$$

i.e. $\ddot{\theta} - n^2 \sin \theta \cos \theta$ along the meridian (2)

and $2n\dot{\theta} \cos \theta$ perpendicular to it. . (3)

The corresponding forces are obtained by multiplying by the moment of inertia A (§ (5)) and are therefore

$A(\ddot{\theta} - n^2 \sin \theta \cos \theta)$ along the meridian (4)

and $2An\dot{\theta} \cos \theta$ perpendicular to it. . (5)

Hence the equation of motion in θ is

$$A(\ddot{\theta} - n^2 \sin \theta \cos \theta) + C\Omega n \sin \theta = 0, \quad (6)$$

with the integral

$$A\dot{\theta}^2 + An^2 \cos^2 \theta - 2C\Omega n \cos \theta = \text{constant}. \quad (7)$$

This integral expresses the kinetic energy as a quadratic function of $\cos \theta$. This case may be compared with simple pendulum motion, with no movement in azimuth, for which the kinetic energy is a linear function of $\cos \theta$; and also with conical pendulum motion, with free and variable movement in azimuth, for which the kinetic energy is a cubic function of $\cos \theta$. The present case is in a sense intermediate. For a pendulum of period $2\pi/p$, with $\theta = 0$ as the downward vertical, and with the vertical plane of swing made to rotate uniformly at the rate n, the equation of motion is

$$\ddot{\theta} - n^2 \sin \theta \cos \theta + p^2 \sin \theta = 0. \quad . \quad (8)$$

The position $\theta = 0$ is a stable position if $p > n$. If $p < n$ the position $\theta = 0$ is unstable, and an inclined position of equilibrium exists given by $\cos \theta = p^2/n^2$, and is stable. The position $\theta = \pi$ is one of equilibrium but is unstable for all values of p/n. (Another simple instance of the same movement occurs in the case of a magnetic needle oscillating in a horizontal plane in the earth's field, with a soft-iron rod horizontal and perpendicular to the needle and rigidly connected with it.)

The equations (6) and (8) are identical if $(C/A)\Omega n = p^2$, and hence the position $\theta = 0$ is stable if $C\Omega > An$. It is unstable if $C\Omega < An$; and a position of equilibrium is then given by $\cos \theta = (C\Omega/An)$. The position $\theta = \pi$ is an equilibrium position but unstable for all values of Ω/n. Hence (*Fig.* 2) when Z is at X the spin agrees in sense with that of the rotation of XY about X, and the position is stable provided $n < (C/A)\Omega$. When Z is at the antipodes of X the senses are opposite, and the position is always unstable. For the first case the spin is customarily so large that the inequality is amply satisfied, and the experimental results are apt to prompt an unqualified statement of stability. The inequality, however, is an essential condition.

The lateral pressure L of the meridian on the gyro-axis is given by

$$L = (2An \cos \theta - C\Omega)\dot{\theta}. \quad . \quad . \quad (9)$$

The force L has a moment $L \sin \theta$ about OX, which has to be supplied by the agent responsible for maintaining the rotation n. He provides therefore a variable torque $L \sin \theta$, which is identically equal to

$$\frac{d}{dt}(An \sin^2 \theta + C\Omega \cos \theta), \quad . \quad (10)$$

the rate of increase of the angular momentum about OX. Further, the agent supplies energy at the rate

$$\tfrac{1}{2}\,\frac{d}{dt}\left[A(\dot{\theta}^2 + n^2 \sin^2 \theta) + C\Omega^2\right]; \quad . \quad (11)$$

and this reduces as it should to $nL \sin \theta$ in virtue of (6) and (7).

If the gyroscope is originally in the unstable position $\theta = \pi$ its axis will pass the position $\theta = \pi/2$ with an angular velocity in θ given by

$$-\dot{\theta} = \left[n^2 + 2(C/A)\Omega n\right]^{\frac{1}{2}} \quad . \quad . \quad (12)$$

and the torque of resistance to the rotation of the meridian at this moment is equal to

$$C\Omega\left[n^2 + 2(C/A)\Omega n\right]^{\frac{1}{2}}. \quad . \quad . \quad (13)$$

For a rapid spin Ω this torque may be considerable even for a value of n too small to show a visible movement of the meridian.

The special conditions $XY=\pi/2$ and $YZ=\pi/2$ involved in the above movement may be removed without alteration of the form of equation (6). The mutual inclination of the lines x and y, y and z may be arbitrary; so that the point Y describes a small circle uniformly about X, and Z keeps at a constant distance from Y. The variable angle XYZ still obeys a rotated-pendulum equation, and may take equilibrium values determined as before. For a rapid spin the stable position of Z is that which gives the smallest value to XZ.

More generally still, if Z is constrained to lie on any rigid curve that is rotated uniformly at a constant rate n about a fixed point X, it is at once apparent that the only positions of equilibrium are those for which the force along ZX is either normal to the curve at Z or else is zero. Hence positions of equilibrium occur at the foot of any normal drawn from X to the curve (Z). The exceptional case of a zero force (giving free movement of the gyroscope, with the guide out of effective action) occurs if $\cos XZ=(C\Omega/An)$; giving all points in which a circle centre X and radius XZ cuts the curve; or more exceptionally if $XZ=0$ or π, which can occur only when the curve passes through X or its antipodes, as in the case first above treated.

It may further and more particularly be shown that the normals give stable positions for a minimum value of XZ when $C\Omega>An$, so that the circle is unreal; and that when $C\Omega<An$, so that the circle is real, the stable positions are given by the minimum values of XZ for points Z outside the circle, and by maximum values of XZ for points Z inside the circle. The other equilibrium positions, reversely, are unstable. For the common cases that arise in present practice n is small compared with Ω, the circle is imaginary, and the minimum values of XZ correspond to the positions of stable equilibrium.

§ (10) General Considerations on Gyroscopic Mechanics.—In considering the rationale of gyroscopic movements the student will be well advised to adhere very strictly to the precise correlation of cause and effect. Even when the spin is large and the gyroscopic torque is dominant the assignment of applied torque and consequent precession as proportional correlatives should be followed in definite detail. In abbreviated verbal reasonings the common use of the word "tendency" is fruitful of much misunderstanding. The "tendency" is usually a movement which is regarded as prevented by a constraint; and as the removal of the constraint would generally be followed by an altogether different movement the latent confusion is extreme.

Of certain well-established statements which must be quoted only with caution and understanding a few may be cited.

"A free gyro tends to keep the axis about which it spins, unaltered in direction." The fixity of direction, in space, of the gyro-axis is not peculiar to the spinning gyroscope, but belongs equally to the non-spinning gyroscope. Indeed any line in any freely balanced body, originally free from rotation, would behave in the same way. The practical effect of the high spin is that the large store of angular momentum demands a much larger value for the time-integral of any disturbing torque to produce an assigned amount of angular displacement; so that the casual disturbing forces, if identical in the two cases, will produce much less angular displacement in the axis of the gyroscope that is rapidly spinning.

"A rapidly spinning gyroscope offers great resistance to any attempt to alter the direction of its axis." It has been seen, § (8) (v.), that if a constraint supplies the gyroscopic torque the agent controlling the movement finds no gyroscopic opposition at all. A gyroscope mounted on a door, so as to spin in the plane of the panel, leaves the door as easy to open or shut as if the gyroscope were not spinning at all. It provides no "resistance," although its axis rotates with the door as the door swings. But a torsional stress (about a horizontal line of the door) is thrown on the hinges. If resistance is desired it can be secured (cf. § (9)) by giving the gyroscope two degrees of freedom relatively to the piece moved by the agent.

"Hurry on the precession and the top will rise in opposition to gravity." This is intended to apply to the slow precession of a top-heavy top leaning at an acute angle from the upward vertical (cf. § (8) (iv.)). The spin and precession circulate in the same sense, and the more general statement of § (6) (γ) covers what is really intended. But as the effect of the forward force applied is (for the case of rapid spin) to produce an angular velocity of erection only, and no sensible increase of the rate of precession at all, the precession is, after all, not "hurried." The meaning seems to be that an attempt is to be made which *would* hurry the precession if the dynamics were *not* gyroscopic. If it is desired actually to hurry the precession the force applied to the axis must be such as to increase the gravity torque.

It may happen on occasion that the effect of "hurrying the precession" is to make it slower, or even to reverse it. A simple example may be given. In the Wheatstone gyroscope the casing Q may be fitted with a weight so that in the absence of spin the axis z is statically vertical for either of two positions—one stable and the other (top-heavy) unstable. If the plane yz is tilted slightly, and the gyroscope spins, a steady motion of slow precession takes place. In the top-heavy case the effect of "hurrying the precession" will be to reduce the tilt, and so leave the rate of precession reduced in the same ratio; and if the precession is so much "hurried" as to annul and reverse the small tilt, then the ensuing precession is reversed in sense. Conversely, in order to produce an actual quickening of the precession it may be momentarily opposed.

The high speed given to gyroscopes in practice, with the consequent dominance of the gyroscopic torque, produces an experimental simplicity of effect which may even obscure the fundamental dynamics. It would appear, *ex. gr.*, that on loading one end of the horizontal axis of the gyroscope of a Wheatstone gyroscope the appropriate rate of precession ensues automatically, and that the axis revolves uniformly in the horizontal plane. If that were so, then neither the extra kinetic energy due to the precession, nor the new angular momentum about the vertical x, can be accounted for; for the attached load is supposed not to have sunk, and its weight has provided no moment about the vertical. If this precise state of motion is to be actually obtained the proper precession must be given initially to the piece P. Without this proviso the point Z (*Fig.* 2) describes in fact not a horizontal great circle but a series of small cycloids with their cusps on the circle, as if generated by a trace-point on a minute wheel rolling below the circle. The mean level of the point Z is below the circle by an amount that accounts for the kinetic energy of the mean rate of precession, and the mean tilt of the axis z gives a component of the spin-momentum about the vertical that is equal and opposite to the angular momentum of the mean precession. The same results in kind hold good if the axis z has a finite slope initially; and the case of a top abandoned with a rapid spin in an inclined position is another form of the same thing. The top appears to execute a steady motion with a precession that is not provided for it; but the actual motion of the axis includes a tremor that involves both a variable precession and a "nutation" in respect of the inclination of the axis to the vertical. (The decay of these rapid tremors, under dissipative forces of friction, etc., is usually very rapid.)

In practical mechanics the attempt is often made to deal with gyroscopic movements by sole reference to the gyroscopic torque, to the complete exclusion of the supplementary torques that are independent of the spin. On occasion the method suffices; but it may lead to meaningless or erroneous results. In the case, § (9), of the gyroscope with an axis free to revolve in a plane that is uniformly rotated, the gyroscopic torque presents a component in the plane itself which no reaction is available to supply. The equation of motion (6) loses all but its last term, and the problem is stultified. It may be further suggested that the dynamical possibilities involved in the use of gyroscopes with moderate spins may presently be developed.

The familiar demand for an "explanation" of the gyroscopic torque of a precessing gyroscope will be found to survive repeated discussions of the phenomenon so long as they are based on the principle of angular momentum; and apparently the demand can only be met (if it need be) by the avoidance of this fundamental sophistication. If the simple case of the movement of § (8) (iii.) is considered, and if the axis of the gyroscope is at the moment pointing east and precessing to the north, and the spin is from zenith to north, then any small portion of the top of the disc is moving northward; but on account of the precession it is located to the west of the meridian both before and after passing the summit, and so has a component acceleration to the west. The bottom of the wheel has similarly an acceleration to the east. Hence the pair of equal forces necessary to account for these accelerations constitute a couple that agrees with the known gyroscopic torque in its plane and its sense (cf. § (6) (δ)). If the mass of the wheel be regarded as replaced by four particles equal in mass and equally spaced round the rim, and two equal particles equally distant from the centre and placed on the axis, so as jointly to preserve the same mass and moments of inertia, the acceleration of each particle may be readily calculated and the forces found in detail. Briefly, if the rim-masses are each m, and the radius a, then $C=4ma^2$. The accelerations of the summit and bottom, to west and east respectively, are $2a\Omega\omega$ (cf. § (9) (iii.)), and all the other accelerations are purely radial. Hence the parallel and opposite forces are of magnitude $2ma\Omega\omega$, with an interval $2a$ between them, and thus give a torque $4ma^2\Omega\omega$, which is equal to $C\Omega\omega$. If the general movement of the gyroscope is considered, in place of this very special steady motion, the additional torques, dependent on the diametral moment-of-inertia A, can be similarly evaluated. The use of the artifice of equivalent particles thus enables the kinetic reaction of the gyroscope to be calculated by appeal to the information supplied by the dynamics of a particle.

HEAT, CONDUCTION OF

§ (1) Introduction.—When one end of a metal bar is heated, a change of temperature can very soon be detected along the bar, due to the passage of heat through the metal. This power of transmitting heat is possessed in varying degree by all material substances, and the phenomenon is known as the Conduction of Heat. It is usual to distinguish it from two other agencies by means of which heat is propagated and which are dealt with in separate sections in this work—namely, Convection and Radiation. In the case of convection the heat is transferred by the actual movement of the heated matter, gaseous or liquid, as distinguished from conduction, in which no transfer of the matter itself is apparent. In fluids both conduction and convection seem to be processes of diffusion. In the case of conduction the action is molecular, due to the diffusion through the substance at rest of its molecules, carrying with them their kinetic energy; in that of convection it is molar, brought about by the movement of small portions of the substance as eddies, or in other ways, thus transferring from point to point the kinetic energy of the molecules which go to form the eddy. Both conduction and convection are comparatively slow in their effects. Radiation, on the other hand, is the transfer of energy by etherial vibration and does not depend on the presence of the matter. Its velocity of propagation, whether in the form of waves of light, heat, or those used in wireless telegraphy, is, of course, enormous.

While it is convenient to adopt this classification of the agencies of heat propagation, it should be realised that the phenomena are probably closely related. For example, from the point of view of the molecular theory, it can be supposed that each molecule, as it becomes heated, affects those around it by radiation or by imparting some of its increased vibration to them by direct contact. The phenomenon of conduction might thus be regarded as a process of intra-molecular radiation or convection. If the analysis is carried further by adopting the modern theory of electrons, capable of diffusing through metallic bodies and conductors of electricity, but capable only of vibration in dielectrics, the mechanism of heat conduction is reduced to diffusion in metallic bodies and radiation in dielectrics. It would be out of place here to enter on a full discussion of the mechanism of heat conduction. The theory will be referred to only so far as is necessary to enable us to deal with the practical subjects treated below. These will include a description of some typical methods of measuring conductivity, together with a summary of the results obtained by various observers and also some applications of the theory to conditions of heat flow which are encountered in practice.

§ (2) Definitions.—The first to give a precise definition of conducting power was Fourier, whose monumental work, *Théorie analytique de la chaleur* (1822), forms the basis of all mathematical treatment of the problems of heat flow.

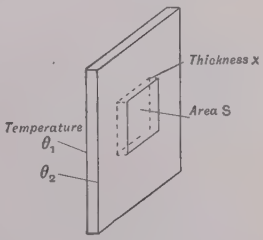

Fig. 1.

(i.) *Conductivity: Steady State.*—A clear conception is, perhaps, best obtained by considering a thin wall of material with parallel faces, one of which is maintained at a temperature θ_1 and the other at a temperature of θ_2 (*Fig.* 1). When the steady flow of heat has been established—that is to say, when the amount of heat flowing into the wall through one face is equal to that flowing out from the other, none being absorbed or given up by the intervening material—it can be shown that the quantity of heat passing through the wall is proportional to the difference in temperature between the faces. The quantity also varies inversely as the thickness x of the wall, and directly as the area S and the time t, so that we have the relation

$$Q = KSt\frac{\theta_1 - \theta_2}{x} \text{ or } KSt\frac{d\theta}{dx}, \quad . \quad . \quad (1)$$

where Q is the quantity of heat and K is a constant depending on the nature of the material of the wall and which is called the "Thermal Conductivity."

It is sometimes convenient to consider the thermal conductivity as being the ratio of the rate of heat flow per unit area to the fall of temperature per unit thickness. The latter quantity $(\theta_1 - \theta_2)/x$ or $d\theta/dx$ is called the "temperature gradient."

Following from the formula above, the unit of conductivity is defined, on the C.G.S. system, as the number of calories per second that would flow through every square centimetre of the surface of a wall of thickness 1 cm. and with a difference of 1° C. between its faces. Another unit commonly used by engineers is the British Thermal Unit[1] per hour, per square foot, per inch thickness, per 1° F. difference. To convert the C.G.S. unit into the other unit it is necessary to multiply by 2903.

In the simple case, which has been taken above, of a wall with parallel faces kept at uniform temperatures, the surfaces of equal temperature in the material, or "isothermal surfaces," will be parallel to the faces of the wall and the lines of heat flow will be straight lines perpendicular to the faces. If, however, the material is not in the shape of a plane wall, or if the conditions of heat supply are different from those assumed, the isothermal surfaces and the lines of flow may be curved and the problem of calculating the heat flow will generally become very complicated. For such cases it is convenient to rewrite the equation in the form

$$Q = Kt(\theta_1 - \theta_2) \times \text{shape factor}, \quad . \quad (2)$$

θ_1 and θ_2 being, as before, the temperatures of isothermal surfaces and the "shape factor" being a constant depending on their shape and relative disposition. The shape factor has been calculated for a few simple cases, such as a sphere heated centrally and a long cylinder heated axially, and approximate formulae have been obtained for some other common forms. These are dealt with in Part II. below.

(ii.) *Diffusivity: Variable State.*—The formulae given above apply only to the flow of heat when the steady state of temperature has been established throughout the body. If, however, the temperature of the body is changing at any point it is obvious that part of the heat inflow (or outflow) will be accounted for by the amount absorbed in raising (or liberated by lowering) the temperature of the body at that point, so that the heat flow will depend partly on the thermal capacity. As a matter of fact, in the equations governing the variable state the constant $K/c\rho$ (or thermal conductivity divided by heat capacity per unit volume) occurs. This constant has been called by Kelvin the "Diffusivity," while Clerk-Maxwell named it the "Thermometric Conductivity," since it measures the change of temperature which would be produced in a unit volume of the substance by the quantity of heat which flows in unit time through unit area of a layer of unit thickness having unit difference of temperature between its faces.

Kelvin's term is the more commonly used, and occasion will be found to refer to it further in dealing with problems arising out of the variable flow of heat.

I. METHODS OF MEASURING CONDUCTIVITY

In general the conductivity of a material is obtained under conditions of steady heat flow, and, as has been indicated above, it can be determined by measuring the heat flowing through a body in a certain time, the temperature at two or more points, and the dimensions of the body. The experimental conditions suitable in particular cases depend mainly on the nature of the material to be tested. It is convenient therefore to consider separately the methods applicable to Solids, Liquids, and Gases, and to subdivide the first mentioned under three main headings, namely, poor, medium, and good conductors. Crystalline or non-isotropic solids are also dealt with separately.

§ (3) SOLIDS: POOR CONDUCTORS (K = 0·00008 to 0·00030). — Under this head come the materials which are used for purposes of heat insulation: for example, in the walls of cold stores and the lagging of boilers. They include such materials as cork, charcoal, kieselguhr, magnesia, slag-wool, asbestos-wool, and so on. Before describing the methods of test, it is as well to get some idea of the structure of the materials and the mode of heat transfer.

The materials are not homogeneous solids in the physical sense, but are loose aggregations of matter with a large number of included air-spaces. Their structure may be either fibrous or, as in the case of cork, cellular, but more often the materials in question are artificial aggregates of small particles or fibres. The transmission of heat through such materials does not take place solely by conduction in the solid particles. The mass of these in a certain volume of the material is relatively small, and their fine state of division gives rise to a high thermal resistance due to the number of point contacts through which the heat has to pass.

---

[1] The British Thermal Unit (B.T.U.) is the quantity of heat required to raise the temperature of 1 lb. of water by 1° F. at its temperature of maximum density, 39° F.

In addition to conduction in the solid material there is the transfer of heat by radiation and convection across the air-spaces. That the former is small can be seen by considering an air-space bounded by parallel walls at absolute temperatures of θ_1 and θ_2. The heat loss by radiation across such a space is independent of its thickness, and is proportional to $\theta_1^4 - \theta_2^4$, or where the difference is small to $\theta_1 - \theta_2$. If now a thin partition of conducting material parallel to the walls is interposed between them, it will take up a temperature intermediate between that of the walls (say, the mean temperature), and the radiation from the hot surface to the partition will be approximately one half of that previously passing between the hot and cold surfaces, and similarly, of course, the radiation from the partition to the cold surface. The effect of the partition is thus to reduce the heat transfer by radiation to about one half. Two partitions will reduce the radiation to about one-third, and so on.

If, for example, we take an air-space 3 inches thick, the temperature of one face being 10° C. and of the other 25° C., the heat loss by radiation for surfaces which are "full radiators" would be about twenty times the heat loss that would take place through the air by conduction only — that is assuming all movement of the air could be prevented so that no transfer took place by convection. Nineteen partitions would thus reduce the radiation loss to about the same amount as that due to pure conduction through the air. The equivalent subdivision of insulating materials is far greater than this.

A somewhat similar argument can be applied as regards convection, though the laws are not so well defined as those of radiation. For the case taken above of an air-gap of 3 inches with a temperature difference of 15° C., and supposing the walls vertical, the convection loss would be of the order of seven times the loss which would be due to conduction only. By subdividing the space the convection loss may be reduced, and if the air-gaps are made small enough to render air currents impossible the heat will be transferred solely by conduction.

Thus we see that the best insulating material is one which most nearly approaches in conductivity to air. By subdividing space by small particles of matter we can reduce the heat loss due to convection and radiation until it is not appreciably different from that of pure conduction through the air, but the introduction of solid matter inevitably increases the total of the conduction losses since all solids conduct better than air. Hence it follows that there is a limit of efficiency to be reached by introducing solid material. This is clearly shown in the results given by Petavel for the heat loss through slag-wool insulation of different densities (*Fig.* 2). It will be seen that the minimum value was obtained for slag-wool packed at 10 lbs. per cubic foot.

The conductivity of the class of poor conductors, or insulators, ranges in value from about 0·00008 to 0·00030 C.G.S. units, the best insulators having nearly twice the conductivity of air (0·00005). The values have a positive coefficient with rise of temperature which is frequently of the same order as that of air.

Some typical methods for testing such materials are described below.

(i.) *Spherical Shell Method — Nusselt.* — Theoretically the simplest form of solid, from the point of view of conductivity measurements, is the sphere or spherical shell. The flow of heat from a source at the centre is symmetrical and follows a simple mathematical law. On the other hand the use of a sphere generally gives rise to considerable experimental difficulties and the material has to be made up into a special shape.

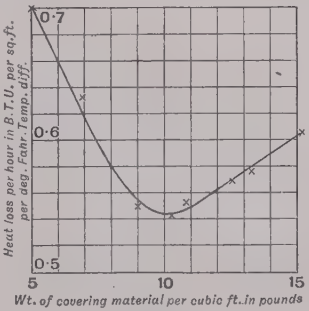

FIG. 2.

However, the method has been successfully adopted by several experimenters, of whom Nusselt[1] may be taken as an example. In his apparatus the shell of material was contained between two spheres of metal. The inner one of copper, 15 cm. in diameter and 1·5 mm. thick, was split into hemispheres which were joined with a bayonet joint so as to give a smooth exterior. The outer sphere was also split into two halves held together by a flanged joint with bolts. It was of zinc 1 mm. thick and either 60 or 70 cm. in diameter. The zinc sphere was coated with paint and its temperature excess above the atmosphere did not exceed 15° C.

---

[1] *Forsch. Ver. d. Ing.*, 1909, Hefte 63 and 64.

The space between the spheres was filled with the material under test, and a constant supply of heat was maintained electrically inside the inner sphere. The temperatures at different points in the material were obtained by means of a number of thermocouples of iron—constantan. Care was taken to ensure that the wires of each couple for a few centimetres from the junction were led along the isothermal plane so as to avoid errors due to conduction in the wires themselves. The importance of this precaution was shown by means of an experiment with infusorial earth, in which the junctions of two thermocouples were embedded in the material at equal distances from the centre of the sphere: that is to say, in the same isothermal plane. In one case the wires from the junction were led away along the radius, and in the other at right angles to the radius (*i.e.* along the isothermal plane). The respective readings obtained were 74·9° C. and 116·3° C.

To obtain the temperature distribution in the material, couples were fixed along three radii at right angles to each other, four couples being arranged symmetrically on each radius. In addition to these 12 couples others were fixed at different points so that the distribution of temperature was studied with some care.

When the steady state of temperature had been reached it was sufficient to know the energy supplied to the central sphere, the temperature of two isothermal surfaces. The conductivity is then obtained from equation (2) above, the value of the shape factor being in this case $2\pi ab/(b-a)$, where a and b are the internal and external radii of the shell.[1]

Nusselt used the apparatus for testing a number of insulating materials such as infusorial earth, slag-wool, asbestos, powdered and slab cork, charcoal, sawdust, wool, silk, cotton. The temperature range extended from that of the atmosphere to 500° C. and the results are stated to be accurate to 1 or 2 per cent.

The packing of the material and the arranging of the thermocouples must have been far from easy, and the apparatus does not therefore lend itself to studying the effect of different densities of packing on the conductivity. Nusselt's results are, however, in very fair agreement with those obtained with other observers, as will be seen from Table I.

(ii.) *Cylindrical Shell Method—Lamb and Wilson.*—A cylindrical shell of material with plane ends was adopted by Lamb and Wilson[2] for the purpose of determining the conductivity.

Their apparatus is illustrated in *Fig.* 3. The material was contained in the space between two cylindrical copper pots kept at a definite distance apart by pieces of vulcanised fibre. The inner pot contained a small motor with a fan attached to the axis. A tinplate cylinder, open at the top and with holes at the bottom, was put inside to direct the currents of air over the inner surface of the inside pot, in the direction of the arrows. Energy was supplied electrically to a heating coil within, as well as to the motor; this constituted an internal supply of heat, which maintained the temperature within the pot at any determined upper limit. The motor and heating coil were connected in series, and leads were carried through a small hole in the lid of the pots to measure the current and the potential difference, and thus the power expended on internal heating. The outer pot was immersed in a tank kept overflowing from the water main, the lid of the pot being made into a sort of saucer, into which the incoming water ran. In this way the surface of the outer pot was kept at a uniform and constant temperature.

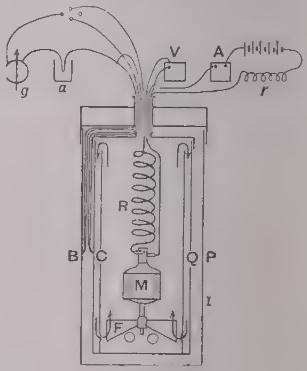

FIG. 3.

The outer pot was 8 inches in diameter and 16 inches high, and there was a clearance of 1 inch between the two pots. The temperatures of the pots were measured by thermojunctions of copper and iron soldered at the points B and C.

Preliminary experiments with couples soldered to different parts of the copper pots had shown that the temperature distribution was constant within 0·5° C., when working with a temperature difference of 25° C., hence the two thermocouples at B and C were relied on to give the temperature difference.

---

[1] See "Heat, Conduction of," Mathematical Theory, Eq. (32*a*).

[2] *Proc. Roy. Soc.*, 1899, lxv. 285.

The shape factor in this case was taken as that of a cylindrical shell of the length of the inner pot plus that of the plane ends, taking their areas as the mean of the end surfaces of the inner and outer pots. This gave a value for the shape factor

$$2\pi\left(\frac{l_1}{\log_e(r_2/r_1)}+\frac{r_1^2+r_2^2}{l_2-l_1}\right),$$

where l_1 and l_2 are the lengths, and r_1 and r_2 the radii of the inner and outer pot respectively. The formula is an approximation, but experiments with 2-inch layers gave results consistent with those for 1-inch layers, so that it may be taken as sufficiently accurate.

TABLE I

POOR CONDUCTORS

The thermal conductivity K is given in the Tables below as the number of calories per sq. cm. per sec. per 1 cm. thickness per 1° C. difference in temperature.

The temperature difference in these experiments was about 20° or 30° C., and the results are summarised in Table I.

As in the case of the spherical shell method, the configuration of the apparatus makes it difficult to secure uniformity of packing, a point of some importance in determining the conductivity of many insulating materials. It is not clear whether the question of heat loss by conduction along the wires leading from the inner pot was considered.

(iii.) *Wall Methods*—(*a*) *Randolph.*—In using the wall method it is assumed that the lines of heat flow are perpendicular to the faces. This is true for the central portion of a wall, but at the edges, unless the leakage of heat laterally can be prevented, the lines of flow will be curved. The "edge effect" thus produced gives rise to troublesome corrections in applying the equation (1) above, and it only becomes negligible if the wall is very large compared to its thickness. The difficulty can, however, be surmounted by the use of the guard-ring principle, the effect of which is to isolate a central portion of the wall where the heat flow is approximately normal to the surfaces.

An example of an apparatus of this kind is that designed by Randolph[1] for measuring the conductivity of insulating materials.

He took a hot plate heated electrically by means of a resistance ribbon wound on mica. The top of this plate is of copper, 7½ inches in diameter and ¼ inch thick, and its temperature is measured by means of couples of platinum and platinum-iridium. The material to be tested, which varied in thickness from ½ inch to 2½ inches, is contained between this hot plate and a water-cooled plate. The latter is in two parts, the central one forming a calorimeter and the outer one a guard-ring. A stream of water is maintained in the calorimeter, and its rate of flow multiplied by the difference in temperature between the inflow and the outflow gives the quantity of heat received by the central disc. A similar stream of water flows through the guard-ring, and its temperature never differed by more than 0·1° C. from the water in the calorimeter. With this small difference in temperature between contiguous portions of the guard-ring and calorimeter, and as there was no metallic connection between the two, there could be no appreciable passage of heat from one to the other. All the heat reaching the calorimeter was thus received directly from the hot plate, and the lines of flow were approximately normal to the surfaces. The conductivity was obtained from equation (1), knowing the temperatures of the hot and cold plates and the thickness of the material.

Randolph used this apparatus for obtaining the conductivity of a number of insulating materials such as asbestos and various asbestos compositions, mineral wool, diatomaceous earth, wool, cotton, eiderdown. A summary of his results will be found in Table I. It is interesting to note that he adopted a standard of compression of the materials which were packed as closely as possible by tapping and were then compressed by 25 per cent. The measurements were easily made with an accuracy of 2 per cent, but variations of 5 per cent were found between different samples of the same material. The cold plate was approximately at atmospheric temperature, while the hot plate ranged from 100° to 600° C. It may be remarked here that the flow calorimeter is not suitable for dealing with small temperature gradients of, say, 10° or 20° C. in the case of insulating materials, since the heat passing through the material would be so small as to give only a minute rise in temperature of the flow. Further, the leakage to or from the surroundings might become comparable with that passing through the test material and thus give rise to considerable errors.

Some of Randolph's values show a tendency to be low, for example, that for wool fibres (at density 0·192) as being 0·000054, or equal to air in conductivity.

(*b*) *National Physical Laboratory.*—In the apparatus described above the heat flowing out through the cold face of the wall of material was measured, but the practice is sometimes adopted of determining the heat supplied to the hot face. This is conveniently done by arranging an electrically heated plate as a sandwich between two exactly similar walls of material. The total energy supplied can easily be measured, and it passes out in approximately equal amounts through the two walls.

Figs. 4 and 5 show an apparatus of this type which is in use at the National Physical Laboratory.[1] The hot plate consists of flat heating units of asbestos-covered wire, or wire wound on mica, which are clamped between sheets of brass or aluminium. The plate is divided into two portions—a central square area A, 3 feet by 3 feet, and a guard-ring B,

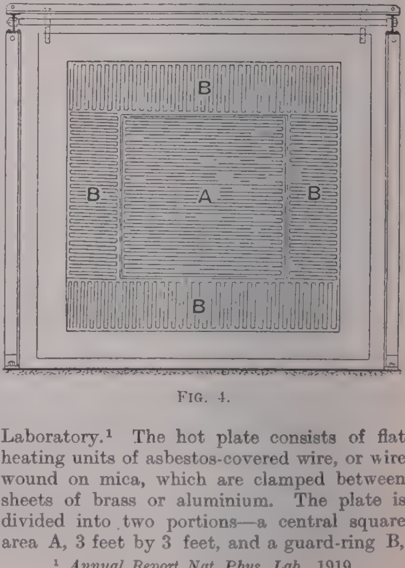

FIG. 4.

---

[1] *Trans. American Electrochem. Soc.*, 1912, xxi. 545.

[1] *Annual Report Nat. Phys. Lab.*, 1919.

1 foot wide, surrounding it. These portions are separated by an air-gap, and are kept apart by four small wedges of wood or fibre. They are independently heated, and the energy supplied to each is adjusted so that the temperatures of the contiguous edges are the same. In order to facilitate this adjustment the energy supplied to the top, bottom, and sides of the guard-ring could be separately controlled (see *Fig.* 4). Under these conditions the heat flows away from the central portion in lines perpendicular to the surface. The outer surface of each wall of the material is in contact with an iron plate, which can be maintained at a constant temperature. This is effected by the circulation of water or brine through a coil of square-section lead pipe, which is clamped on to the back of the plate (*Fig.* 5). The plate and coil are contained in a wooden case packed with insulation, which is not shown in the figure. The coil is wound in a bifilar manner, so that inflow and outflow pipes alternate, and thus the temperature is uniform over the whole surface. The cold plates can conveniently be run at any temperature from −25° C. to +15° C. The temperature distribution is studied by means of a number of thermocouples let into grooves in the hot and cold plates. By taking due precautions the plates can be kept uniform in temperature to within about 0·01° C.

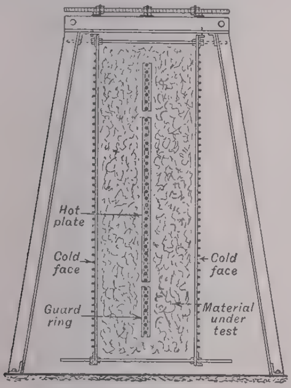

Fig. 5.

By means of this apparatus walls of insulating material have been tested under conditions corresponding closely to those prevailing in cold stores. Some of the results obtained are given in Table I.

§ (4) Solids, Medium Conductors (K=0·0003 to 0·01).—The division between the poor and medium conductors is purely one of convenience. All non-metallic bodies not included in the former class fall into the latter. Examples of the medium conductors are the various kinds of woods and other organic substances, the refractory materials and bricks used in furnace construction, rocks and mineral substances. The limits of conductivity may be said to be from 0·0003 to 0·01 C.G.S. units. No general rule can be laid down as to the change of value with temperature. As may be expected, the more granular materials show an increase in conductivity with rise of temperature, while the homogeneous solids generally show a decrease.

(i.) *Cylindrical Method.*—A number of experimenters have used a solid cylinder of material heated axially to measure the conductivity. The heat is generally supplied by a wire along the axis, and the temperature is measured at two or more points at different distances from the axis. If Q is the quantity of heat generated per unit length of the heating wire, then

$$Q=\frac{2\pi K(\theta_1-\theta_2)}{\log_e(r_2/r_1)}.$$

We may take as examples the experiments of Niven, Poole, Clement and Egy.

(*a*) *Niven.*—The conductivity of a number of materials such as wood, sawdust, sand, plaster of Paris, and garden mould was measured by Niven.[1]

A general view of the apparatus is shown in *Fig.* 6, while the arrangement of the wires for heating and measuring temperature are shown in *Fig.* 7. For the central heating wire CD, platinoid of gauge 34 or 40 was used. The wires AA and BB were of platinum. They were prepared by coating a platinum wire with copper and drawing down till the platinum had a thickness of 0·035 mm. and the copper 0·27 mm. The latter was then dissolved off. The change of resistance of

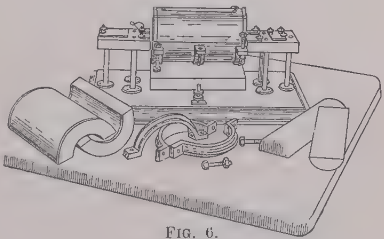

Fig. 6.

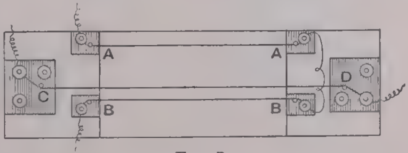

Fig. 7.

---

[1] *Proc. Roy. Soc.*, 1905, lxxvi. 34.

these wires gave the difference in temperature between the isothermal surfaces, whose distances from the axis could be accurately measured. Niven experienced considerable difficulty in the use of these fine wires, and eventually abandoned them in favour of thermo-junctions consisting of German silver wire and iron 0·2 mm. in diameter.

When solid material was being tested in this apparatus, it was in the form of two half cylinders. One of these was moved up underneath the wires until they rested on its face, and the other half-cylinder was then fixed on top. For loose materials cylindrical wooden shells were used as containers.

Niven gives an approximate calculation as to the time taken for the flow of heat to reach the steady state. Assuming the temperature to be taken at two points respectively 1 and 3 cm. from axis, and taking sand which has a diffusivity of about 0·0032, the time taken for the temperature difference to reach within 5 per cent of its final value was 1½ hours, and within 1 per cent of its final value 7½ hours.

A summary of Niven's results is included in Table II.

It is not clear from the description given whether any special precautions were taken to guard against "end effect" due to the conduction of heat at the ends of the heating wire and cylinder. Apart from this point the method does not seem to be open to criticism.

(*b*) *Poole.*[1]—This experimenter made use of a cylinder of material for measuring the conductivity of rocks. The cylinder was heated axially by means of a wire dissipating a known amount of energy, and it was contained inside an electric furnace maintained at a constant temperature which ranged up to 600° C. Several modifications of apparatus were used, one of which is illustrated in *Fig.* 8.

The furnace consisted of a copper tube wound with insulated nichrome wire and contained in a lagged case. The specimen cylinder of rock A fitted roughly into the furnace, the ends of which CC were filled with pulped asbestos millboard. The cylinder was 15 cm. long by 3·6 cm. diameter and had a hole bored down its axis. With a soft rock such as limestone, a hole as small as 1·5 mm. diameter could be bored, but with hard rocks like granite or basalt the hole was nearer 4·5 mm. in diameter. In the latter cases the hole was either filled in with cement, through which a smaller hole could then be bored, or the platinum heating wire (0·3 mm. in diameter) was wound with asbestos cord to keep it central in the hole. A constant current was passed through the wire, and the potential drop was measured on the central portion 10 cm. in length. By using a

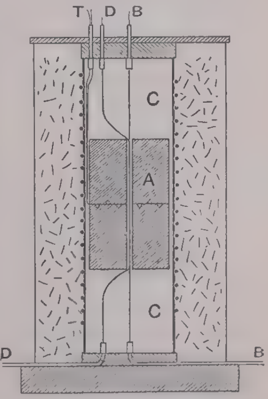

FIG. 8.

---

[1] *Phil. Mag.*, 1912, xxiv. 45, and 1914, xxvii. 58.

cylinder relatively long compared to its diameter, and by measuring the energy dissipated in the portion of the wire well within the cylinder, the troublesome end effect found in preliminary experiments was eliminated. The difference in temperature of two isothermal surfaces and the mean of the temperatures of the surfaces were measured by means of couples of platinum and platinum-iridium 0·1 mm. in diameter. The couples were all in the central plane of A perpendicular to the axis, the cylinder being cut in half at this point. The arrangement of the couples is shown in *Fig.* 9, which is a plan of the lower half of the cylinder. The junctions of the couples are fixed in circular grooves cut in the face, the grooves being connected by radial grooves for carrying the wires between the circular grooves and for carrying them out of the cylinder. It will be seen that the couples are arranged so that the mean E.M.F. gives the mean difference in temperature of the circular grooves. The diameters of the latter were respectively 2·61 cm. and 0·725 cm. They are V-shaped, 2·5 mm. deep and 1·5 mm. wide, while the radial grooves were 0·5 mm. deep. The couple wires were cemented in the bottom of the grooves, and the two half-cylinders were cemented together. In the right-hand half-cylinder a groove was cut at a distance from the axis equal to the geometric mean between the radii of the grooves on the opposite face. A single couple, fixed in this groove, thus served to give the mean temperature of the isothermal surfaces. The temperature difference between these isothermals was of the order of 10° C., while the mean temperature of the whole apparatus could be fixed at any point by an automatic control. The measurements were made when the steady state had been approximately reached, and a method is given for correcting for small departures from the steady flow. Poole also made use of a cylinder cut into two parts longitudinally instead of transversely. This has the advantage of enabling the axial groove to be made very small and accurate. A similar arrangement for determining the difference in temperature between isothermal surfaces is adopted, the junctions of the couples being, of course, in a longitudinal plane instead of a transverse plane as before.

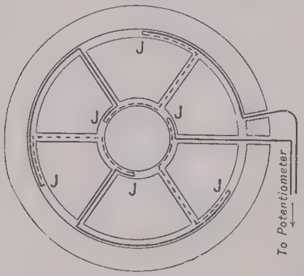

FIG. 9.

Poole made a study of the variation of conductivity of limestone, granite, and basalt by means of his apparatus. He shows that the two former give decreases of conductivity with rise of temperature, while basalt shows a slight rise to about 200° C., above which the conductivity is constant. On prolonged heating all three materials show a permanent fall in conductivity, due apparently to small cracks in the rocks.

(*c*) *Clement and Egy.*—A similar method to those described immediately above was used by Clement and Egy[1] for obtaining the conductivity of fireclay bricks. The specimens were in the form of hollow cylinders heated by a coil of nickel wire wound on a porcelain tube fixed along the axis of the specimen. Two holes were bored parallel to the axis for the insertion of thermocouples.

The method has the disadvantage that specimens were required of special form differing from that in which the material is used, and there would seem to have been some uncertainty in the measurement of the radial distances.

(ii.) *Wall or Slab Methods.*—A number of observers have determined the conductivity of materials of medium conductivity by experiments on walls or slabs. In the important class of refractory materials, the methods adopted by Wologdine, Dougill, Hodsman and Cobb, Boyd Dudley, and Griffiths are described, while for other materials the work of Lees is referred to.

(*a*) *Wologdine.*—An extended investigation of the thermal conductivity of refractory materials of French manufacture was made by Wologdine.[2]

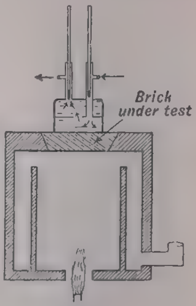

FIG. 10.

A diagram of the apparatus he employed is shown in *Fig.* 10. The specimen under test was specially made in the form of a circular disc, 5 cm. in thickness, with a bevelled edge forming a portion of the walls of a gas-heated muffle. The temperature gradient through the slab was obtained by embedding two platinum, platinum-rhodium couples at a depth of 5 mm. from each face. An additional thermo-element in the air near the hot face gave the furnace temperature.

---

[1] *Phys. Rev.*, 1909, xxviii. 71 ; *Bull. Univ. Illinois*, 1909, xxxvi.

[2] *Met. and Chem. Eng.*, 1909, vi. 383, 433, translated by Queneau.

The heat transmitted through the slab was measured by a flow calorimeter in the form shown in the figure.

The design of the calorimeter is the weakest point in the method, since the presence of a cooled area on the upper surface must distort the flow lines from normal. A guard-ring around the calorimeter would have eliminated this source of error.

The couples were calibrated by reference to the freezing-points of copper, common salt, and aluminium, together with the boiling-points of sulphur and naphthalene. With the exception of sulphur, the values assumed for these fixed points are in fair agreement with the values accepted at the present time. For the boiling-point of sulphur the value 455° was taken instead of the generally accepted value 445·5°.

In the case of each material, samples were fired at two temperatures, 1050° C. and 1300° C., and it was found that the conductivity increased with the firing temperature. Thus silica bricks fired at 1300° C. showed a value 50 per cent greater than those burnt at 1050° C. Wologdine also found that thermal conductivity increased with temperature, except possibly in the case of chromite brick, for which the value was nearly constant.

(*b*) *Dougill, Hodsman, and Cobb.*—The thermal conductivities of some fire-clay, silica, and magnesia bricks were investigated by Dougill, Hodsman, and Cobb.[1] Their apparatus was somewhat similar to Wologdine's, but designed to take ordinary sized samples. The heat transmitted was measured by the evaporation of water from a vessel cemented on to the top surface of the brick. This calorimeter was composed of a large vessel, 9 inches long by 4½ wide by 3 inches high, with a plane base. Within the larger vessel was fixed the calorimeter proper, consisting of a chamber 4 inches long by 2 inches wide by 2½ inches high. Steam distilling from this inner vessel passed through a sloping tube to a condenser, the water being collected in a measuring jar.

The usual rate of evaporation was about 5 c.c. per minute. The authors state that it was found advantageous to surround the inner chamber with a non-conducting jacket, and for this purpose sheet rubber was found to be satisfactory.

Probably it would be better if, in this method, the calorimeter was entirely separated from metallic connection with the larger vessel, since the existence of a slight gradient of temperature across the metal base might seriously vitiate the results.

An interesting fact brought out by the investigation is the marked decrease with temperature in the thermal conductivity of magnesia brick.

(*c*) *Boyd Dudley.*—Experiments on fire-clay, silica, and magnesia bricks of American manufacture were carried out by Boyd Dudley.[2] The material under test constituted one wall of a furnace heated by means of by-product coke. By careful regulation of the draught a uniform combustion through a depth of 26 inches was obtained. The bricks composing the wall were 9 inches by 4½ inches, and built so as to produce a flat surface. The heat transmitted through a definite area of the wall was measured by a flow calorimeter 8 inches by 8 inches, fitted with a guard-ring. A period from eight to nine hours was allowed to elapse after starting the fire before observations were commenced.

The temperature gradient through the bricks was obtained by means of a platinum, platinum-rhodium couple inserted to various depths in holes bored to within ¼ inch of the inner face, measurements being made every ¼ inch to within ¼ inch of the cold face.

This method of ascertaining the temperature at various points is simple, but suffers from the disadvantage that the couple wires are perpendicular to the isothermal planes and the readings may be vitiated by conduction along the wires cooling the junction.

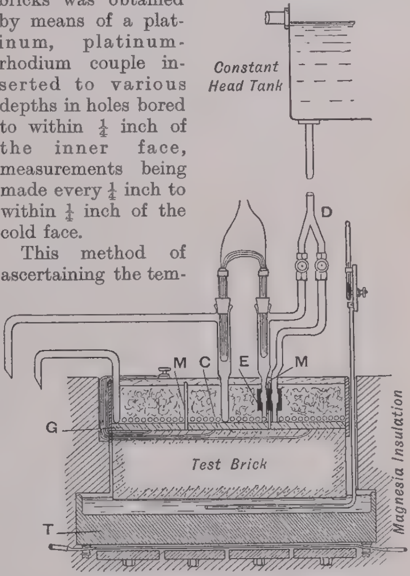

FIG. 11.

Dudley found that the conductivity of magnesite was practically constant between 445° and 830°; which is contrary to the results of Dougill, Hodsman, and Cobb.

(*d*) *Griffiths.*—An apparatus used by Griffiths[3] for measuring the conductivity of slabs of refractory materials is illustrated in *Fig.* 11. The faces of these materials are always irregular and are generally slightly curved, so that it is difficult to obtain a uniform surface temperature. With a view to meeting the difficulty the heat was transmitted to the hot face of the brick by means of molten metal, which adapts itself to the irregularities of the surface. Tin was found to be satisfactory for the purpose at low temperatures. It was contained in the cast-iron tray T, which has a uniformly distributed heating coil attached to its under surface. The depth of the molten metal is about 1 cm., and the brick under test rests on three projections, so that the free surface of the tin around the edges stands at a level of about 2 mm. above the immersed surface of the brick.

---

[1] *Journ. Soc. Chem. Ind.*, 1915, xxxiv. No. 9, 465.

[2] *Met. and Chem. Eng.*, 1915, p. 315.

[3] *Trans. Faraday Soc.*, 1917, xii. 109.

The temperature of the molten tin was obtained by means of a platinum-platinum-iridium couple. The details of the construction of this couple are shown in *Fig.* 12. The wires were separately insulated in the quartz tubes, which are enclosed in an outer sheath, the external diameter of which was approximately 5 mm. The bulb B was sealed off in the oxycoal-gas blowpipe after the insertion of the wires, and no difficulty was found in bending the tube into the L form with the wires *in situ*, provided the heating was not unduly prolonged. By rotating the couple the temperature distribution over a wide arc could be explored, and the insulation of the quartz was sufficiently good to prevent any leakage from the heating circuit into the potentiometer.

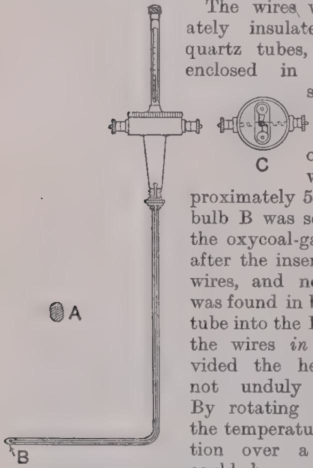

FIG. 12.

The temperature of the cold surface of the brick was determined by several iron-eureka (constantan) thermocouples bedded just flush with the surface. The calorimeter was attached to this surface by means of a thin layer of Purimachos cement.

The construction of the flow calorimeter will be understood from *Fig.* 11. The guard-ring G is separated from the calorimeter proper C by a narrow gap about 1 mm. wide, the space being filled with mica plates M set on edge so as to produce a level surface. The inflowing water divides at D, and flows through adjacent turns of piping in the calorimeter and the guard-ring. Since the temperatures of the two streams are the same, this tends to eliminate any gradient of temperature across the gap separating the calorimeter from the guard-ring. The ratio of flow was adjusted to produce equal temperature rise. Differential couples of six pairs of copper-constantan measured the rise in temperature in the water flowing through the calorimeter. The tube containing the inflowing couple is separated from metallic contact with the calorimeter by a short connecting piece of ebonite E. A steady stream of water is obtained by the constant-level tank shown, and the rate of flow through the calorimeter determined by the time required to collect one litre of water.

In order to detect any systematic errors the experimental conditions were varied by altering the rate of flow, changing the differential couples, and the thickness of slab experimented on.

In experiments at temperatures above 450° the hot face was maintained at a uniform temperature by pressing it against a flat iron plate forming a portion of the wall of a large uniformly heated muffle. In this case the hot-face temperature was determined by two bare nickel-copper, nickel-chromium couples of No. 19 gauge wire cemented on the surface.

Data for the same sample over the same temperature range obtained by two different modes of heating were in close agreement; the molten metal bath method giving more concordant results than the muffle method.

(*e*) *Lees.*—Lees [1] has determined the conductivity of small thin slabs of material by means of a somewhat novel method. His arrangement is shown diagrammatically in *Fig.* 13. A small hot plate is formed of two copper discs C and U, between which is sandwiched a heating coil of platinoid insulated by mica. The thickness of the coil with the insulation was ·11 cm., the thickness of C ·103 cm., and U ·312 cm.

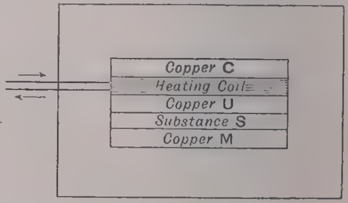

FIG. 13.

S was the substance whose conductivity was to be measured, while M was another copper disc ·32 cm. thick. The contacts of S with U and M were improved by smearing the surface with glycerine and sliding them together. The diameter of all the discs was 4 cm. At opposite ends of a diameter of each copper disc were soldered a platinoid and copper wire which formed a thermojunction for the measurement of temperature.

---

[1] *Phil. Trans. Roy. Soc.*, 1898, cxci. 399.

When the discs had been assembled they were varnished to give them the same emissivity, and the pile was suspended in a constant temperature enclosure. The current was switched on in the heating coil, and after a due time had been allowed for the steady state to be reached, the energy was measured and the temperatures of the three copper discs.

The theory may be briefly stated as follows:

Let H = rate of energy supplied to the heating coil,
h = heat loss per second per sq. cm. for 1° excess, of temperature of the discs over that of the enclosure,
v = the excess of temperature over that of the enclosure,
t = thickness of disc,
r = radius of the discs.

Now the heat received per second by the disc M and given up to the air is

$$\pi r^2 h\left(1+\frac{2t_M}{r}\right)v_M.$$

Similarly the heat received by S and given up to the air from its exposed surface or passed on to M is

$$\pi r^2 h\left(1+\frac{2t_M}{r}\right)v_M+\pi r^2 h\frac{2t_S}{r}\left(\frac{v_M+v_U}{2}\right).$$

If K is the thermal conductivity of the disc S, then the heat flowing through the disc is

$$\pi r^2 K\left(\frac{v_U-v_M}{t_S}\right).$$

Assuming that the heat flowing through the disc to be the mean of the heat flowing into and out of the disc, *i.e.* the mean of the first two quantities above, we get

$$K\left(\frac{v_U-v_M}{t_S}\right)=h\left\{v_M+\frac{2}{r}\left(\overline{t_M+\frac{t_S}{4}}\cdot v_M+\frac{t_S}{4}v_U\right)\right\}.$$

Which gives us a relation between K and h. Further, the total heat imparted to the system must equal that given up to the air from all the exposed surfaces, and therefore we get the equation

$$H=\pi r^2 h\left\{v_M+v_C+\frac{2}{r}\left(t_M v_M+t_S\cdot\frac{v_M+v_U}{2}+t_U v_U+t_C v_C\right)\right\}.$$

From these two equations the values of K and h can be determined by measuring H and the temperatures of the discs.

Lees worked out the correction for the conduction of heat along the thermocouple wires and the leads to the heating coil.

He used this method for determining the conductivity, and variation of conductivity with temperature, of a number of substances, such as glass, sulphur, ebonite, shellac, fibre, naphthalene, lard. He also extended this method to apply to liquids in the manner described below (§ (7 ii.)).

§ (5) Solids: Metals (K = 0·015 to 1·00).—The class of metals is distinguished by its high conductivity alike of heat and electricity. This is explained by the supposed dependence of the two phenomena on the diffusion of electrons, and a mathematical relationship has been established between them which, as will be shown below, is partially confirmed by experiment. In the non-metallic solid, on the other hand, the electron is supposed to be capable of vibration only, so that heat conduction is assumed to be due to internal radiation. While this theory explains the known facts better than any yet advanced, it should be pointed out that it fails to account for the fact that some dielectrics have a higher conductivity than the worse conducting metals, *e.g.* the conductivity of quartz parallel to the axis (K = ·029) is greater than that of bismuth (K = 0·016 to 0·019).

The conductivities of metals range from 0·015 to 1·00 C.G.S. units. Practically all the pure metals have a small negative coefficient of conductivity with rising temperature, while the alloys show a positive coefficient.

The high conducting power of metals gives rise to certain modifications in the types of apparatus described above. Thus it is necessary to use a considerable thickness of metal to obtain appreciable temperature gradients, and the measurement of the boundary temperatures is very difficult. This latter point is well illustrated by the early experiments in which a slab of metal was heated on one side by steam or hot water and cooled on the other side by ice or cold water. Under these conditions the temperatures of the faces of the metal were assumed to be those of the steam, ice, or water as the case may be. Acting on this assumption, Clement obtained a value for the conductivity of copper which was 200 times too low, while Péclet, who was aware of the source of error in Clement's work, and took extraordinary precautions to secure efficient stirring, still obtained a value for copper which was about one-fifth of the true value. The difficulty is due to the fact that, even with the most vigorous stirring, there is always in contact with the metal surface a thin film of fluid which is at rest, and thus has a temperature gradient through it. If d is the thickness of the metallic plate (of true conductivity K) and d_1 and d_2 of the stationary films of fluid (of conductivity K′) on each side, it can easily be shown that the effect of assuming the temperatures of the metallic surfaces to be those of the moving liquid on each side is to give an apparent conductivity of the metal equal to the true conductivity divided by

$$1+\frac{K}{K'}\frac{(d_1+d_2)}{d}.$$

In the case of copper and water the value of K/K' is about 700, so that the value of d_1 and d_2 would only have to be $\frac{2}{700}$ of the thickness of the copper to obtain an apparent conductivity one-fifth of its true value.

(i.) *Plate Method. Hall.*—In spite of the difficulties mentioned above, the plate method has been used—notably by Hall,[1] to whom is due an ingenious method of determining the difference in temperature between the two faces of a thin metal plate.

He experimented with a disc of iron 10 cm. in diameter and 2 cm. thick. Each side of the disc was coated with copper to a thickness of 2 mm. By attaching a copper wire to each side a differential thermocouple was obtained the E.M.F. of which gave the difference in temperature between the two surfaces of the disc. Hall had a number of copper wires attached to the copper faces, which were immersed in streams of water at different temperatures. The heat coming through the disc was given by the rate of flow of the cold water (about 20 gm. per second) and the rise in temperature (about 0·5° C.). The difference in temperature between the faces of the iron disc was of the order of 1° C., which corresponded to 10 microvolts of the differential couple. The individual wires gave readings differing by as much as 10 per cent, which was a serious source of uncertainty. Hall obtained values of conductivities as follows :

Cast iron, 0·1490 C.G.S. units at 30° C., temperature coefficient − 0·00075.

Pure iron, 0·1530 C.G.S. units at 30° C., temperature coefficient − 0·0003.

The value for pure iron is in good agreement with recent determinations, while the value for cast iron seems to be too high.

(ii.) *Bar Methods.*—For the reasons which have been indicated above, bars have been commonly adopted instead of plates for the purpose of conductivity measurements.

(*a*) *Forbes.*—One of the earliest methods of determining the conductivity of a metallic bar was that due to Forbes. He took a long bar kept at a fixed temperature at one end. When the steady state of heat flow had been reached, the temperature at a series of points was measured by means of mercury thermometers let into holes in the bar. By plotting these observations and drawing a smooth curve through them, the complete temperature distribution along the bar was determined. The tangent to the curve at any point gave the temperature gradient $(d\theta/dx)$ at that point.

To obtain the heat flowing across the particular cross-section of the bar, Forbes determined the total heat loss from the surface between this section and the cool end of the bar — the two quantities are obviously equal. For this purpose a separate experiment was made on a similar bar which was uniformly heated and left to cool in the same surroundings as the first bar. From the rate of cooling of this bar and a knowledge of its heat capacity, the rate of heat loss per unit area could be determined for any temperature. The data obtained were used for computing the heat loss from the surface of the first bar, measured from the particular cross-section. The temperature gradient having been determined in the first experiment, the conductivity was at once obtained.

Forbes used for the first experiment, which has been called the "static" experiment since it dealt with the steady state of heat flow, a bar of wrought iron 8 feet long and 1¼ inch square section. The hot end of the bar was fixed into any iron crucible which was maintained at the temperature of melting lead or solder. The experimental conditions were varied by having the metal bright polished in one case and covered with white paper applied with a little paste in another case. The surface emissivity in the latter condition was eight times that in the former.

For the second or "dynamic" experiment in which the emissivity was determined for various temperatures, a bar of the same material and cross-section was used, but only 20 inches in length.

Forbes obtained the conductivity of wrought iron for a number of temperatures up to 200° C. He assumed, however, that the specific heat of iron was constant, whereas it increases by some 10 per cent for every 100° C. rise. For this reason Forbes' values are obsolete. When corrected by Tait and Mitchell, they were brought more into line with modern values but were still unsatisfactory. Apparently another source of error arises from the fact that the "dynamic" experiment does not give the true emissivity coefficients applicable to the "static" experiment, owing to the temperature distribution inside the bar being different in two cases. This would not, however, account for the large discrepancies in the experiments, of which no satisfactory explanation has been given. Thus Forbes, using two bars respectively 1¼-inch and 1-inch square section, obtained values differing by some 20 per cent, while Mitchell repeating the experiments on one bar and cooling it in the centre obtained a value differing by 8 per cent.

In spite of the criticism that has been levelled at it, Forbes' experiment is interesting as being the first attempt to determine the conductivity of a metal in absolute measure. His method has been followed, with improvements, by a number of experimenters, notably Mitchell, Stewart, Lees, Callendar, and Nicholson.[1] The two last-mentioned made several important modifications in the method. To avoid uncertainties of surface loss a large bar 4 inches in diameter was used and the loss from the bar was reduced to a quarter by lagging. The end of the bar, which was 4 feet long, was surrounded by a calorimeter and cooled by a stream of water. The rate of flow of the water and the temperature rise gave the quantity of heat passing out at the end of the bar. The heat leakage through the lagging could be computed and was only a small fraction of that absorbed by the calorimeter. The uncertainties of Forbes' method are much reduced by the above-mentioned modifications. The apparatus is illustrated in *Fig.* 14.

---

[1] *Proc. Amer. Acad.*, 1898, xxxiv. 283.

Griffiths[2] has also made use of a similar method for measuring the conductivity of a series of aluminium alloys, intended for aeroplane engines, up to a temperature of 350° C. In his apparatus the heat was supplied by a nichrome strip wound on one end of a bar, while on the other end a spiral pipe was wound which acted as a flow calorimeter. The electrical input into the heating coil was found to equal the amount of heat flowing out through the calorimeter plus the amount lost laterally through the lagging, so that the thermal balance sheet was checked. Some of the results obtained by Griffiths are given in Table III.

(*b*) *Berget.*—Berget[1] made use of a guard-ring method for the purpose of determining the conductivity of a number of metals such as copper, iron, brass, mercury. The arrangement of the apparatus used for the mercury determination is shown in *Fig.* 15. A cylindrical column of mercury was contained in a glass tube AB, which was surrounded by an annular column of mercury which acted as a guard-ring. The surface of the mercury columns was heated by steam, and the base of the outer column rested in an iron plate C which was cooled by ice. The tube carrying the central column of mercury projected through the iron plate into a Bunsen ice calorimeter as shown. The temperature distribution was determined by means of four iron wires which projected into the central column. Each pair of these wires, with the intervening mercury, formed a differential iron-mercury couple which gave the difference in temperature between the ends of the two iron wires. The distribution of temperature was found to be linear when the steady state has been reached. The ice calorimeter gave the quantity of heat passing through the column, and thus the conductivity was obtained.

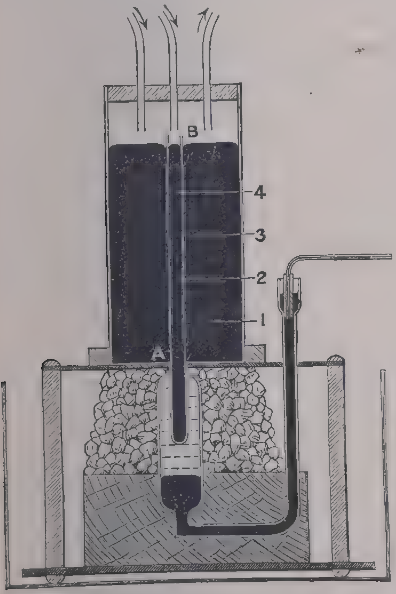

FIG. 15.

Berget's value for mercury of 0·0201 is in close agreement with recent determinations such as that of Nettleton. Having obtained the value for mercury, he measured the conductivity of other metals by comparison. A column of mercury was superposed on a column of metal, each surrounded by a guard-ring, and from a comparison of the temperature gradients the conductivity was deduced.

(*c*) *Lees.*—Lees[2] determined the conductivity of a number of pure metals and alloys over a range of temperature from −180° C. to 30° C.

His apparatus is illustrated in *Fig.* 16.

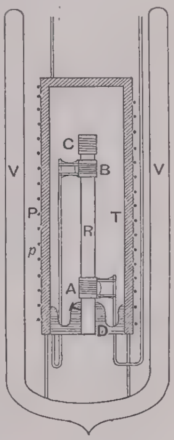

FIG. 16.

R was a rod of metal 7 or 8 cm. long and about 0·5 cm. in diameter. The lower end fitted into a copper disc D, which formed the bottom of a copper cylinder T closed at the top. A, B, and C were three thin brass sleeves, fitting closely to the rod with which good thermal contact was secured by a film of olive oil. Of these A and B carried platinum coils for the measurement of temperature while C carried a heating coil of platinoid wire. The copper cylinder T was placed on a wire frame resting on the bottom of the Dewar flask V. Around the outside of T was wound a platinoid wire *p* of the same resistance as the heating coil C, and whenever the current was switched off from C it was switched on to *p*, so that the rate of heat supply to the apparatus as a whole was constant throughout the experiment. A further heating coil P wound on T enabled the temperature of the apparatus to be raised rapidly if desired.

The experiments were started at liquid-air temperature. The current was switched on to C until a suitable difference of resistance (generally equivalent to about 5° C.) was obtained between A and B. The current was then switched on to *p*, and after five or ten minutes the difference in resistance between the coils A and B was again measured, as well as the actual resistance of the lower one A. The difference in temperature between A and B when the heating current flowed round C, less the mean difference in temperature (before and after) when the current was flowing through *p*, gives the difference in temperature which would be produced if the heating current were continued in C and the surrounding tube T kept at a constant temperature, *i.e.* assuming the rate of rise of temperature of the apparatus was constant which was secured, as explained above.

---

[1] *Jour. de Phys.*, 1888, vii. 503.

[2] Lees, *Phil. Trans. Roy. Soc.*, 1908, ccviii. 381.

While the general theory of the experiments was simple, they are remarkable for the skill and care with which Lees explored the various sources of error. Thus the sleeves were of appreciable length and size, but formulae were obtained giving the approximate effect of the dimensions of the sleeves and of the small difference in temperature between the rod and platinum resistance coils on the sleeves. Again corrections were worked out for the effect of the leads to the heating coil C and the platinum coils A and B, while the fact that the observations did not apply strictly to the steady state of temperature distribution was shown to be of small effect.

Lees' experiments over the range from − 170° to 30° C. confirmed generally the conclusions of Jaeger and Diesselhorst—from their work between 0° and 100° C.—that the pure metals show a slight decrease in conductivity with rise of temperature. He did not, however, find that the maximum conductivity always occurred at the lowest temperature.

The electrical conductivity of the metal rods was also measured by Lees, and his conclusions as to the relation between thermal and electrical conductivity will be referred to later (§ (10 i.)).

(iii.) *Electrical Methods.*—Several methods for measuring the conductivity of a bar of metal have been proposed in which heat is supplied by passing an electric current through the bar itself. If the ends are kept at a constant temperature, there will be established throughout the bar a certain distribution of temperature, which will depend on the strength of the electric current, the electrical and thermal conductivity of the material, and the heat loss (if any) from the surface of the bar.

(*a*) *Kohlrausch: Jaeger and Diesselhorst.*—Kohlrausch[1] took the case where all heat loss from the surface of the bar was prevented. Calling

K = thermal conductivity,
λ = electrical conductivity,
θ = temperature at any point,
v = electrical potential at any point,

he obtained the following solution of the differential equations for thermal and electrical equilibrium:

$$\theta = \tfrac{1}{2}\frac{\lambda}{K}v^2 + Av + A',$$

where A and A′ are constants. Hence, by determining the temperatures and potentials at three points, A and A′ can be eliminated, and we get

$$\frac{\lambda}{2K} = \frac{\theta_1(v_2 - v_3) + \theta_2(v_3 - v_1) + \theta_3(v_1 - v_2)}{(v_1 - v_2)(v_2 - v_3)(v_3 - v_1)}.$$

Kohlrausch also showed that if the conductor is of any shape, and is thermally and electrically insulated except for the two areas through which the current is supplied and through which heat is abstracted, the same solution holds. Hence, if holes are drilled in a bar for the purpose of inserting thermometers, the method will still be exact, provided that the temperatures and potentials are measured at the same points.

Jaeger and Diesselhorst carried out Kohlrausch's method into practice. They took cylindrical bars of metal, 25 cm. long and generally about 2 cm. in diameter, with their ends fitted into copper blocks, which were screwed into large water-baths. The bar was surrounded by a cylindrical jacket, kept at a constant temperature by water or steam circulating outside it, the space between the bar and the jacket filled with wadding. There was, of course, a certain amount of heat loss through the wadding, which was estimated by varying the temperature of the jacket surrounding the bar. For the discussion of this and other corrections, reference must be made to the original paper. The temperatures were measured by thermocouples.

The determination of the temperatures and potentials at three points gives the ratio of the thermal and electrical conductivities, and the latter constant being easily determined, the thermal conductivity was obtained.

Jaeger and Diesselhorst carried out a very extensive investigation on a number of pure metals and a few alloys for temperatures between 18° and 100° C. They found that pure metals, with one or two exceptions, showed a slight decrease of conductivity with increasing temperature, and that they obeyed approximately Lorenz's law—that the ratio of the thermal and electrical conductivities divided by the absolute temperature is a constant. Lorenz's constant showed a slight positive temperature coefficient.

Their work represents a most important contribution on the subject of conductivities, and their values have been amply confirmed by subsequent observers.

The method of Jaeger and Diesselhorst has been used by Meissner[2] for measuring conductivities down to a temperature of 20° abs. His work confirmed generally the values of Lees, but he found that both the resistivity (1/K) and Lorenz's constant decreased rapidly as the temperature of liquid hydrogen was approached, showing a reduction at 20° abs. of about 85 per cent on the value at 0° C.

(*b*) *Callendar.*—Callendar[3] has also devised a method of determining the conductivity of a rod of metal which is heated by the passage of an electric current. The ends of the rod are kept at constant temperature by insertion into water-cooled copper blocks. The rod is also surrounded by a jacket at the same temperature, which is taken as the zero of reference. If R_0 is the resistance per unit length of the rod at the zero temperature, α is its temperature coefficient, then the resistance of a small element of the rod at a distance x from the centre is

[3] *Encycl. Brit.* 11th Ed. "Conduction of Heat."

$$R_0(1+\alpha\theta)dx.$$

The heat generated in this element by the passage of a current C is

$$C^2R_0(1+\alpha\theta)dx.$$

As there is a gradient of temperature from the centre of this rod to the ends, heat will pass through the element dx by conduction, and the excess of heat entering the element by conduction over that leaving it will be

$$KA\frac{d^2\theta}{dx^2}dx,$$

K being the conductivity and A the area of the cross-section of the bar. When the steady state has been reached, this excess of heat will be balanced by the heat loss due to radiation and convection from the surface of the element, less the heat generated in the element by the passage of the current. By Newton's law the former quantity will be $Ep\theta dx$, E being the surface emissivity and p the perimeter of a cross-section of the rod. Equating these quantities we get[1]

$$C^2R_0(1+\alpha\theta)=Ep\theta-KA\frac{d^2\theta}{dx^2}.$$

The current C is so adjusted that $C^2R_0\alpha=Ep$, *i.e.* that the loss of heat from the surface of the rod is compensated at all points by the increase of resistance with rise of temperature. The equation then reduces to

$$\frac{d^2\theta}{dx^2}=-\frac{C^2R_0}{KA}=\text{constant}.$$

So that, $2l$ being the length of the rod,

$$\theta=\frac{C^2R_0}{2KA}(l^2-x^2).$$

This gives the temperature at all points of the rod, and it can be shown that the mean temperature is $C^2R_0{}^2l^2/3KA$. Hence, if R_m is the mean resistance per unit length, we get

$$K=\frac{C^2R_0l^2\alpha}{3A(R_m-R_0)}.$$

The distribution of temperature is always nearly parabolic, if the dimensions of the rod are suitably chosen. It is not therefore necessary to set the current to the value $Ep/R_0\alpha$ very accurately, as the correction for external loss is small in any case. The chief source of error is in the measurement of the small change of resistance accurately, and of avoiding stray thermo-electric effects.

Duncan,[2] using this method, found the conductivity of copper at 33° C. to be 1·007, which is about 8 per cent higher than that obtained by Jaeger and Diesselhorst.

(*c*) *Mendenhall and Angell.*—Another example of an electrical method is that suggested by Mendenhall, and described in a paper by Angell,[3] for measuring the conductivity of metals at high temperatures.

If a cylindrical rod is connected at its ends to two heavy electrodes and heated by a constant current, there will be a rising temperature gradient from the ends towards the middle of the rod. This longitudinal gradient will decrease as the middle is approached, and for an appreciable distance on each side of the centre will be negligible. There will be no tendency, therefore, for the heat generated in this portion of the rod to flow towards the ends. The temperature gradients will be radial, and the heat will flow radially and be dissipated at the surface. Consider now a length of rod l within the central zone. Let r be the radius, E the fall of the potential per centimetre, I the current density (which is assumed uniform over the cross-section), θ_2 and θ_1 the temperatures at the axis and circumference respectively.

Then, since the heat generated within any cylindrical surface of radius r passes radially to the surface, we have

$$\pi r^2IEl=-2\pi rlK\frac{d\theta}{dr}.$$

Integrating we get

$$K=\frac{EIr_1{}^2}{4(\theta_2-\theta_1)}.$$

The above formula depends on the assumption that the current density is uniform over the cross-section. This is not strictly the case, since there is a temperature gradient from the axis to the circumference which gives rise to a variation of resistivity. Angell shows, however, that for metal rods of less than 2 cm. in diameter the effect of the variation is negligible. In the actual experiments a hollow cylinder was used, and the formula in this case is

$$K=\frac{EI}{2(\theta_2-\theta_1)}\left\{\frac{r_1{}^2-r_2{}^2}{2}-r_2{}^2\log\frac{r_1}{r_2}\right\}.$$

By measuring the dimensions of the cylinder, the values of E and I, and the temperatures of the inner and outer surfaces, the value of K was obtained.

The apparatus used is illustrated in *Fig.* 17. The metallic rod was 1·2 cm. in diameter and about 15 cm. long. An inner hole was bored through the rod 0·17 cm. in diameter, and this was enlarged, as shown in the figure, except for the central length of 3 cm. The resistance on each side of the central portion being thus increased, the heat generated towards the ends was greater and the portion of the rod with no longitudinal gradient was increased. Thus at 1000° C. the variation in temperature over 1 cm. length in the centre was less than 0·1 per cent.

---

[1] The heat developed by the Thomson effect is very small and is eliminated by keeping the two ends at the same temperature.

[2] *McGill Coll. Report*, 1899.

[3] *Phys. Rev.*, 1911, xxxiii. 421.

The temperature inside the rod was measured by a fine platinum, platinum-rhodium couple with a junction at the centre. The measurement of the surface temperature presented great difficulties. A fine thermo-junction was rolled out to a thickness of ·01 mm., and the wires were attached to two springs S as shown. By rotating in opposite directions the rings to which the springs were attached, the connecting wires assumed a diagonal position relative to the rod, and brought the junction in contact with the surface, which was highly polished. In order to get a uniformly radiating surface at the junction, a small piece of the rod material was rolled to a thickness of 0·01 mm., placed over the junction, and held in position by a weighted quartz fibre. The rod and connections were surrounded by a water-cooled enclosure, which could be exhausted.

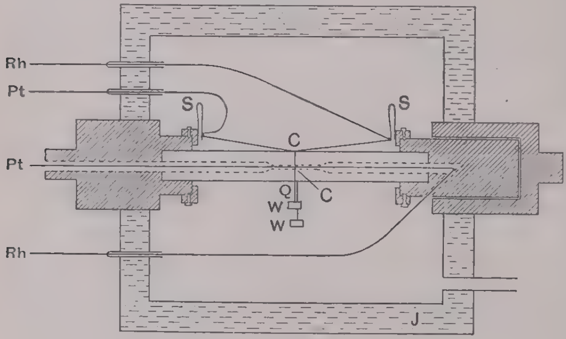

FIG. 17.

For energy supply a welding transformer was used, capable of furnishing 1700 amps alternating at a voltage of 2½. The energy was determined by measuring the current and making a separate experiment to determine the resistance of the central centimetre of the rod. For this purpose the rod was turned down to a small diameter and the volt drop measured on the central centimetre for a known current. The resistance of the original rod at various temperatures could thus be calculated.

Angell used the above apparatus to determine the conductivity of aluminium and nickel. He found that the former increased in conductivity from 0·49 at 100° C. to 1·0 at 600° C., while nickel decreased in conductivity from 0·125 at 300° C. to 0·07 at the critical temperature of 700° C. Between 700° and 1200° the conductivity decreases slowly to a value 0·06.

The method is an interesting attempt to measure conductivity at high temperatures. Its success depends entirely on the accuracy with which the small gradient of temperature between the axis and surface of the rod can be measured. This must be considered as a drawback, having regard to the experimental difficulties in measuring the surface temperature. Further, it is not clear that the longitudinal gradient in the central portion of the rod, though very small, was negligible compared with the radial gradient.

(*d*) *Worthing, Langmuir.*—Somewhat resembling the two methods described immediately above is that due to Worthing [1] for determining the conductivity of lamp filaments to a temperature of 2100° C.

If w is the rate of heat production, and E the rate of radiation per unit area, at any point on the filament, the maximum values being w_m and E_m at the middle of the filament, and if l is the distance measured along the filament, the total length of which is 2L, then he derives the expression

$$K = \frac{2E_m}{r(dT/dl)}\int_l^L \left(\frac{w}{w_m} - \frac{E}{E_m}\right) dl.$$

The full details of the experiments cannot be given here, but they resolved themselves into determining E as a function of T and of l, and w as a function of l. Worthing found, for example, that $E = \sigma T^\beta$, where $\beta = 5{\cdot}35$.

His conclusion as to the conductivity of tungsten was that it varied from ·234 C.G.S. units at 1200° to ·342 at 2100° C. Tantalum showed a change from ·174 at 1400° C. to 0·198 at 1800° C., while carbon gave values of ·0201 and ·0210 at the two temperatures just named.

Langmuir [2] also considered the question of conductivity of tungsten at high temperatures. His value for β was 4·96, and he states that the resistance can be expressed as

$$R = cT^\rho,$$

where $\rho = 1{\cdot}242$. On the basis of these experimental facts, he deduces from Worthing's data that the conductivity of tungsten is nearly independent of temperature and has a value of ·273 at 2100° C., as against ·342 found by Worthing. He also contends that the value of Lorenz's constant is of the order that would be expected from Jaeger and Diesselhorst's value at 18° C., and the temperature coefficient which they found between 18° C. and 100° C. This was contrary to the very large change in the constant which Worthing found over the range 1200° C.-2200° C.

[2] *Ibid.*, 1916, vii. 151.

(iv.) *Indirect Methods.*—In the case of metals it is often convenient to determine the conductivity by comparison with some other metal whose conductivity is known.

(*a*) *Wiedemann and Franz.*—As an example, the method of Wiedemann and Franz [1] may be quoted. These experimenters took a bar of metal, one end of which was maintained at a constant temperature, and which was submitted along its length to the effect of cooling by radiation and convection inside a constant temperature enclosure. When the steady flow of heat had been established, the temperatures at three points at equal distances apart were measured.

The temperature distribution along a bar under the conditions indicated is given by (cf. equation in § (5) (iii.) (*b*))

$$\mathrm{KA}\frac{d^2\theta}{dx^2}=\mathrm{E}p\theta$$

If now the temperatures θ_1, θ_2, and θ_3 are measured at three equally spaced points at a distance a apart, it can be shown that

$$a\sqrt{\frac{\mathrm{E}p}{\mathrm{KA}}}=\log_e(n+\sqrt{n^2-1}),$$

where $n=\dfrac{\theta_1+\theta_3}{2\theta_2}$.

So that if we take two bars of different materials, but with the same cross-section A, the same perimeter p, and the same coefficient of heat loss E, and determine the temperatures in each case at three equally spaced points at the same distances apart, we get the ratio of conductivities from the following equation

$$\sqrt{\frac{\mathrm{K}}{\mathrm{K}'}}=\frac{\log(n'+\sqrt{n'^2-1})}{\log(n+\sqrt{n^2-1})}.$$

The rods used by Wiedemann and Franz were half a metre long and 6 mm. in diameter, and in order to secure the same surface emissivity for all the rods, they were electroplated. One end of the rod was heated by steam and the remainder was surrounded by a water-cooled enclosure which could be exhausted if required. The temperatures at three equidistant points were measured by means of a sliding thermocouple.

Wiedemann and Franz drew up a table of relative conductivities of a number of metals. The experiments represented a considerable advance at the time they were carried out (nearly seventy years ago), but some of their results must now be regarded as obsolete, the probable cause being the presence of impurities in their specimens.

There is also the point, to which Péclet drew attention as long ago as 1860, that the assumption of Newton's law of cooling, which only holds approximately for small differences of temperature, must introduce considerable error.

(*b*) *Voigt.*—Another method of comparing the conductivities of two metals is that due to Voigt.[2] He took thin plates of the two materials cut in the form of right-angled triangles, and placed them in contact along their hypotenuses. The lengths of the sides a and b (*Fig.* 18) are chosen so as to be approximately in proportion of the conductivities of the plates. Heat is then applied by means of a copper bar at 70° to 90° C. along the short side b of the good conductor or the long side a of the bad conductor. The whole surface of the composite plate was coated with a layer of elaïdic acid to which wax and turpentine are added. The acid melts at 45° C. and solidifies in crystals yielding a well-defined isothermal curve. The ratio of the conductivities is derived from measurements of the angles which the isothermal makes with the common hypotenuse, being in the proportion of the tangents of the angles. The limit of accuracy of which the method is capable is about 2 per cent.

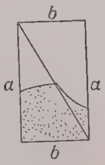

FIG. 18.

Rietzsch [3] used this method for measuring the conductivity of copper containing varying amounts of phosphorus and arsenic. It has also been used for glasses.

(v.) *Periodic Flow Methods.* (*a*) *Ångström.*—The method [4] is of interest in that it differs in principle from those previously described which have all been concerned with the steady state of heat flow. In this case the conductivity was deduced from observation of the periodic flow of heat in a long bar.

If we consider any thin cross-section of a rod the temperature of which is changing, the difference between the heat flowing into and out of this section must be equal to the heat lost from the surface of the section plus the heat required to raise the temperature of the section itself. So that we have (cf. § (5) (iii.) (*b*)

$$\mathrm{KA}\frac{d^2\theta}{dx^2}=\mathrm{E}p\theta+\mathrm{AC}\frac{d\theta}{dt}.$$

If the rod is surrounded by a guard-ring which prevents heat loss from the surface, the first term on the right-hand side vanishes and the equation becomes

---

[1] *Ann. de Chimie*, 1854, xli. 107.

[2] *Annal. Phys. Chem.*, 1898, lxiv. 95.

[3] *Ann. der Phys.*, 1900, iv. (3) 403.

[4] *Phil. Mag.*, 1863, xxv. 130.

$$h^2\frac{d^2\theta}{dx^2}=\frac{d\theta}{dt},$$

where h^2 is the diffusivity or the conductivity K divided by the heat capacity per unit volume C.

Now, supposing that a simple harmonic oscillation of temperature is impressed on one end of the bar, it can be shown from the above equation that

$$h^2=\frac{\lambda^2}{4\pi T},$$

where T is the periodic time and λ the wave-length of the temperature oscillations. It follows also that the amplitude of the temperature oscillations at any point at a distance x from the source is proportional to $e^{-2\pi x/\lambda}$. The amplitudes thus decrease as we recede from the hot end and likewise the mean temperature. The temperature distribution at any instant is of the form shown in *Fig.* 19, in which the dotted line represents the mean temperatures.

It is obvious if we determine the complete temperature distribution the wave-length λ can be measured, and thus the diffusivity. From the latter the conductivity may be obtained, if the heat capacity per unit volume is known.

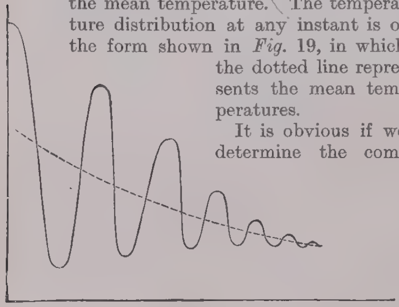

FIG. 19.

It is, however, sometimes convenient to deduce the conductivity from temperature—time observations at two points. The general solution of either of the equations above for a simple harmonic oscillation is of the form

$$\theta=A\sin\left(\frac{2\pi}{T}t+\delta\right).$$

The values of A and δ can be determined experimentally for the two points, and it can be shown that if l is their distance apart

$$h^2=\frac{\pi l^2}{T(\delta-\delta')\log A/A'}.$$

If the temperature oscillations are periodic but are not simple harmonic vibrations, they can be resolved into a number of terms of the form

$$\theta=A_0+A_1\sin(\omega t+\delta_1)+A_2\sin(2\omega t+\delta_2)+A_3\sin(3\omega t+\delta_3)+\ldots$$

where $\omega=\pi/T$.

Again, taking two points, each pair of the terms of the above expression leads to an independent value of h^2,

$$h^2=\frac{n\pi l^2}{T(\delta_n-\delta_n')\log A_n/A_n'}.$$

In practice these series may be limited to the first three or four terms as the coefficients A_0, A_1, A_2, etc., rapidly diminish.

In Ångström's experiments a small section of a bar was enclosed and was submitted alternately to heating and cooling by steam and cold water respectively. The periods of heating and cooling were 12 minutes each, and when they had been continued for some time, the temperatures at each point of the bar became steadily periodic. Mercury thermometers were let into the bar at intervals of 5 cm. for temperature readings.

Ångström used for his first experiments bars 57 cm. long and of 2·4 cm. square section, while for some subsequent experiments he used a bar 118 cm. long and 3·5 cm. thick. His values for the conductivity of copper and iron at 50° C. were

	First Experiments.	Second Experiments.
Copper . .	·910	$\cdot982\,(1-0\cdot001520\theta)$
Iron . .	·163	$\cdot199\,(1-0\cdot00214\theta)$

The values obtained in the second experiments are much higher than those now accepted. The negative sign of the coefficient is confirmed by the work of Jaeger and Diesselhorst and of Lees though the magnitudes are different.

Callendar [1] has applied Ångström's method to the apparatus illustrated in *Fig.* 14. He varied the pressure of the steam in the heater so as to produce approximately simple harmonic oscillations, using periods of 60, 90, and 120 minutes. Callendar found a value for cast iron at 54° C. of $0\cdot1144\,(1-0\cdot00006\theta)$, which is in close agreement with modern values obtained by other methods.

There is no doubt that Ångström's method gives satisfactory results if due precautions are taken. It involves, however, the taking of large numbers of observations and their analysis may be very laborious.
